Sandwich Panel Failure Modes

Honeycomb panel failures can be divided into three categories: insufficient strength, local instability, and general instability.

Insufficient strength failure modes are described subsequently. See Fig. 2 for pictorial representations of these modes.

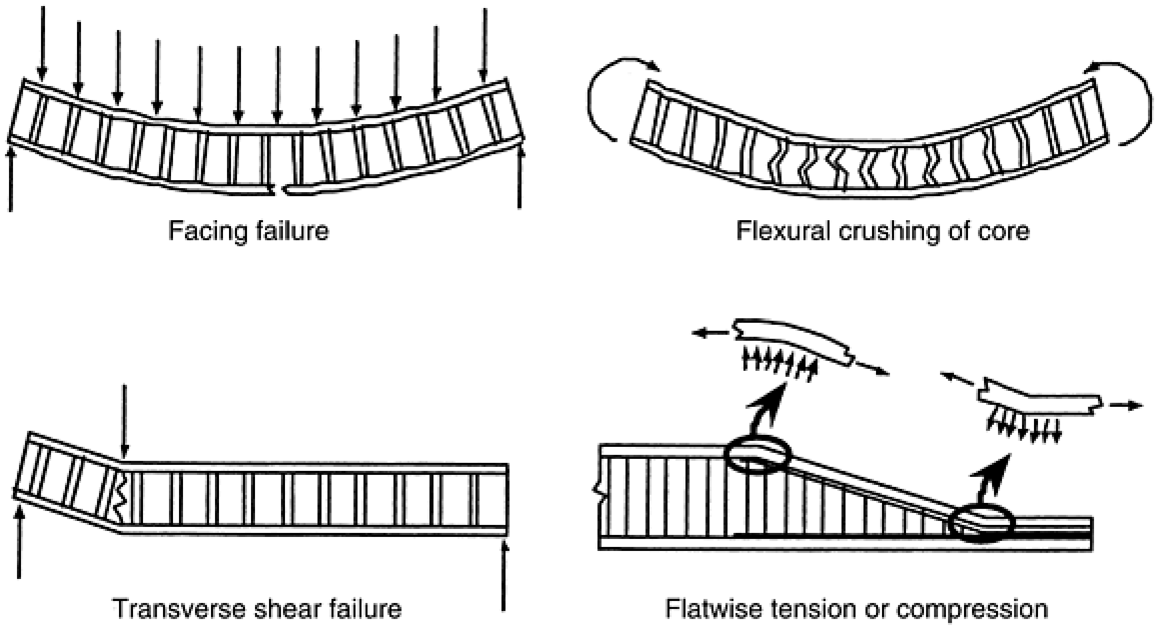

Fig. 2 Failures caused by insufficient strength

- *Facing failure* is simply characterized by cracked facesheets. This failure occurs when the facesheet strength is exceeded.
- *Transverse shear failure* can manifest itself as face-to-core debonding or as a shear failure in the core itself. This failure occurs when the core or the face-to-core adhesive has insufficient shear strength.
- *Flexural core crushing* is a concern when the facesheets tend to move toward each other under the influence of bending. This failure mode occurs when the core has insufficient compression strength.
- *Flatwise tension or compression* occurs in the ramp area where the bag-side facesheet changes direction. The flatwise, or interlaminar, stresses are induced at the ramp radii. A flatwise tension stress can cause face-to-core debonding, while a flatwise compression stress can cause core crushing.

Local instability includes the following two failure modes illustrated in Fig. 3:

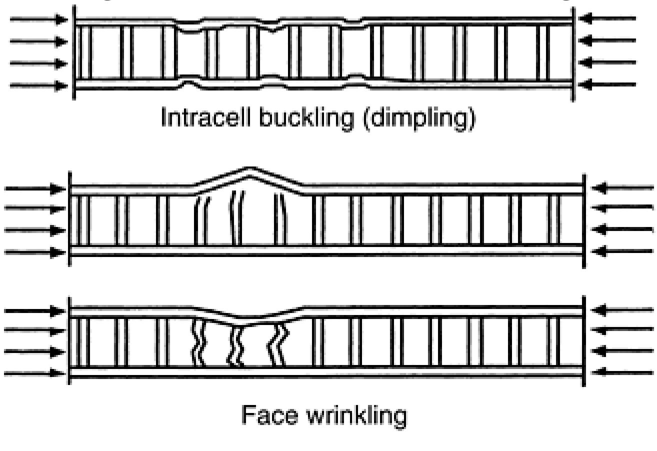

Fig. 3 Failures caused by local instability

- *Intracell buckling*, or face dimpling, is a local instability characterized by the buckling of a facesheet into or out of the confines of a single cell. This failure can occur when the facesheets are thin.
- *Face wrinkling* is a local instability characterized by the inward or outward buckling of the face, accompanied by core crushing, core tearing, or face-to-core debonding. This failure can occur when the core has a low density.

General instability failure modes are given subsequently and are shown in Fig. 4:

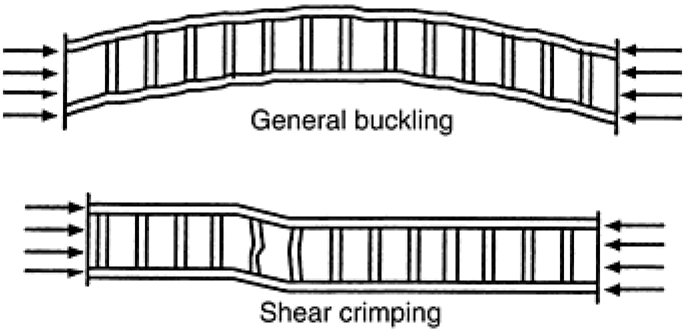

Fig. 4 Failures caused by general instability

- *General buckling* of a sandwich panel resembles the classical buckling of plates or columns. The facesheets and core remain intact in this type of failure.
- *Shear crimping* is an instability that can occur if the wavelength of each buckle is of the same order as the cell size. The crimping phenomenon is characterized by a local core shear failure and the lateral dislocation of the facesheets. Since the wavelengths are so short, shear crimping appears to be a local instability failure, but it is really a form of general instability. This failure mode can occur when the core shear modulus is low.

Nomenclature and Definitions for Loads, Geometry, and Material Properties

The variables used throughout this section to represent the loads and characteristics applied to a flat sandwich panel are given in Table 2. Figure 5 gives a pictorial representation of the general load state for a flat sandwich panel. The geometry of the honeycomb sandwich is shown in Fig. 6.

Table 2 Nomenclature and definitions

Symbol	Definition	SI units	Customary units	Comment
c	Core depth at any point in the honeycomb panel	m	in.	For $x \le L_{AB}$ $c = 0$ (no core)
				For $L_{AB} < x < L_{AC}$ $$c = \frac{x - L_{AB}}{L_{AC} - L_{AB}} t_c$$
				For $x \ge L_{AC}$ $c = t_c$
C_{zx}, C_{zy}	Compliance factors for panel strips parallel to the *x*- and *y*-directions, respectively	1/MPa	in.^{3}/lb	…
d	Distance between the face midplanes at any point in the	m	in.	$x \le L_{AB}$

	honeycomb panel			$$d = t_e - \frac{t_t + t_b}{2}$$
				$L_{AB}<x<L_{AC}$ $$d = (t_c - t_e + t_t + t_b)\frac{x - L_{AB}}{L_{AC} - L_{AB}} + \left(t_e - \frac{t_t + t_b}{2}\right)$$
				$x \geq L_{AC}$ $$d = t_c + \frac{t_t + t_b}{2}$$
				$x \geq L_{AC}$ $$d = t_c + \frac{t_t + t_b}{2}$$
D_{zx}, D_{zy}	Flexural stiffnesses for panel strips parallel to the *x*- and *y*-directions, respectively	N/m	lb/in.	Per unit width
E_{cc}	Core compression modulus in the *z*-direction	MPa	psi	…
E_x, E_y, $E_{x\ \mathrm{f}}$, $E_{y\ \mathrm{f}}$	Facesheet elastic moduli parallel to the *x*- and *y*-directions, respectively	MPa	psi	“f” subscript indicates it is the modulus for the face being checked.
$f_{x\ \mathrm{flat}}$, $f_{y\ \mathrm{flat}}$	Flatwise tension or compression stresses at the ramp radii	MPa	psi	…
$f_{x\ \mathrm{f}}$, $f_{y\ \mathrm{f}}$	In-plane facesheet stress in *x*- and *y*-direction, respectively	MPa	psi	For face being checked
$f_{xy\ \mathrm{f}}$	In-plane facesheet stress	MPa	psi	For face being checked
G_{xy}	Facesheet shear modulus in the *xy* plane	MPa	psi	…
G_{zx}, G_{zy}	Core shear moduli in the *xz* and *yz* planes, respectively	MPa	psi	…
H_{zx}, H_{zy}	Out-of-plane shear stiffnesses for panel strips parallel to the *x*- and *y*-directions, respectively	N/m	lb/in.	Per unit width
K_x, K_y	In-plane (axial) stiffnesses for panel strips	N/m	lb/in.	Per unit width

	parallel to the *x*- and *y*-directions, respectively			
L_{AB}	Distance from the fastener centerline to the start of the ramp	m	in.	…
L_{AC}	Distance from the fastener centerline to the end of the ramp	m	in.	…
L_{AD}	Distance from the fastener centerline to the panel center	m	in.	…
L_x, L_y	Length of a rectangular panel in the *x*- and *y*-directions, respectively	m	in.	…
M_x, M_y	Edge bending moments per unit width	Nm/m	in. · lb/in.	M_x acts along the edge normal to the *x*-direction and induces compression in the tool side of the panel.
				M_y acts along the edge normal to the *y*-direction and induces compression in the tool side of the panel.
M'_x, M'_y	Bending moments caused by eccentric in-plane load	Nm/m	in. · lb/in.	Per unit width
M_x, M_y	Pressure-induced bending moments	Nm/m	in. · lb/in.	Per unit width
N_x, N_y, N_{xy}	In-plane panel forces per unit width	N/m	lb/in.	N_x acts along the edge normal to the *x*-direction and induces tension in the *x*-direction.
				N_y acts along the edge normal to the *y*-direction and induces tension in the *y*-direction.
				N_{xy} acts along all edges and induces tension in the +45° direction, where the *x*-direction is considered to be 0° and the *y*-direction is considered to be 90°.
$N_{x\ t}$, $N_{y\ t}$, $N_{xy\ t}$	In-plane loads for the tool-side facesheet	N/m	lb/in.	Per unit width
$N_{x\ b}$, $N_{y\ b}$, $N_{xy\ b}$	In-plane loads for the bag-side facesheet	N/m	lb/in.	Per unit width
P	Point load	N	lb	Concentrated load in classic beam formulas
p	Uniformly distributed load	N/m	lb/in.	Uniform distributed load in classic beam formulas
P_z	Uniform pressure	MPa	psi	P_z acts normal to the *xy* plane, in the downward direction (–*z*), and induces compression in the tool side of the panel.
P_{zx}, P_{zy}	Midspan pressures applied to the *x*- and *y*-beams,	MPa	psi	$P_{zx}+P_{zy} = P_z$

	respectively			
R_{zx}, R_{zy}	Out-of-plane edge reactions	N/m	lb/in.	R_{zx} acts along the edge normal to the *x*-direction and is directed upward (+*z*).
				R_{zy} acts along the edge to the *y*-direction and is directed upward (+*z*).
s	Honeycomb cell size	m	in.	Measured side-to-side, see Fig. 1
t	Distance between the external face surfaces	m	in.	…
t_t, t_b, t_f	Facesheet thicknesses for the tool and bag sides, respectively, or the thickness of the face being checked	m	in.	t_1, t_2 are also used to indicate the face thicknesses in equations
t_e	Edgeband thickness	m	in.	…
t_c	Core depth outside the ramp region where the facesheets are parallel to each other	m	in.	…
V_{zx}, V_{zy}	Core shear loads for panel strips in the *x*- and *y*-directions, respectively	N/m	lb/in.	Per unit width
w	Deflection	m	in.	Deflection in beam formula
δ	Deflection	m	in.	Panel deflection
η_x, η_y	Rotational fixity factor for panel edges normal to the *x*- and *y*-directions, respectively	…	…	1.0 for fully fixed, 0.0 for simply supported
ν_{xy}, ν_{yx}	Facesheet Poisson's ratios	…	…	The term, ν_{xy}, is defined as the absolute ratio of strain in the y-direction to strain in the *x*-direction when load is applied uniaxially in the *x*-direction, $E_x\nu_{xy}=E_y\nu_{xy}$
φ	Ramp angle with respect to the tool-side face	Degree	Degree	…
θ	Angle of bag-side facesheet at any point in the honeycomb panel	Degree	Degree	For *x*, L_{AB}, θ= 0
				$L_{AB}<x<L_{AC}$ θ=φ/2 at center of ramp radii =φ at flat portion of ramp
				$x \geq L_{AC}$ θ= 0

Other symbols used in this section are common to plate analysis and matrix representations.

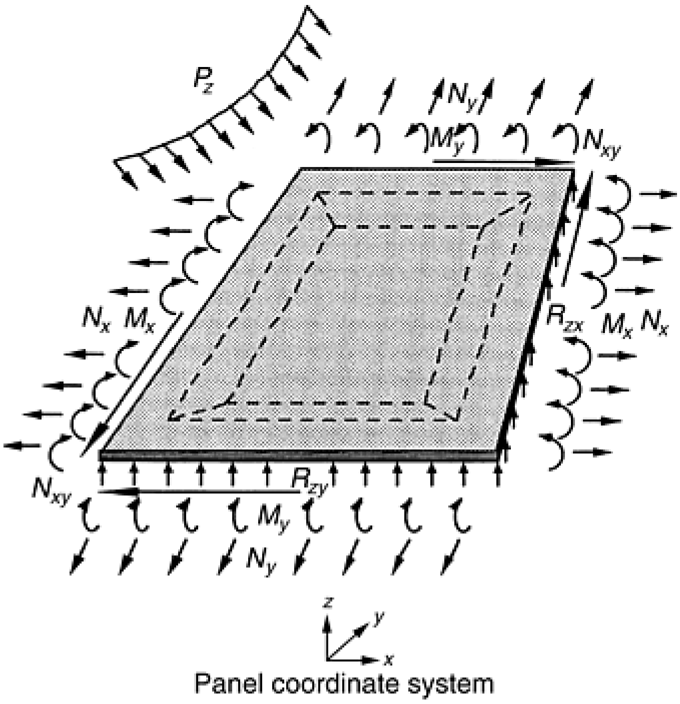

Fig. 5 Generalized load state for a flat sandwich panel. The loads are expressed in terms of the panel coordinate system, which may or may not be coincident with the core coordinate system shown in Fig. 1. Often the *L*-direction (parallel to the core ribbon) and the *x*-direction are identical and parallel to the short side of a rectangular panel.

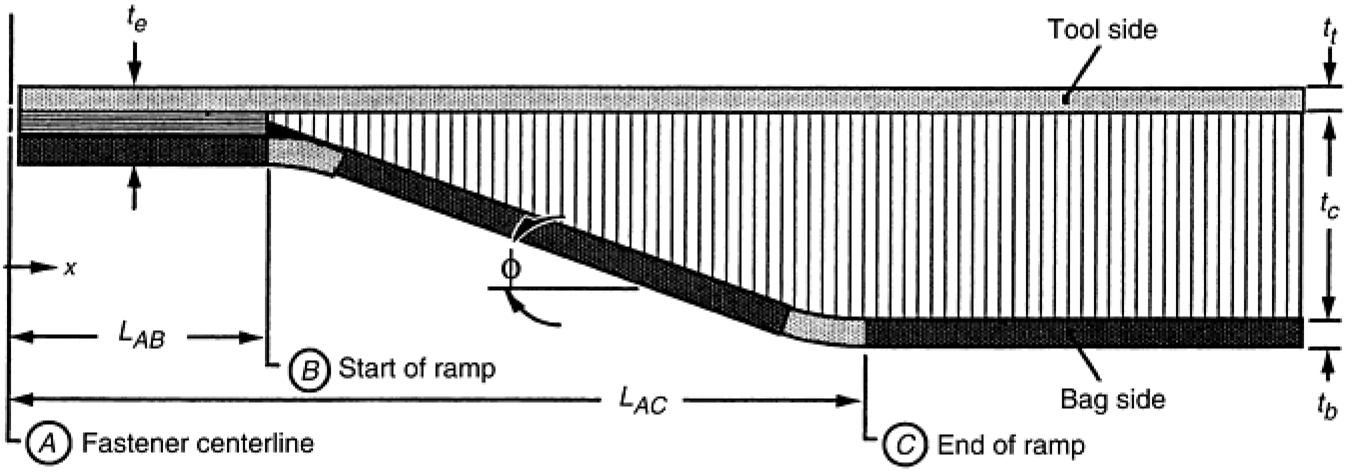

Fig. 6 Geometry of the honeycomb sandwich

Assumptions and Definitions. The analysis of honeycomb sandwich panels is made easier when a few assumptions are made. The following statements are considered true for every honeycomb sandwich analysis method, unless otherwise noted:

- The in-plane stiffness of the honeycomb core is negligible with respect to the facesheets: ($E_{x\ \mathrm{core}}=E_{y\ \mathrm{core}}=G_{xy\ \mathrm{core}}= 0$).
- The centroid of the whole sandwich element is coincident with the centroid of the facesheets by themselves. This is implied by the previous assumption.
- The facesheets are thin, and the moments of inertia about their own centroids are negligible; that is, $t_t^3 = t_b^3 = 0$.
- The distance between the facesheet midplanes is considered to be equal to the distance between the face centroids.
- The point at which in-plane load is applied to the edgeband is considered to be halfway between the face centroids (midplanes).

- Normal (out-of-plane) shear forces are carried exclusively by the core and are distributed evenly through the core thickness.
- The honeycomb panels in this article are all rectangular, and the load coordinate system (*x*, *y*, *z*) is coincident with the core material system (*L*, *W*, *T*).
- The *midplane* of a sandwich element is located halfway between the face surfaces: $y_{midplane}=t/2$.
- The *centroid* of a sandwich element is located at the point where no bending strain occurs in a flat panel. When the facesheets have unequal thicknesses, the centroid does not coincide with the midplane:

$$y_{centroid} = \frac{\sum_{i=1}^{2}(t_i \cdot y_i)}{\sum_{i=1}^{2}(t_i)}$$

- The *neutral axis* of a sandwich element is similar to the centroid in that it is located at the point where zero strain is induced under the influence of bending loads. For a flat panel, the neutral axis coincides with the centroid, but, for a curved panel, the neutral axis does not coincide with the centroid.

Strength Checks

Edgeband and Ramp. Figure 7 shows the areas where a flat sandwich panel should be checked for adequate strength. Each fastener around the edgeband must be checked for adequate bearing/bypass strength.

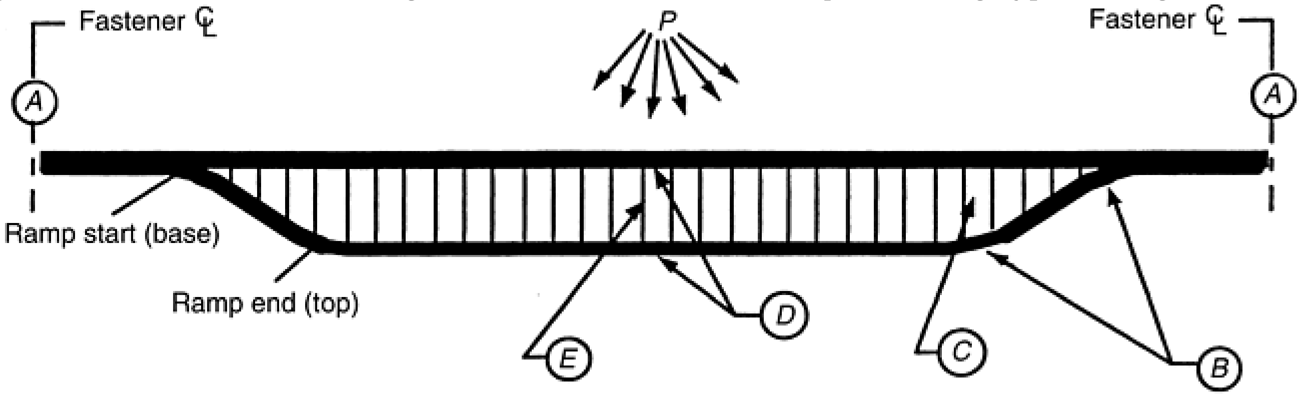

Fig. 7 Critical strength-check locations for a flat sandwich panel. *A*, bearing/bypass; *B*, flatwise tension and/or compression; *C*, core shear; *D*, face strength and instability; *E*, flexural core crushing

In the area where the bag-side facesheet changes direction, the core is subject to flatwise tension and/or compression. In the case of flatwise tension, the face-to-core adhesive must provide an adequate bond, and in the case of flatwise compression, the core must have adequate crushing strength.

The shear force normal to the panel reaches a maximum at the fastener centerline. In the ramp region, the bag-side face and the honeycomb core both react to the shear load. The core is checked for adequate shear strength in the entire ramp region, but it is often critical at the top of the ramp when pressure is the only applied load. At this location, the core is assumed to carry 100% of the out-of-plane shear.

Analysis Overview of Panel Acreage. The following procedure is recommended for the stress analysis of sandwich panels in areas away from core ramps and edgebands. The center of the panel is exposed to a peak bending moment, and the facesheet strength, flexural core crushing, local instability, and general instability failure modes are often critical at this location.

1. Determine the sandwich panel and the stiffness properties of the individual faces as defined by their [A], [B], [D], [G] matrices. Use appropriate ply properties based on temperature and moisture environment. Determine allowable strengths for the facesheet, core, and adhesive materials.
2. Obtain internal loads acting on the sandwich panel, either through a finite element analysis or with specialized closed-form solutions or computer programs.
3. Using the stiffness properties, determine the sandwich panel strains and curvatures. Determine the internal loads acting on each individual facesheet.
4. Determine the damage assumptions and associated strength requirements for durability and damage tolerance by referring to the appropriate design criteria.
5. Determine the margin of safety of each local failure mode:
6.
    1. Check both facesheets' in-plane failures resulting from tension, compression, and shear loads.
    2. Check core transverse shear failure.
    3. Check core crushing from local loads and flexure-induced crushing.
    4. Check flatwise tension in core and adhesive.
    5. Check face wrinkling on both faces.
    6. Check face dimpling on both faces.
7. Determine, if necessary, the margin of safety for general instability:
8.
    1. Check general buckling.
    2. Check shear crimping.

Stiffness and Internal Loads

Plate Stiffness Analysis. The first step in the analysis is to define the stiffness properties for the whole panel and for the individual faces. The best approach is to use a laminate analysis program to calculate the different stiffness matrices. Calculate first the [A], [B], and [D] matrices of the *whole panel*. Use the individual ply properties and assume that the core is a special type of ply with no in-plane stiffness, but with the correct transverse shear stiffness:

$$\begin{bmatrix} N \\ M \end{bmatrix} = \begin{bmatrix} A & B \\ B & D \end{bmatrix} \begin{bmatrix} \varepsilon \\ \kappa \end{bmatrix} \quad \text{(Eq 1)}$$

Use a program that will also determine the transverse shear stiffness coefficients, A_{44}, A_{45}, and A_{55}, of the plate:

$$\begin{bmatrix} Q_x \\ Q_y \end{bmatrix} = \begin{bmatrix} A_{55} & A_{45} \\ A_{45} & A_{44} \end{bmatrix} \begin{bmatrix} \gamma_{xz} \\ \gamma_{yz} \end{bmatrix} = [G] \begin{bmatrix} \gamma_{xz} \\ \gamma_{yz} \end{bmatrix} \quad \text{(Eq 2)}$$

If such a program is not available, assume that the core alone provides the transverse shear stiffness. This is valid if the faces are thin compared to the core, say less than 5% of the core thickness. Calculate the coefficients as follows:

$$A_{55} = cG_{xz\text{core}} \quad A_{45} = 0$$
$$A_{44} = cG_{yz\text{core}} \quad A_{54} = 0 \qquad \text{(Eq 3)}$$

Using the same laminate analysis program or hand analysis formulae, determine the stiffness properties, that is, the [A], [B], and [D] matrices, of *each individual face*:

$$\begin{bmatrix} N \\ M \end{bmatrix}_1 = \begin{bmatrix} A & B \\ B & D \end{bmatrix}_1 \begin{bmatrix} \varepsilon \\ \kappa \end{bmatrix}_1$$
$$\begin{bmatrix} N \\ M \end{bmatrix}_2 = \begin{bmatrix} A & B \\ B & D \end{bmatrix}_2 \begin{bmatrix} \varepsilon \\ \kappa \end{bmatrix}_2 \qquad \text{(Eq 4)}$$

It is important to realize the difference between the face matrices (Eq 4) and the overall plate matrices (Eq 1), and to always use the appropriate matrices for each analysis. For instance, when checking global buckling, use the plate [D] matrix, but when checking face dimpling or wrinkling, use the facesheet [D] matrix. Some formulas, such as those for face wrinkling, call for the face extensional modulus E_x (Eq 6) or E_y, but since wrinkling involves face bending deformation, it is more accurate to use the flexural modulus (Eq 5) instead of (Eq 6):

$$E_{x\text{flex}} = \frac{12D_{11}}{t_1^3} \qquad \text{(Eq 5)}$$

assuming that B_{ij}= 0 and κ_y= 0, κ_{xy}= 0.

$$E_{x\text{ext}} = \frac{A_{11}}{t_1} \qquad \text{(Eq 6)}$$

assuming that B_{ij}= 0 and ϵ_y= 0 , γ_{xy}= 0.

Equation 6 would be appropriate if the deformation involved only a face extensional deformation. Note also that these two definitions imply that the deformations (both curvatures and strains) are constrained in the transverse direction. Conversely, if the forces and moments are zero in the transverse direction, one should use

$$E_{x\text{flex}} = \frac{12}{t_1^3 D'_{11}} \qquad \text{(Eq 7)}$$

for bending assuming that, B_{ij}= 0 and M_y= 0, M_{xy}= 0. For extension, one should use:

$$E_{xext} = \frac{1}{t_1 A'_{11}} \qquad \text{(Eq 8)}$$

assuming that B_{ij}= 0 and N_y= 0, N_{xy}= 0 and where:

$$\begin{bmatrix} A' & B' \\ B'^T & D' \end{bmatrix} = \begin{bmatrix} A & B \\ B & D \end{bmatrix}^{-1}$$

Thus, when using any equation which calls for a face stiffness modulus, use the definition of E_x, which corresponds to the mode of deformation.

Beam Stiffness Analysis. Many methods are available to calculate the deflections, bending moments, and shear force distribution in beams under various types of loading and boundary conditions. All these formulae require the use of the beam bending stiffness, D. First, calculate the overall plate bending stiffness matrix [**D**] as explained previously. Then, depending on the aspect ratio of the beam, which is the beam width (b) to thickness (d) ratio, use the following relations (where the "1" direction is along the beam length). For wide beams (b/d> 6): D=D_{11} (assumes the transverse curvature, κ_y= 0). For narrow beams (b/d< 6): $D = 1/D'_{11}$ (assumes the transverse moment, M_y= 0). Note also that, in general, the transverse shear deformation of the core cannot be neglected.

For instance, the transverse deflection at the free end of a cantilevered beam subjected to a concentrated load, P, can be expressed as:

$$w_{max} = \left(\frac{PL^3}{3Db} + \frac{PL}{A_{55}b} \right)$$ (Eq 9)

where the first term represents the deflection due to bending and the second term represents the additional deflection due to the transverse shear deformation.

Similarly, the maximum transverse deflection of a simply supported beam subjected to a uniform distributed load, *p*, can be expressed as:

$$w_{max} = \left(\frac{5pL^4}{384Db} + \frac{pL^2}{8A_{55}b} \right)$$ (Eq 10)

The deflection of a general beam can be determined using the following differential equation:

$$\frac{d^2y}{d^2x} = \frac{M_x}{D} + \frac{1}{A_{55}} \left(\frac{dV_x}{dx} \right)$$ (Eq 11)

Once the maximum bending moment and shear resultant are obtained, determine the core stresses and facesheet line loads and strains, and then check all the potential failure modes shown in Fig. 2, 3, and 4.

Combined Transverse and In-Plane Loadings. If a plate or beam is subjected to both transverse loads (e.g., pressure) and in-plane compression or shear, additional deflections and stresses will be created beyond the simple superposition of the deflections and stresses created by each loading. If no computer program is available to handle this type of effect, use the following procedure:

1. Calculate the deflections and stresses created by the transverse loads.
2. Calculate the stresses due to the in-plane loads, P.
3. Calculate the critical (buckling) load under the in-plane loads, P_{cr}.
4. Multiply the stresses and deflections due to transverse loads by the ratio $R = 1/[1-(P/P_{cr})]$ where (P/P_{cr}) is the buckling ratio.
5. Add together the stresses due to in-plane loads and the amplified stresses due to transverse loads.

Facesheet Internal Loads. Typically, the plate or beam stiffness properties will be input into a finite element (FE) model or into a specialized plate analysis program that will return the internal loads in the form of the plate force, moment, and transverse shear resultants. The sandwich plate strains and curvatures are calculated with the stress-strain relations shown previously or with the help of a laminate analysis program. The facesheet strains and loads can be calculated from:

$$\begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{bmatrix}_1 = \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{bmatrix}_{plate} + \left(\frac{c+t_2}{2} \right) \begin{bmatrix} \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{bmatrix}_{plate}$$

$$\begin{bmatrix} N_x \\ N_y \\ N_{xy} \end{bmatrix}_1 = [A]_1 \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix}_1 + [B]_1 \begin{bmatrix} \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{bmatrix}_{plate}$$ (Eq 12)

Similar equations are used for the other face.

Flat Panel Internal Loads and Stresses—Pressure Loading

The analysis methods described in the following sections are formulated for flat rectangular honeycomb panels subject to in-plane loads (N_x, N_y, and N_{xy}) and uniform pressure (P_z). This section is intended to give an approximate solution for a pressure-loaded plate for instances where a more detailed analysis, such as a FE model, are not available or not required. The analysis steps are:

1. Idealize the panel as two wide beams perpendicular to each other and intersecting in the middle of the panel. Compute the flexural and shear stiffnesses for each of the beams.
2. Split the total pressure into two uniform parts. One part is carried exclusively by the *x*-beam, and the other part is carried exclusively by the *y*-beam. Compute the pressure split by equating the midspan deflections for each beam.
3. Impose an inverted triangular pressure distribution on each of the two beams. Each beam carries the full pressure magnitude at the supported ends, but, at the midpoint, they share the total pressure based on the split calculated in the previous step. Note that all internal loads are derived from the inverted triangular pressure distribution, and the uniform distributions in step 2 are only used to compute the pressure split between the two beams.
4. Compute the bending moment and vertical shear reactions at the beam ends. Use a factor to account for partial rotational fixity.
5. Develop a freebody diagram to derive in- plane facesheet loads and core shear loads at any point along the beams.

Flexural and Shear Stiffnesses. When uniform pressure is applied to a sandwich panel, it is useful to think of some of the pressure being carried by a panel strip from fastener line to fastener line in the *x*-direction and by another strip from fastener line to fastener line in the *y*-direction. In this way, the panel is idealized as two mutually perpendicular wide sandwich beams. See Fig. 8.

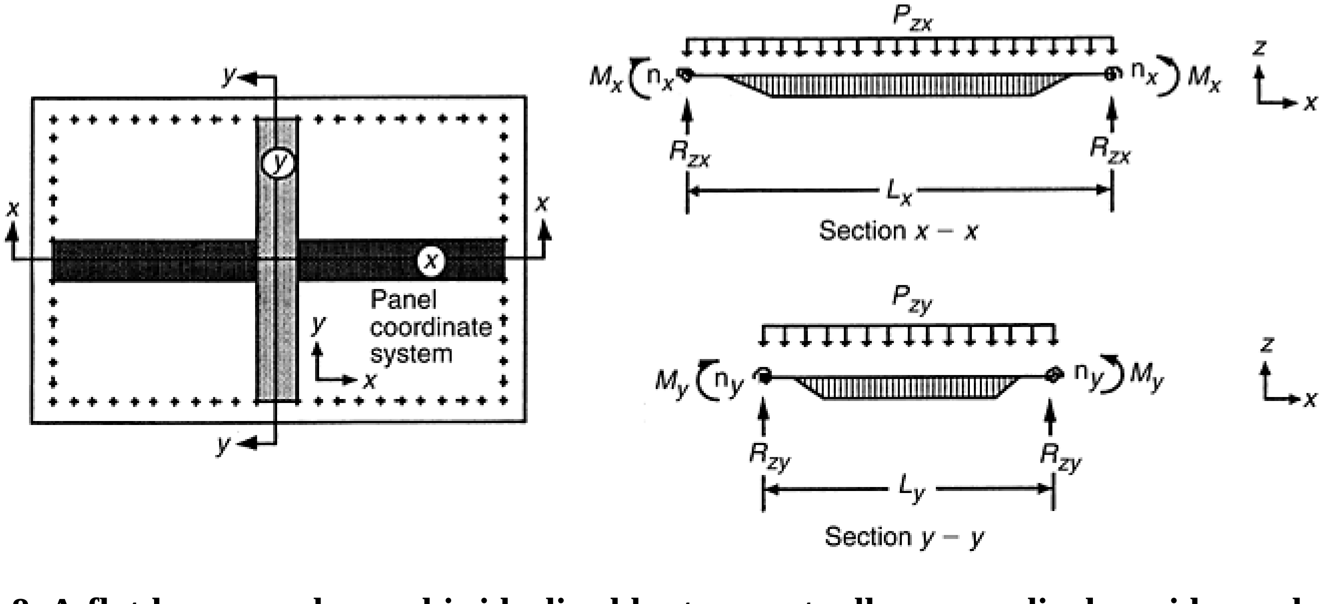

Fig. 8 A flat honeycomb panel is idealized by two mutually perpendicular wide sandwich beams

The flexural stiffness of a beam is a quantity that relates bending moment to curvature. So, for a beam parallel to the *x*-direction, the curvature at any point along the span, κ_x, is equal to the bending moment at that point divided by the flexural stiffness of the beam, D_{zx}.

For a narrow beam, D_{zx} is simply equal to $E_x I_x$. A wide beam, however, has greater flexural stiffness than a narrow beam, because the curvature in the plane normal to the applied moment is constrained to be negligible. Thus, for beam *x*, $\kappa_y = 0$, and for beam *y*, $\kappa_x = 0$.

The flexural stiffnesses, D_{zx} and D_{zy}, for the two mutually perpendicular panel strips are derived below. The subscripts, "*t*" and "*b*," refer to the tool-side and bag-side facesheets, respectively.

$$D_{zx} = \frac{d^2}{\left(\frac{1-\nu_{xy}\nu_{yx}}{E_x t}\right)_t + \left(\frac{1-\nu_{xy}\nu_{yx}}{E_x t}\right)_b}$$

$$D_{zy} = \frac{d^2}{\left(\frac{1-\nu_{xy}\nu_{yx}}{E_y t}\right)_t + \left(\frac{1-\nu_{xy}\nu_{yx}}{E_y t}\right)_b} \quad \text{(Eq 13)}$$

The shear stiffness of a beam is a quantity that relates shear force to slope. So, for a beam parallel to the *x*-direction, the slope at any point along the span is equal to the shear force at that point divided by the shear stiffness of the beam, H_{zx}.

The shear stiffnesses (H_{zx} and H_{zy}) for each of the two panel strips are derived below:

$$H_{zx} = cG_{zx}$$

$$H_{zy} = cG_{zy} \quad \text{(Eq 14)}$$

Midpanel Deflection and Pressure Split. As stated in the previous section, the total uniform panel pressure can be split between two mutually perpendicular beams in the *x*- and *y*-directions. The fraction of pressure carried by a beam is directly proportional to its stiffness, and the pressure split between the two beams can be determined by enforcing deflection compatibility at their midspans.

The deflection of a conventional panel subject to uniform pressure is usually a function of flexural stiffness only. However, since the low shear modulus of the core allows significant shear deformations, the deflection of a sandwich panel requires the consideration of *flexural stiffness and shear stiffness*. See Fig. 9.

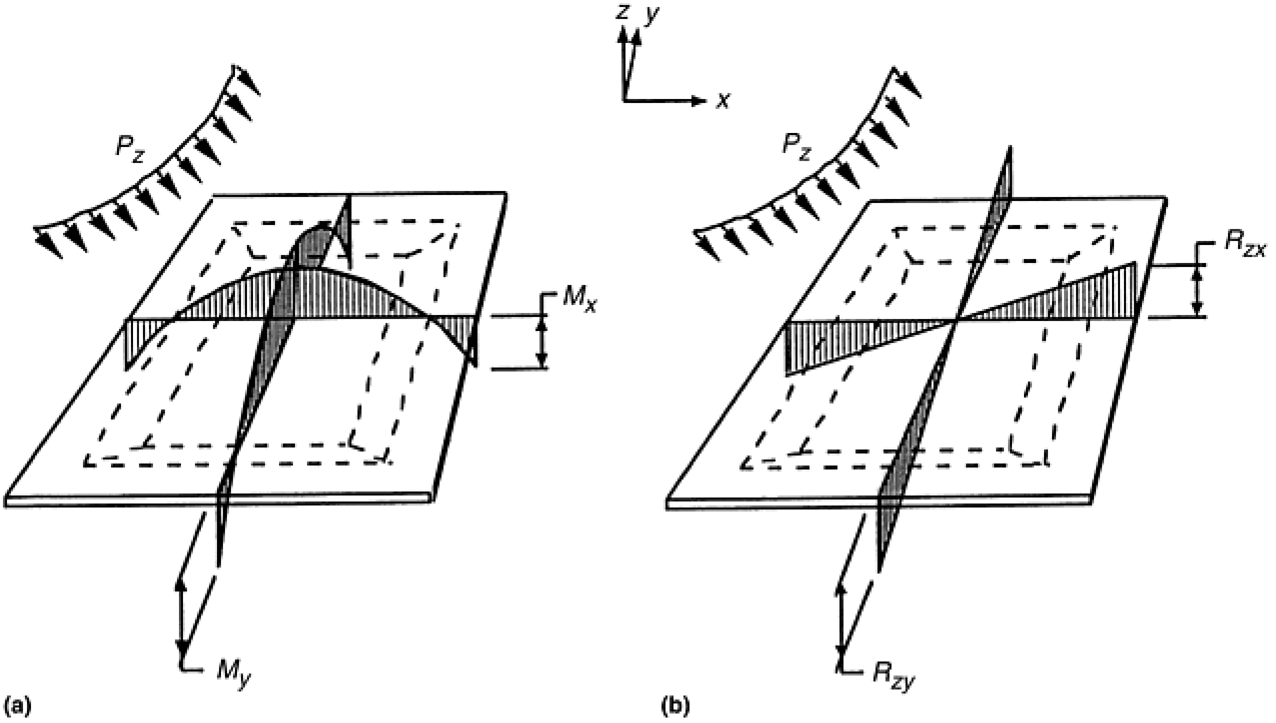

Fig. 9 Approximate midpanel moment (a) and shear (b) distributions for a flat panel exposed to uniform pressure (P_z)

It is useful to express the maximum midspan deflection of a beam in terms of a compliance factor. So, for a beam parallel to the *x*-direction, the midspan deflection, δ_{xmid}, is equal to the amount of uniform pressure carried by the beam, P_{zx}, multiplied by the compliance factor of the beam, C_{zx}.

The out-of-plane compliance factors, C_{zx} and C_{zy}, for the two mutually perpendicular panel strips are derived below:

$$C_{zx} = \frac{(5-4\eta_x)L_x^4}{384D_{zx}} + \frac{L_x^2}{8H_{zx}}$$

$$C_{zy} = \frac{(5-4\eta_y)L_y^4}{384D_{zy}} + \frac{L_y^2}{8H_{zy}} \quad \text{(Eq 15)}$$

Note that the compliance factors are comprised of two terms. The first term represents the deflection due to flexure, and the second term represents the deflection due to shear.

Each of the beams carries the amount of uniform pressure required to equalize its midspan deflections. The pressure reacted by the *x*-beam, P_{zx}, plus the pressure reacted by the *y*-beam, P_{zy}, is equal to the total pressure, P_z. Deflection compatibility:

$$\delta_{x\mathrm{mid}}=C_{zx}\,P_{zx}=\delta_{y\mathrm{mid}}=C_{zy}\,P_{zy}$$

Total pressure:

$$P_{zx}+P_{zy}=P_z$$

By combining the previous two equations, the pressure reacted by each beam can be derived:

$$P_{zx} = \frac{C_{zy}}{C_{zx}+C_{zy}}P_z$$

$$P_{zy} = \frac{C_{zx}}{C_{zx}+C_{zy}}P_z \quad \text{(Eq 16)}$$

An approximate expression for the maximum deflection of a sandwich panel subject to uniform pressure is:

$$\delta_{\max} = \left(\frac{C_{zx}C_{zy}}{C_{zx}+C_{zy}}\right)\cdot P_z \quad \text{(Eq 17)}$$

Inverted Triangular Pressure Distribution. The pressure split derived in Eq 16 applies only at the intersection point of the two beams. Thus, the applied pressure at the midspan of the *x*- beam has a magnitude of P_{zx} and the applied pressure at the midspan of the *y*-beam has a magnitude of P_{zy}. It would not be appropriate, however, to say that the *x*-beam, for example, is subject to P_{zx} uniformly across its length. This is due to the fact that as the end of the *x*-beam is approached, it will tend to carry proportionately more pressure than the corresponding *y*-beam. In other words, when proceeding from the midspan to the end of the *x*-beam, the load path in the *x*-direction appears to get stiffer with respect to the *y*-direction.

Therefore, an inverted triangular pressure distribution is considered to be an appropriate model. The *x*-beam and the *y*-beam carry P_{zx} and P_{zy} at their respective midspans, and they carry the full pressure magnitude, P_z, at their ends. Between the midspan and the ends, the pressure distribution varies linearly. This is illustrated in Fig. 10.

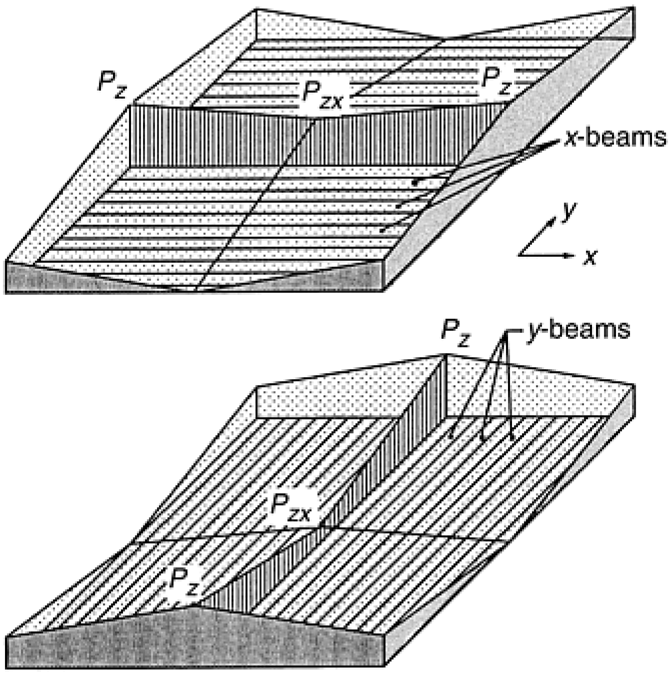

Fig. 10 The inverted triangular pressure distribution. The flat panel can be divided into any number of *x*-beams and *y*-beams, but the critical beams are the two that pass through the panel center. These midspan beams carry the full pressure magnitude at their ends, and they each react a percentage of the total pressure at their intersection point. The sum of the two inverted triangular pressure distributions equals the total uniformly applied pressure.

The end reactions, both vertical shear and bending moment, are computed below for both the *x*-beam and the *y*-beam:

$$R_{zx} = (P_z + P_{zx})\frac{L_x}{4}$$
$$R_{zy} = (P_z + P_{zy})\frac{L_y}{4}$$
$$M_x = -\eta_x \frac{L_x^2}{96}(3P_z + 5P_{zx}) \qquad \text{(Eq 18)}$$
$$M_y = -\eta_y \frac{L_y^2}{96}(3P_z + 5P_{zy})$$

Note that the equations for the end moments, M_x and M_y, contain fixity factors for rotation, η_x and η_y. The fixity factors are equal to 1.0 for fixed ends, and they are equal to 0.0 for pinned ends. The fixity factors are equal to the actual end moments divided by the moment that would have been generated had the end been fully fixed.

A bending peak occurs at the midspan of the beam, as given by Eq 19. Also refer to Fig. 11 for a graphic representation of the pressure distribution and the resulting shear and moment distributions. Note that the midspan bending moments given below are distinguished by double tick marks. This means that the moments are a result of the applied pressure only, and the effect of the offset in-plane load, N_x, is not included. The moment contribution from the offset in- plane load is discussed in the following section.

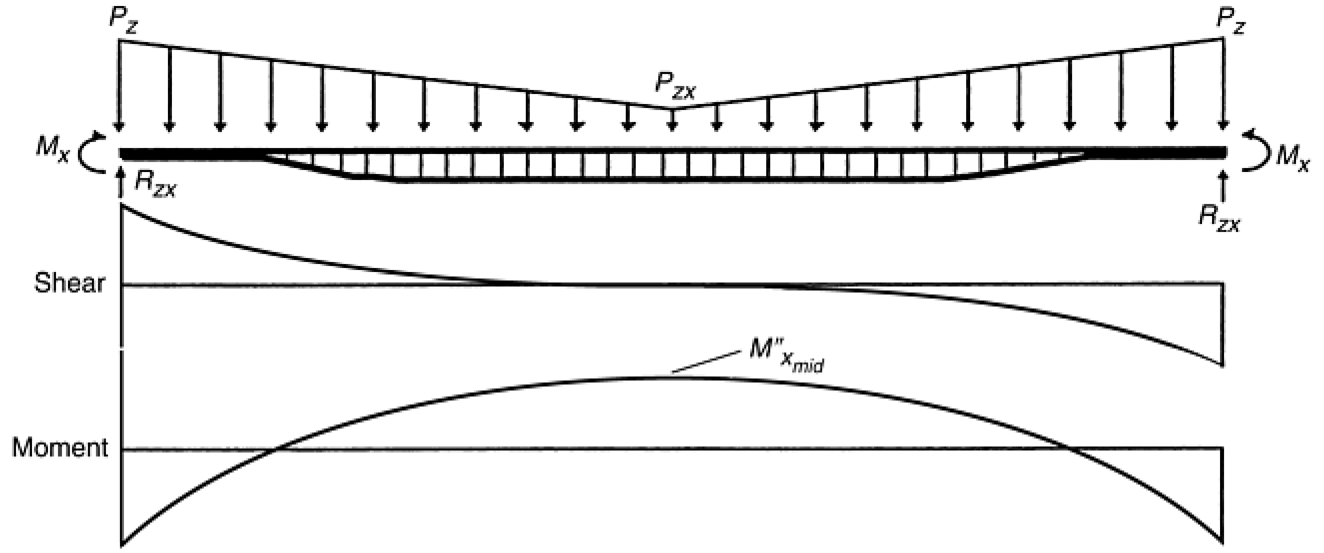

Fig. 11 Shear and moment diagrams for a panel strip. Notation is for the *x*-beam. The *y*-beam would be similar.

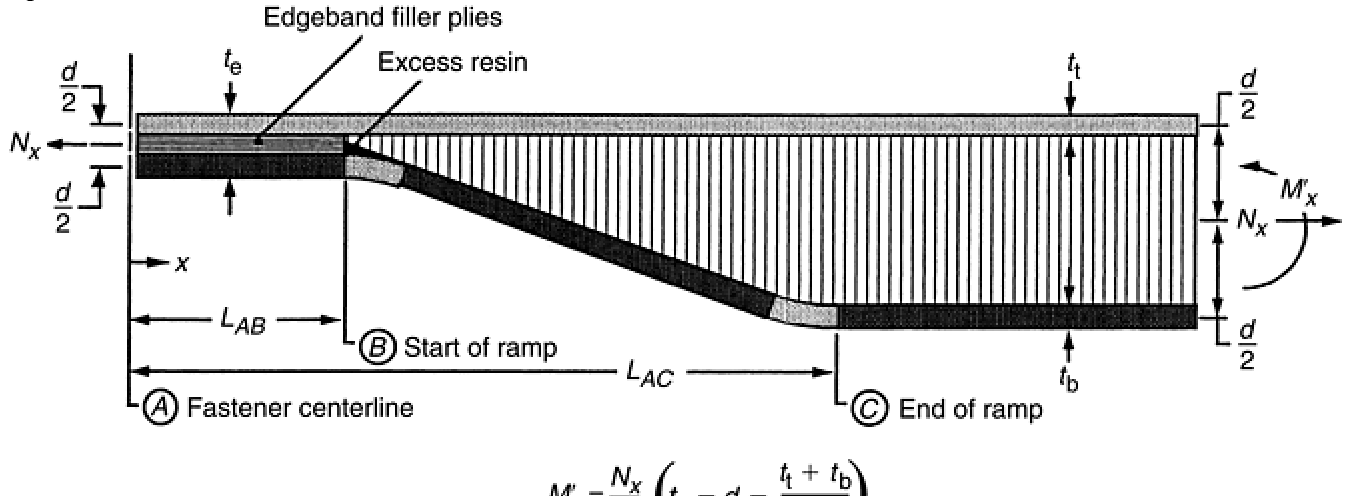
$$M''_{x\mathrm{mid}} = \frac{L_x^2}{96}[P_z(4-3\eta_x)+P_{zx}(8-5\eta_x)]$$

$$M''_{y\mathrm{mid}} = \frac{L_y^2}{96}\left[P_z(4-3\eta_y)+P_{zy}(8-5\eta_y)\right] \quad \text{(Eq 19)}$$

Internal Shear and Moment Distributions. Having established the pressure distribution and resulting end reactions, the internal shear and bending moment can be derived at any point along either of the two mutually perpendicular beams. Before this is done, however, the effect of an applied in-plane load must be considered.

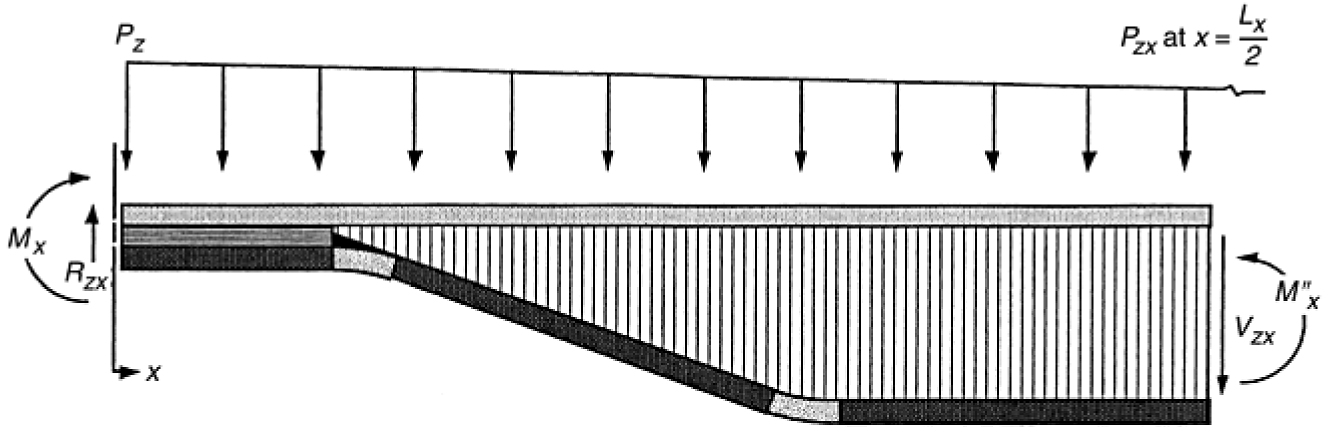
The in-plane load, N_x, is applied halfway between the face midplanes, and, because the halfway point shifts away from the tool side elsewhere in the sandwich beam, a bending moment is developed. The total moment at any point along the beam, therefore, is comprised of two components, namely, the component from the eccentric in-plane load, M'_x, and the component from the out-of-plane pressure load, M''_x . Both bending moment components, M'_x and M''_x, must be added together to arrive at the full bending magnitude.

The freebody diagram in Fig. 12 shows how to derive the moment due to an offset in-plane load. The in-plane load, N_x, induces no bending in the edgeband. From there, the bending moment varies linearly through the ramp region. The moment then becomes a constant value where the facesheets become parallel. The freebody diagram in Fig. 13 illustrates the bending moment due to applied pressure only. The freebody diagrams in Fig. 12 and 13 use notation for the *x*-beam parallel to the *x*-direction. The freebody diagrams for the *y*-beam are analogous.



$$M'_x = \frac{N_x}{2}\left(t_e - d - \frac{t_t + t_b}{2}\right)$$

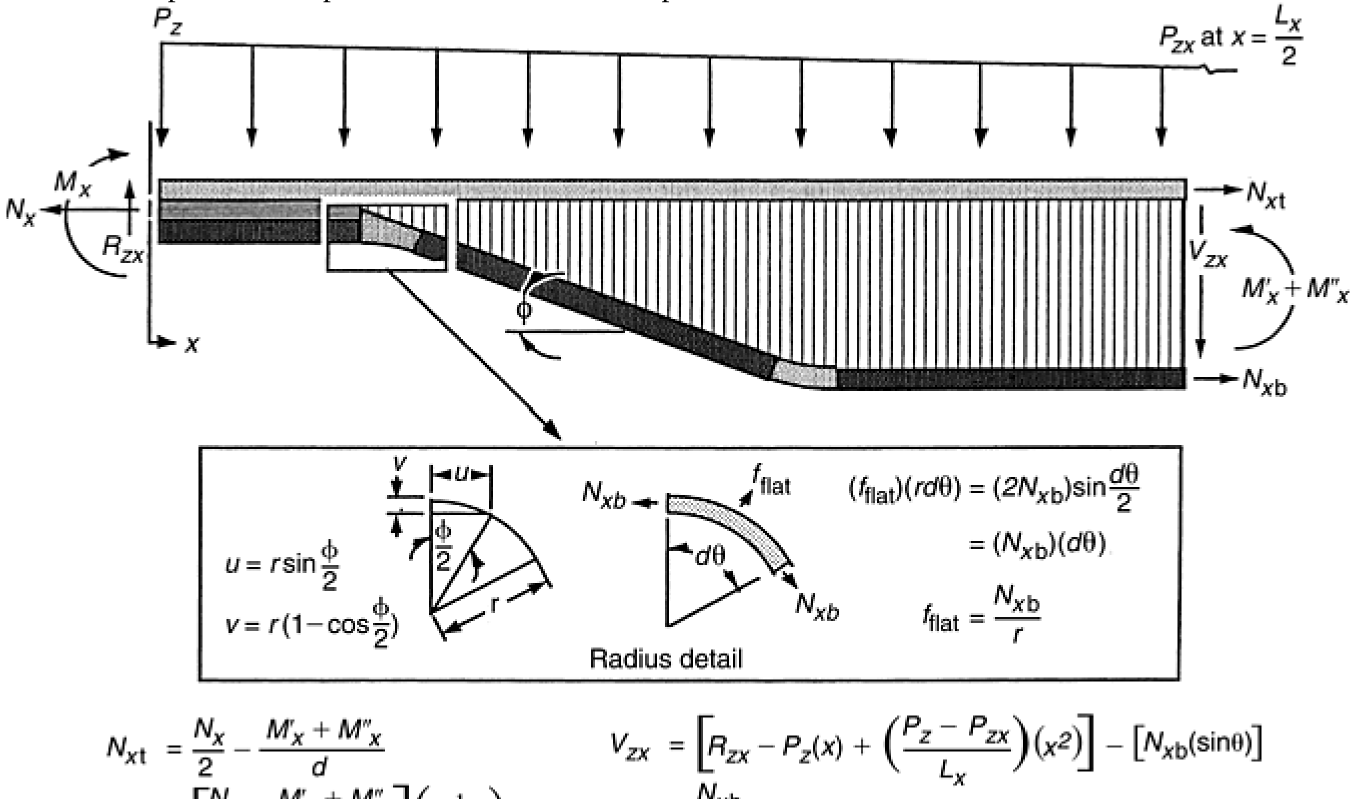
Fig. 12 Bending moments from in-plane load. The bending moment from offset in-plane load, N_x, is a function of the facesheet separation, d. The distance, d, varies linearly through the ramp region.



$$M''_x = M_x + R_{zx}(x) - P_z\left(\frac{x^2}{2}\right) + \left(\frac{P_z - P_{zx}}{L_x}\right)\left(\frac{x^3}{3}\right)$$

Fig. 13 Bending moments from pressure load

The facesheets resist the entire bending and in-plane loads, while the core resists the vertical shear uniformly through its thickness. Figure 14 shows the general freebody diagram with the equations for the facesheet loads ($N_{x\,t}$ and $N_{x\,b}$) and core shear (V_{zx}). In the ramp region, the bag- side facesheet changes direction, so the equations for facesheet loads and core shear are dependent on the angle of the bag-side face. The angle, θ, goes to zero at the top of the ramp where the faces become parallel.



$$N_{xt} = \frac{N_x}{2} - \frac{M'_x + M''_x}{d} \qquad V_{zx} = \left[R_{zx} - P_z(x) + \left(\frac{P_z - P_{zx}}{L_x}\right)(x^2)\right] - \left[N_{xb}(\sin\theta)\right]$$

$$N_{xb} = \left[\frac{N_x}{2} + \frac{M'_x + M''_x}{d}\right]\left(\frac{1}{\cos\theta}\right) \qquad f_{x\,\text{flat}} = \frac{N_{xb}}{r}$$

Fig. 14 Freebody for internal panel loads

At the ramp radius locations, flatwise stresses (f_{flat}) develop between the bag-side facesheet and the core. These stresses tend to either crush the core or pull the face away from the core, depending on their direction. The flatwise stress MPa (psi) is simply computed as the facesheet load N/m (lb/in.) divided by the ramp radius m (in.) for small angles. This calculation is illustrated in Fig. 14.

This analysis method can only approximate the internal load state for a honeycomb panel. The face-sheets are considered to be ineffective in reacting to vertical shear, and the core is considered to be ineffective in reacting to in-plane and bending loads. All bending moments are carried as a tension-compression couple in the facesheets, and the core shear is considered to be uniformly distributed through the core thickness. These and other simplifications are made to facilitate hand calculations. To obtain a more accurate picture of the internal load state, especially in the ramp region where some of the shear is reacted in the facesheets, a FE model may be required.

Core Shear Stress Distribution. The maximum vertical shear stress occurs at the panel edges. However, this does not necessarily mean that the core closest to the panel edge is exposed to the highest shear magnitude. This is because the bag-side facesheet can react to some of the vertical shear in the ramp area. The core shear needs to be evaluated at all points through the ramp area, to the point where the facesheets become parallel. Note that because the core thickness approaches zero at the base of the ramp, the core shear stress mathematically approaches infinity. To get a more accurate representation of the core shear stress distribution in the ramp area, a FE model may be required.

The face-to-core adhesive shear is considered to be equal to the shear in the core itself. However, the adhesive shear allowables are invariably higher than those for the honeycomb core, and a face-to-core shear failure is typically considered not to be a problem.

Facesheet Internal Loads and Stresses. The facesheet fiber strain (ϵ) is often critical at the center of a panel where the bending moment is high. The bending moment can also be large near the edges of a panel, so a moment diagram should be constructed for each of the two mutually perpendicular panel strips to make sure that the most critically loaded portion of the panel is analyzed. The following equations are based on an analysis at the middle of the honeycomb panel where the *x*-beam and the *y*-beam intersect each other. The bending moment is carried as a tension-compression couple in the facesheets. For each face, the in-plane loads are augmented or diminished by the bending loads, as shown by Eq 20. A positive moment puts tension in the bag-side face and compression in the tool- side face.

The applied shear load is split between the two facesheets in Eq 22, based on their relative in- plane shear stiffnesses. Note that the subscript, “t,”refers to the tool side, “b” refers to the bag side, and “f” refers to one face or the other.

$$N_{xf} = \frac{N_x}{2} \pm \frac{M'_x + M''_{xmid}}{d}$$
$$N_{yf} = \frac{N_y}{2} \pm \frac{M'_y + M''_{ymid}}{d} \qquad \text{(Eq 20)}$$
$$N_{xyf} = \frac{(N_{xy})t_f G_{xyf}}{t_t G_{xyt} + t_b G_{xyb}}$$

Add the terms for the bag-side face, and subtract the terms for the tool-side face. Nx_f, Ny_f, Nxy_f are the in-plane facesheet loads for the face being checked, N/m (lb/in.). M''_{xmid}, M''_{ymid} are the midspan bending moments from pressure load Nm/m (in. · lb/in.).

The *x*- and *y*-facesheet stresses are computed using the following equations, or a laminate analysis code:

$$f_{xf} = \frac{N_{xf}}{t_f}$$
$$f_{yf} = \frac{N_{yf}}{t_f} \qquad \text{(Eq 21)}$$

$f_{x\,f}$, $f_{y\,f}$ are the in-plane facesheet stresses for the face being checked, MPa (psi). $N_{x\,f}$, $N_{y\,f}$, $N_{xy\,f}$ are the in-plane facesheet loads for the face being checked, N/m (lb/in.).

The facesheet shear stress can be calculated with Eq 22. The sign of the shear stress does not matter in the margin calculation, so the absolute value is taken.

$$f_{xy\mathrm{f}} = \left| N_{xy} \left(\frac{G_{xy\mathrm{f}}}{G_{xy\mathrm{t}} t_{\mathrm{t}} + G_{xy\mathrm{b}} t_{\mathrm{b}}} \right) \right| \quad \text{(Eq 22)}$$

$f_{xy\ \mathrm{f}}$ is in-plane facesheet shear stress for the face being checked, MPa (psi). N_{xy} is applied in-plane shear load at the panel edges, N/m (lb/in.).

Analysis of Sandwich Structures

Stephen Ward, SW Composites; Lawrence Gintert, Concurrent Technologies Corporation

Curved Sandwich Panel Internal Loads and Stresses

Up to this point, only flat honeycomb panels have been considered. This section includes an analysis to quantify the effect of significant panel curvature. It is convenient to idealize a panel as two mutually perpendicular strips. Each strip, then, is a sandwich beam and can be analyzed as such. Figure 15 shows the geometry for a curved sandwich beam. In addition to considering the effect of beam curvature, the effect of in-plane core stiffness is also included in the following analysis procedures.

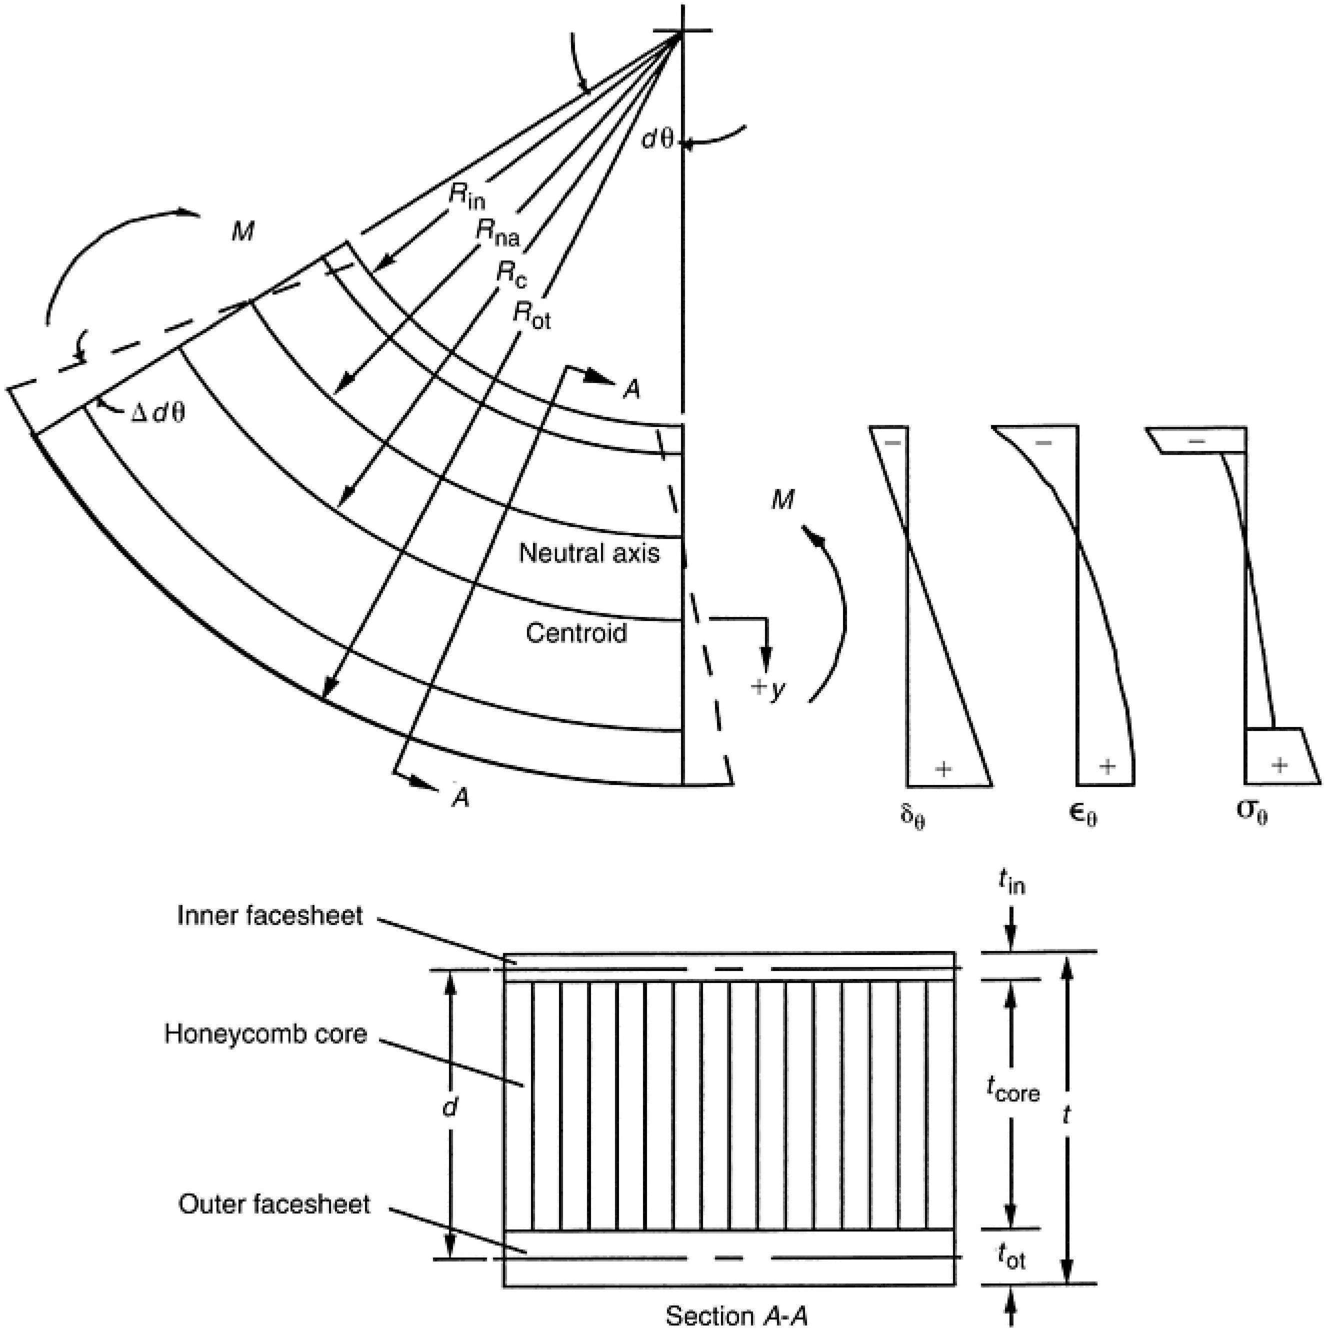


Fig. 15 A curved sandwich beam subjected to pure bending. A positive moment puts tension in the fiber furthest from the center of the curvature. Locations through the thickness of the beam are measured from the centroid, the positive direction being away from the center of the curvature. As the radius of a curved beam gets smaller, the neutral axis shifts from the centroid toward the center of curvature, and the bending strain distribution becomes increasingly nonlinear.

General Equations and Analysis Method. The bending strain distribution for a straight beam is linear from one extreme fiber to the other, but a curved beam has a nonlinear bending strain distribution. For a curved beam, the strain (ϵ_θ) through the thickness is represented by a smooth curve passing through zero at the neutral axis. As with any composite, the stress distribution (σ_θ) is a step function that cannot be represented by a single equation. For this reason, the following general bending equation for composite curved beams is written for strain (ϵ_θ), not stress (σ_θ):

$$\varepsilon_\theta = K_r \cdot \frac{(M)(y)}{D_\theta} \qquad \text{(Eq 23)}$$

The K_r term is dependent on the fiber location in addition to the cross-sectional properties. K_r is greater than 1 for the fiber closest to the center of curvature, less than 1 for the fiber furthest from the center of curvature, and 0 at the neutral axis. As a beam looses its curvature and becomes more straight, the K_r term approaches 1.

$$K_r = \left(\frac{D_\theta}{K_\theta}\right)\left(\frac{1}{(R_c)(y)}\right)\left[1+\frac{1}{Z_\theta}\left(\frac{y}{R_c+y}\right)\right] \qquad \text{(Eq 24)}$$

K_θ = Axial (circumferential) stiffness per unit width

$$\sum_{i=1}^{n}(A_i)(E_i)$$

with units of N/m (lb/in.).
D_θ= Bending stiffness per unit width

$$\sum_{i=1}^{n}(E_i)(I_i)$$

with units of Nm (lb · in.).
Z_θ= Dimensionless property

$$\sum_{i=1}^{n}-\frac{1}{t_i}\int_{t_i}\frac{y}{R_c+y}dt$$

M= Bending moment per unit width with units of Nm/m (in. · lb/in.).
A positive moment puts tension in the fiber furthest from the center of curvature. R_c= Radius of curvature to the sandwich centroid in m (in.). y= Distance from the sandwich centroid in m (in.). Measurements away from the center of curvature are positive. Measurements toward the center of curvature are negative.
The *axial, or circumferential, stiffness* of the curved sandwich beam is equal to the cross-sectional area times the modulus (*AE*) of the facesheets plus the *AE* of the honeycomb core. In this analysis, both faces are considered to have identical moduli, E_{face}. Note that the core modulus is very small compared to the facesheet modulus and is typically neglected. It is included in this and other calculations in order to quantify the effect of core stiffness.

$$K_\theta = E_{face}(t_{in}+t_{ot}) + E_{core}t_{core} \qquad \text{(Eq 25)}$$

E_{face}= Facesheet modulus in the circumferential direction, MPa (psi). E_{core}= Honeycomb core modulus in the circumferential direction, MPa (psi). E_{core} can be considered to be equal to 2 $\cdot G_{core}$, where G_{core} is the shear modulus in the plane of the applied moment. t_{in}, t_{ot}= Inner and outer facesheet thicknesses, respectively, m (in.). t_{core}= Core thickness, m (in.).
The centroid dimension for a curved sandwich beam is computed in the same way as for a straight beam. However, unlike a straight beam, the centroid does not coincide with the neutral axis:

$$R_c = \frac{1}{K_\theta}\left[E_{face}(t_{in}+t_{ot})\left(R_{ot}-\frac{t_{ot}}{2}-\frac{(d)(t_{in})}{t_{in}+t_{ot}}\right) + E_{core}t_{core}\left(R_{ot}-t_{ot}-\frac{t_{core}}{2}\right)\right] \qquad \text{(Eq 26)}$$

R_{in}, R_{ot}= Radii of curvature for the inner and outer facesheets, respectively, m (in.). d= Distance between facesheet midplanes, m (in.), R_{ot}–R_{in}–(t_{in}+t_{ot}/2).
The flexural stiffness, or bending stiffness, D_θ, for a narrow sandwich beam is equal to the modulus times the moment of inertia (*EI*) for the facesheets plus the *EI* for the honeycomb core. A wide beam is stiffer in bending than a narrow beam, but the following equation does not take this augmented stiffness into account. The following equation for flexural stiffness is an approximation. The centroid and midplane of each facesheet are considered to be coincident. In addition, the centroid of the two combined faces is considered to be coincident with the centroid of the core, so their respective moments of inertia can be directly superimposed to obtain the moment of inertia for the entire sandwich element:

$$D_\theta = E_{\text{face}}\left(\frac{d^2 t_{\text{in}} t_{\text{ot}}}{t_{\text{in}} + t_{\text{ot}}}\right) + E_{\text{core}}\left(\frac{t_{\text{core}}^3}{12}\right) \qquad \text{(Eq 27)}$$

The Z_θ term of Eq 24 is a property of the cross section somewhat similar to the moment of inertia. This dimensionless property is written for the sandwich section:

$$Z_\theta = -1 + \frac{R_c}{K_\theta}\left[E_{\text{face}} \cdot \ln\left(\frac{R_{\text{ot}}}{R_{\text{in}}}\right) + (E_{\text{core}} - E_{\text{face}}) \times \ln\left(\frac{R_{\text{ot}} - t_{\text{ot}}}{R_{\text{in}} + t_{\text{in}}}\right)\right] \qquad \text{(Eq 28)}$$

The facesheet stresses in the circumferential direction, σ_θ, are computed as follows:

$$\sigma_{\theta\text{in}} = K_{\text{rin}} E_{\text{face}}\left(\frac{(M)(c_{\text{in}})}{D_\theta}\right)$$

$$\sigma_{\theta\text{ot}} = K_{\text{rot}} E_{\text{face}}\left(\frac{(M)(c_{\text{ot}})}{D_\theta}\right)$$

$$K_{\text{rin}} = \left(\frac{D_\theta}{K_\theta}\right)\left(\frac{1}{(R_c)(c_{\text{in}})}\right)\left[1 + \frac{1}{Z_\theta}\left(\frac{c_{\text{in}}}{R_c + c_{\text{in}}}\right)\right]$$
$$K_{\text{rot}} = \left(\frac{D_\theta}{K_\theta}\right)\left(\frac{1}{(R_c)(c_{\text{ot}})}\right)\left[1 + \frac{1}{Z_\theta}\left(\frac{c_{\text{ot}}}{R_c + c_{\text{ot}}}\right)\right] \qquad \text{(Eq 29)}$$

c_{in}= Distance from sandwich centroid to the midplane of the inner facesheet, m (in.) =–[(R_c–R_{in}–(t_{in}/2)]. c_{ot}= Distance from sandwich centroid to the midplane of the outer facesheet, m (in.) =+[(R_{ot}–R_c (t_{ot}/2)].

The face-to-core bondline stresses in the radial or flatwise direction, σ_r, are computed below. The following equations consider $\sigma_{\theta\text{in}}$ and $\sigma_{\theta\text{ot}}$ to be uniformly distributed through the inner and outer facesheet thicknesses, respectively:

$$\sigma_{\text{rin}} = +\sigma_{\theta\text{in}} \frac{t_{\text{in}}}{R_{\text{in}} + t_{\text{in}}}$$
$$\sigma_{\text{rot}} = -\sigma_{\theta\text{ot}} \frac{t_{\text{ot}}}{R_{\text{ot}} - t_{\text{ot}}} \qquad \text{(Eq 30)}$$

Stephen Ward, SW Composites; Lawrence Gintert, Concurrent Technologies Corporation

Local Strength Analysis Methods

The following subsections contain analysis methods for each of the various sandwich panel failure modes.

Facesheet Fiber Strain. Facesheet material allowables are often available in terms of strain values. Given facesheet internal loads calculated with either a closed form or finite element analysis of the panel, the loads in the facesheets can be converted to strains with Eq 31. The load-to- strain conversion and the strain rotation can also be accomplished by using a laminate analysis computer program:

$$\varepsilon_{xf} = N_{xf}\left(\frac{1}{tE_x}\right)_f - N_{yf}\left(\frac{\nu_{yx}}{tE_y}\right)_f$$

$$\varepsilon_{yf} = N_{yf}\left(\frac{1}{tE_y}\right)_f - N_{xf}\left(\frac{\nu_{xy}}{tE_x}\right)_f \quad \text{(Eq 31)}$$

$$\gamma_{xyf} = N_{xyf}\left(\frac{1}{tG_{xy}}\right)_f$$

ϵ_{xf}, ϵ_{yf}, γ_{xyf}= In-plane facesheet strains, 10^{-6} m/ m (μin./in.). $N_{x\ f}$, $N_{y\ f}$, $N_{xy\ f}$= In-plane facesheet loads, N/m (lb/in.). E_x, E_y, G_{xy}, ν_{xy}, ν_{yx}, t= Material properties and thickness for the face being checked.

Each of the fiber orientations needs to be checked, and this may require rotating the *x*- and *y*-strains to other directions. The angle, α, is measured counterclockwise from the *x*-direction.

$$\varepsilon_{\alpha f} = \left(\frac{\varepsilon_{xf}+\varepsilon_{yf}}{2}\right) + \left(\frac{\varepsilon_{xf}-\varepsilon_{yf}}{2}\right)\cos(2\alpha) + \left(\frac{\gamma_{xyf}}{2}\right)\sin(2\alpha) \quad \text{(Eq 32)}$$

or

$$\varepsilon_{\alpha f} = \varepsilon_{xf}\cos^2\alpha + \varepsilon_{yf}\sin^2\alpha + \gamma_{xyf}\sin\alpha\cos\alpha$$

$\epsilon_{\alpha f}$= In-plane facesheet strain with respect to the fiber being checked, 10^{-6} m/m (10^{-6} in./in.). ϵ_{xf}, ϵ_{yf}, γ_{xyf}= In-plane facesheet strains, 10^{-6} m/m (10^{-6} in./in.). α= Angle of fiber being checked, in degrees.

Core Shear. For panels subjected to normal pressure loading, transverse shear loads, Q_x and Q_y, are carried by the core. Use a laminate analysis program that can determine the maximum transverse shear stresses, τ_{xz} and τ_{yz}, in the core caused by transverse shear forces, or use the simplified relations below. For panels with facesheet thickness less than 5% of the core thickness, assume that the core carries all the shear load:

$$\tau_{xz} = \frac{Q_x}{c} \quad \tau_{yz} = \frac{Q_y}{c} \quad \text{(Eq 33)}$$

If the facing thickness is greater than 5% of the core thickness, the faces will carry some of the shear and:

$$\tau_{xz} = \frac{Q_x}{c + \frac{t_1+t_2}{2}}$$

$$\tau_{yz} = \frac{Q_y}{c + \frac{t_1+t_2}{2}} \quad \text{(Eq 34)}$$

Calculate the core margin of safety (MS) based on the appropriate core shear allowables, F_{sl},F_{sw} (in ribbon longitudinal and ribbon transverse direction, respectively), or the face-to-core bond strength, with the following equation. Equation 35 assumes that the ribbon longitudinal direction is oriented along the *x*-axis:

$$\text{MS} = \frac{1}{\sqrt{\left(\frac{\tau_{xz}}{F_{sl}}\right)^2 + \left(\frac{\tau_{yz}}{F_{sw}}\right)^2}} - 1 = \frac{F_{sl}F_{sw}}{\sqrt{F_{sw}^2\tau_{xz}^2 + F_{sl}^2\tau_{yz}^2}} - 1 \quad \text{(Eq 35)}$$

Flatwise Tension and Compression. At the edges of a typical honeycomb sandwich panel, the bag-side facesheet ramps up over the core (Fig. 14). At the start and finish of the ramp, where the facesheet changes direction, interlaminar stresses (flatwise tension or compression) are induced at the face-to-core bondline. A flatwise tension stress can cause debonding between the face and the core, and a flatwise compression stress

can induce core crushing. The flatwise stress should be computed at the center of each ramp radius. The following equations provide approximate magnitudes for the flatwise stresses. A *FE* model may be required to provide a more accurate assessment of the stress state in the ramp areas.
The subsequent equation is based on the assumption that the flatwise stress is uniformly distributed around the radius from the start of curvature to the end of curvature. Note that the computation requires the load in the bag-side facesheet, and this is dependent on, among other things, the distance between the faces and the angle of the bag side with respect to the tool side. The gap between the faces and the angle of the bag side are both variables in the ramp region, so the analyst needs to take care in obtaining the proper geometry.
The following equations use loads in the *x*- direction. The panel strip in the *y*-direction must also be checked, and similar equations can be written:

$$f_{x\text{flat}} = \pm \frac{N_{x\text{b}}}{R} \quad \text{(Eq 36)}$$

Use "+" for concave radii and "–" for convex radii. $f_{x\text{flat}}$= Flatwise stress at radius, MPa (psi). $N_{x\text{b}}$= Load in the bag-side facesheet, N/m (lb/ in.). R= Ramp radius, m (in.).
At the radius closest to the edgeband, the critical stress is considered to be interlaminar tension between the plies of the bag-side laminate. At the radius furthest from the edgeband, the failure modes are considered to be either separation of the bag-side face from the core due to flatwise tension or core crushing due to flatwise compression. Flatwise compression allowables are equivalent to the crushing strength of the core material, F_{cc}.
The flatwise tension and compression margin of safety is computed from the equation:

$$\text{MS}_{x\text{flat}} = \frac{F_{\text{flat}}}{f_{x\text{flat}}} - 1 \quad \text{(Eq 37)}$$

MS_{flat}= Flatwise stress margin of safety. F_{flat}= Flatwise stress allowable, MPa (psi). f_{flat}= Flatwise stress at radius, MPa (psi).
Flexural Core Crushing. As a sandwich panel bends, the core must restrain the facesheets from moving toward each other. In this way, a compressive or crushing force is induced in the core. This failure mode is checked at the location of the maximum bending moments. The core crushing stress is computed using:

$$f_{\text{crush}} = \frac{M_x^2}{d\,D_{zx}} + \frac{M_y^2}{d\,D_{zy}} + P \quad \text{(Eq 38)}$$

f_{crush}= Core compressive stress, MPa (psi). M_x,M_y= Bending moments from in-plane and pressure loads, Nm/m (in. · lb/in.). P= Normal pressure or locally applied load, MPa (psi)
The margin of safety is calculated using:

$$\text{MS}_{\text{crush}} = \frac{F_{\text{cc}}}{f_{\text{crush}}} - 1 \quad \text{(Eq 39)}$$

MS_{crush}= Core crushing margin of safety. f_{crush}= Core compressive stress, MPa (psi). F_{cc}= Core compressive strength, MPa (psi).
Intracell Buckling. *Intracell buckling*, or *face dimpling*, is a local instability failure where a facesheet buckles within the confines of a single cell. The honeycomb cell walls serve as nodal points while one or both of the faces buckle, inwardly or outwardly, within the unbonded region of the cell interior. Dimpling of the facings may not lead to failure, unless the amplitude of the dimples becomes large. This could cause the dimples or buckles to grow across core cell walls and result in wrinkling of the facings. Dimpling that does not cause total structural failure may be severe enough so that permanent dimples remain after removal of load.
Intracell buckling can be induced in facesheets subjected to in-plane compression or in-plane shear. The critical location normally occurs at the middle of the panel, where the bending moment is high. The following subsections contain simplified formula for intracell buckling analysis. Alternatively and for combined loading cases, a laminated plate buckling computer program can be used. The conservative approach is to assume a square simply supported plate with edge length equal to *s*, the core cell size, and use the stiffness properties for the individual facesheet being checked. Determine the loading acting on each individual face and apply these loads in the buckling analysis to determine the margins of safety. For curved panels, this approach remains valid, because the cell size is usually much smaller than the panel curvature.
The facing properties shall be values at the condition of use; that is, if the structure is at elevated temperature, then facing properties at that environment shall be used in design. The facing modulus of elasticity is the

effective value at the facing stress. If this stress is beyond the proportional limit value, an appropriate tangent, reduced or modified compression modulus of elasticity, shall be used.
The following analysis methods assume that the panel faces are not subjected to normal pressure.
Compression Intracell Buckling. The *intracell buckling critical* stress is the same for both the *x*- and *y*-directions, and the expression is given:

$$F_{\text{Cdimple}} = \left(\frac{\pi^2}{12}\right)\left(\frac{E_x(1+\nu_{yx})+E_y(1+\nu_{xy})}{1-\nu_{xy}\nu_{yx}} + 4G_{xy}\right) \times \left(\frac{t_f}{s}\right)^2 \quad \text{(Eq 40)}$$

Equation 40 is valid for facesheets that are orthotropic. If the faces were quasi-isotropic (a homogeneous 25/50/25 lay-up), the previous expression reduces to:

$$F_{\text{Cdimple}} = \left(\frac{\pi^2}{3}\right)\left(\frac{E}{1-\nu^2}\right)\left(\frac{t_f}{s}\right)^2 \quad \text{(Eq 41)}$$

F_{Cdimple}= Compression intracell buckling critical stress, MPa (psi).
The margin of safety for compression intracell buckling is given below. Only compressive stresses produce buckling, and all tensile stresses should be ignored or set to zero in the following interaction equation:

$$\text{MS}_{\text{Cdimple}} = \frac{F_{\text{Cdimple}}}{f_{xf}+f_{yf}} - 1 \quad \text{(Eq 42)}$$

$\text{MS}_{\text{Cdimple}}$= Margin of safety for compression intracell buckling, MPa (psi). F_{Cdimple}= Intracell buckling critical stress, MPa (psi). $f_{x\,f}$, $f_{y\,f}$= in-plane facesheet compression stresses for the face being checked, MPa (psi).
Shear Intracell Buckling. An empirical expression for the intracell buckling critical stress for shear is shown below.

$$F_{\text{Sdimple}} = (0.60)E_{xf}\left(\frac{t_f}{s}\right)^{1.5} \quad \text{or} \quad F_{\text{Sdimple}} = (0.60)E_{yf}\left(\frac{t_f}{s}\right)^{1.5} \quad \text{(Eq 43)}$$

F_{Sdimple}= Intracell buckling critical stress for shear, MPa (psi).
The intracell buckling margin of safety for shear is computed below. The allowable can be expressed in terms of the *x*- or the *y*-directions. Use the lowest of the two.

$$\text{MS}_{\text{Sdimple}} = \frac{F_{\text{Sdimple}}}{f_{xyf}} - 1 \quad \text{(Eq 44)}$$

$\text{MS}_{\text{Sdimple}}$= Margin of safety for shear intracell buckling. F_{Sdimple}= Intracell buckling critical stress for shear, MPa (psi)
Combined Compression and Shear Intracell Buckling. For facesheets with combined compression and shear loads, the following interaction equation may be used:

$$R_c = \frac{(f_{xf}+f_{yf})}{F_{\text{Cdimple}}}$$

$$R_s = \frac{f_{xyf}}{F_{\text{Sdimple}}} \quad \text{(Eq 45)}$$

$$\text{MS}_{\text{dimple}} = \frac{2}{R_c + (R_c^2 + 4R_s^2)^{1/2}} - 1$$

Face Wrinkling. *Face wrinkling* occurs when the core material or the face-to-core bond does not adequately stabilize the facesheets. It is similar to the buckling of a facesheet into or away from the elastic foundation of the honeycomb core.

Face wrinkling can be induced in facesheets subjected to in-plane compression or in-plane shear, and the critical location normally occurs at the middle of the panel where the bending moment is greatest. Analysis of this localized buckling behavior is complicated by the unknown waviness of sandwich facings. Thus, the designer must, in effect, consider the buckling of a column (facing) that is supported on an elastic foundation (core), that is not initially straight. The initial curvature or deflection (waviness) is not easily defined or easily measured. Growth of initial waves causes stresses in the core and in the bond between the facings and core. Final failure may occur suddenly, and the facing may buckle inward or outward, depending on the flatwise compression strength of the core relative to the flatwise tensile strength of the bond between the facing and core. The analysis in this section should be used in conjunction with information on general buckling and instability. The final design should be checked to ascertain whether wrinkling of the sandwich facings might occur at the design load. Because of uncertainties in analysis and values of material properties, it is recommended that the final design be checked by tests of a few specimens.

As with other cases, the facing properties shall be values at the condition of use. If the structure is at elevated temperature, then facing properties at that environment shall be used in design. The facing modulus of elasticity is the effective value at the facing stress. If this stress is beyond the proportional limit value, an appropriate tangent, reduced or modified compression modulus of elasticity, shall be used.

Compression Face Wrinkling. The compression stress allowable for face wrinkling is given below for both the *x*- and *y*-directions. The following equations have been found to correlate well with test data from panels with relatively soft cores, such as Nomex (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE). For very stiff metallic cores, these equations may produce unconservative results. In these cases, an analysis that includes facesheet waviness and core-to-facesheet bond strength may be required. These analyses can be found in MIL-HDBK-23. (This handbook is in the process of being converted and expanded by the MIL-HDBK-17 committee, and it will be released as a separate MIL-HDBK-17 volume in the future.)

In the *x*-direction, use the lower of:

$$F_{xfwrinkle} = -0.44(E_{xf}E_{cc}G_{xz})^{1/3}$$

$$F_{xfwrinkle} = -0.247(E_{xf}E_{cc}G_{xz})^{1/3} - 0.078\frac{G_{xz}^2}{G_L}\frac{t_c}{t_f} \quad \text{(Eq 46)}$$

In the *y*-direction, use the lower of:

$$F_{yfwrinkle} = -0.44(E_{yf}E_{cc}G_{yz})^{1/3}$$

$$F_{yfwrinkle} = -0.247(E_{yf}E_{cc}G_{yz})^{1/3} - 0.078\frac{G_{yz}^2}{G_L}\frac{t_c}{t_f} \quad \text{(Eq 47)}$$

$F_{x\ \mathrm{fwrinkle}}$, $F_{y\ \mathrm{fwrinkle}}$= Face wrinkling allowables, MPa (psi). $E_{x\ \mathrm{f}}$, $E_{y\ \mathrm{f}}$= Elastic flexural moduli in the *x*- and *y*-directions for the face being checked, MPa (psi). $E_{i\ \mathrm{f}}= 12D_{ii}/t^3$ (not necessarily equal to axial modulus, $E_i=A_{ii}/t$). For stresses above the material yield stress, use the reduced modulus for $E_{i\ \mathrm{f}}$. G_L= Core shear modulus in the ribbon direction, MPa (psi).

The MS for compression face wrinkling is computed subsequently. In flat panels, only compressive stresses produce buckling, and all tensile stresses should be ignored or set to zero in the following interaction equation. The following equation is used when $f_{y\ \mathrm{f}}$ is the maximum compressive stress. When $f_{x\ \mathrm{f}}$ is the maximum compressive stress, the *y*-term should be cubed instead of the *x*-term. If only one load is compressive, the cubed exponent is left off:

$$\mathrm{MS}_{Cwrinkle} = \frac{1}{\left(\frac{f_{xf}}{F_{xfwrinkle}}\right)^3 + \left(\frac{f_{yf}}{F_{yfwrinkle}}\right)} - 1 \quad \text{(Eq 48)}$$

$\mathrm{MS}_{Cwrinkle}$= Face wrinkling margin of safety. $F_{x\ \mathrm{fwrinkle}}$,$F_{y\ \mathrm{fwrinkle}}$= Face wrinkling allowables, MPa (psi).

Shear Face Wrinkling. The shear wrinkling allowable can be expressed in terms of the *x*- or the *y*-directions. Use the lowest of the following four equations:

$$F_{\text{Sfwrinkle}} = \frac{0.44(E_{45\text{f}}E_{\text{cc}}G_{xz})^{1/3}}{\sqrt{3}}$$

$$F_{\text{Sfwrinkle}} = \frac{0.44(E_{45\text{f}}E_{\text{cc}}G_{yz})^{1/3}}{\sqrt{3}}$$

$$F_{\text{Sfwrinkle}} = \frac{0.247(E_{45\text{f}}E_{\text{cc}}G_{xz})^{1/3} + 0.078\dfrac{G_{xz}^2}{G_L}\dfrac{t_\text{c}}{t_\text{f}}}{\sqrt{3}} \qquad \text{(Eq 49)}$$

$$F_{\text{Sfwrinkle}} = \frac{0.247(E_{45\text{f}}E_{\text{cc}}G_{yz})^{1/3} + 0.078\dfrac{G_{yz}^2}{G_L}\dfrac{t_\text{c}}{t_\text{f}}}{\sqrt{3}}$$

$F_{\text{Sfwrinkle}}$= Face wrinkling allowable for shear, MPa (psi). $E_{45\text{f}}$= Elastic flexural moduli in direction 45° to the *x*-direction for the face being checked, MPa (psi).

$$\frac{1}{E_{45\text{f}}} = \frac{1}{4E_{x\text{f}}} + \left(\frac{1}{4G_{xy}} - \frac{\nu_{xy}}{2E_{x\text{f}}}\right) + \frac{1}{4E_{y\text{f}}}$$

For stresses above the material yield stress, use the reduced modulus for $E_{i\ \text{f}}$. G_L= Core shear modulus in the ribbon direction, MPa (psi).

The shear wrinkling margin of safety is computed with the following equation.

$$\text{MS}_{\text{Sfwrinkle}} = \frac{F_{\text{Sfwrinkle}}}{f_{xy\text{f}}} - 1 \qquad \text{(Eq 50)}$$

$\text{MS}_{\text{Sfwrinkle}}$= Margin of safety for shear wrinkling. $F_{\text{Sfwrinkle}}$= Wrinkling allowable for shear, MPa (psi).

Core Shear Crimping. *Core shear crimping* is a general instability failure that can occur when the core shear modulus is low. The compression and shear allowables for crimping are computed for the *x*-, *y*-, and *xy*-directions:

$$F_{x\text{crimp}} = -(0.75)\left(\frac{d^2}{t_\text{f}t_\text{c}}\right)G_{xz}$$

$$F_{y\text{crimp}} = -(0.75)\left(\frac{d^2}{t_\text{f}t_\text{c}}\right)G_{yz} \qquad \text{(Eq 51)}$$

$$F_{xy\text{crimp}} = -(0.75)\left(\frac{d^2}{t_\text{f}t_\text{c}}\right)\sqrt{G_{xz}G_{yz}}$$

$F_{x\ \text{crimp}}$, $F_{y\ \text{crimp}}$, $F_{xy\ \text{crimp}}$= Crimping allowables, MPa (psi).

The shear crimping margins are computed subsequently. A suitable interaction equation for biaxial and/or shear loading is not known, so a margin of safety is computed for each direction individually. Only compressive stresses produce buckling, and all tensile stresses should be ignored.

$$\text{MS}_{x\text{crimp}} = \frac{F_{x\text{crimp}}}{f_{x\text{f}}} - 1$$

$$\text{MS}_{y\text{crimp}} = \frac{F_{y\text{crimp}}}{f_{y\text{f}}} - 1 \qquad \text{(Eq 52)}$$

$$\text{MS}_{xy\text{crimp}} = \frac{F_{xy\text{crimp}}}{f_{xy\text{f}}} - 1$$

$\text{MS}_{x\text{crimp}}$, $\text{MS}_{y\text{crimp}}$, $\text{MS}_{xy\text{crimp}}$= Margins of safety for shear crimping. $F_{x\ \text{crimp}}$, $F_{y\ \text{crimp}}$, $F_{xy\ \text{crimp}}$= Crimping allowables for shear, MPa (psi).

Flat Panel Stability Analysis Methods

The article "Instability Considerations" in this Volume offers a general treatment of composite panel buckling. General stability solutions are best obtained from a computer analysis, using either a closed-form buckling solution or a FE analysis. The analysis must include the influence of the core transverse shear flexibility. In most cases of sandwich panels with thin orthotropic facesheets, the panel stiffness matrix terms A_{16}, A_{26}, B_{ij}, D_{16}, and D_{26} are usually small or zero. Thus, the analysis method does not have to include the capability for including the effects of these terms. Most panel buckling codes, and all finite element codes, can analyze combinations of in-plane compression (axial or biaxial) and shear loads.

Some computerized buckling analysis tools will predict the shear crimping instability mode. This mode occurs when the core shear stiffness is low. This mode can be detected from the analysis output by either a large number of half- waves or a very short wavelength of the critical stability mode shape.

In most cases, linear eigenvalue buckling analyses will overstate the buckling load of panels and cylinders because panel imperfections and nonlinear responses are not included. Empirically derived correlation factors are often used to reduce the predicted buckling loads from an eigenvalue analysis to provide sufficient levels of conservatism. The NASA Langley Reseach Center has published an extensive number of documents on various advanced methods for predicting the stability of composite structures.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

Introduction

MOST APPLICATIONS of advanced fiber- reinforced composite materials require detailed analysis and design at component, substructure, and system levels to evaluate the structural response under applied static, dynamic, fatigue, and impact loads. Accurate static load analysis and natural frequency extraction are often considered essential first steps in many design processes, before more complex analyses, such as transient, fatigue, dynamic durability, crash energy absorption, and shape and size optimization, are performed. This article provides an overview of finite-element-based analyses (FEA) of advanced composite structures highlighting the key aspects. Additional information on the general use of FEA is provided in the article "Finite Element Analysis" in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

The analysis and design of fibrous composite structures is hierarchical by nature. While the static stiffness and modal response can be computed from the macrolevel analyses, the computation of more complex structural characteristics, such as ultimate load-carrying capability under static and dynamic loads, static and dynamic fatigue life, and impact-crash energy absorption, require a very detailed knowledge of material behavior at the micro, or fiber-matrix, level. Thus, understanding the damage mechanisms at the micromechanical level is the key to successfully designing the fibrous composite structures. A reliable micromechanical analysis of properties of fibrous composite materials is the crucial first step in subsequent macromechanical analysis and design of structures manufactured from these materials. See the articles "Micromechanics" and "Macromechanics Analysis of Laminate Properties" in this Volume.

Because fibrous composite materials offer a wide range of fiber-matrix combinations in many forms, *analysis, rather than experimentation*, becomes a more practical procedure to obtain physical materials properties, such as elastic constants, coefficients of thermal and moisture expansion, viscoelastic properties, thermal conductivity, and static strengths. Thus, as Hashin (Ref 1) pointed out, the relevant methods for evaluating such properties are those of applied mechanics, rather than those of materials science.

The preceding statement is also true in performing the macrolevel analysis of structures manufactured from these highly tailorable fibrous composite materials. It is far more practical to analyze and optimize the design concepts for different materials combinations on a computer, rather than manufacturing and testing each concept. Use of appropriate, accurate, and efficient computer-aided engineering tools, rather than the costly and time-consuming physical testing, is the most cost-effective way to analyze, design, and optimize fibrous composite structures subjected to various types of applied load, such as static, dynamic, cyclic fatigue, and impact-crash. The National Aeronautics and Space Administration (NASA) and the defense, automotive, and civil infrastructure industries have been unrelenting in the development of advanced composite analysis and design tools, through individual efforts as well as through mutual cooperation and collaborations with universities.

Two classical examples from the mechanics of composite materials are solved in this article using FEA approach. These numerical examples illustrate the two unique aspects of the analysis of multilayered composite structures:

- The continuity of transverse stresses at the layer interfaces
- The free-edge, or boundary layer, effects

For an in-depth study, the reader is referred to various texts (e.g., 2, 3 4, 5 6, 7 8, 9 10, 11 12, 13 14, 15 16, 17) covering a wide range of topics in the FEA of composite structures.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

Overview of Finite Element Analysis

Finite element analysis has emerged as one of the most powerful tools to solve complex engineering problems and has become an integral part of every established computer-aided design, manufacturing, engineering, and optimization process. The acronyms CAD, CAM, CAE, and CAO have been "coined" to designate these processes, respectively. In their text, Bathe and Wilson (Ref 2) describe numerous ways to classify the finite element (FE) formulations, even when restricting oneself to the solution of structural mechanics problems based on variational principles. A FE formulation can be displacement- based, stress-based, mixed, or hybrid. The displacement-based FE formulation is the most widely used because of its simplicity, generality, and good numerical properties. Moreover, the convergence criteria for the displacement-based FE formulations are precisely established as compared to the other formulations. The concepts of FE method have been successfully used to develop a wide variety of beam, plate, shell, plane stress, plane strain, axisymmetric, and three-dimensional (3-D) solid elements.

In a FEA, the structure is represented as an assemblage of a finite number of elements. The principle of *virtual work* forms the basis of displacement-based FE formulations. The displacement field of each element is approximated in the form of a function whose unknown coefficients are treated as *generalized coordinates*. This type of FE formulation is often termed the *generalized coordinate finite element formulation.* However, in most standard commercial FE analyses, the generalized coordinates are further expressed in terms of the element *nodal displacements.* Depending upon the type of formulation used, either the generalized coordinatesor the nodal displacements are unknowns in the analysis. First, the solution to these unknowns is obtained; subsequently, the displacements, stresses, and strains in the finite elements of the structure are computed.
Once the geometry definition (or the CAD data) of a component or substructure system is known, the following steps are required to perform FE-based structural analysis:

1. Select type of FEA: static, modal, dynamic, thermal, coupled-fluid structure, linear, or nonlinear.
2. Select type of FE: beam, plate, shell, plane strain/stress, axisymmetric or solid, and mesh (coarse or fine) discretization.
3. Define constitutive models: full 3-D orthotropic/anisotropic, two-dimensional (2-D) orthotropic/anisotropic, equivalent orthotropic, or laminate model.
4. Define static, dynamic, and/or cyclic applied loads of forces, moments, temperatures, accelerations, and so on.
5. Prescribe kinematical boundary conditions, the translational and rotational restraints.
6. Choose solution method (direct sparse, preconditioned conjugate gradient iterative, arc- tangent, etc.) and the solution control parameters.
7. Obtain the deformation patterns, strains, and stresses at various locations in the structure and evaluate the ultimate load-carrying capacity of the structure.

While all the above steps are common to the analysis of both the metallic as well as composite structures, steps 2, 3, and 7 make the FEA of composites different, tedious, and complex. Aspects of a detailed FEA that can seem overwhelming include:

- Input of fiber architecture definition
- Input of material data
- Extraction of stresses and strains in the material coordinate system
- Availability of many different criteria to determine the damage initiation and progression

The two key aspects of the FEA of composite structures are:

- Homogenization of materials properties to obtain the elemental constitutive law
- Post-processing of numerical results to recover strains and stresses in the principal material directions for subsequent failure prediction analysis

These are also the most important characteristics that distinguish the composite FEA from the metal FEA, and make the analysis of composites more complex and time-consuming. In the analysis of composite structures, the homogenization of materials properties occurs at two levels, one based on micromechanics and the other based on macromechanics. A structure created from different composite raw-material forms, such as unidirectional lamina, roving, braids, woven fabrics, sandwich, or chopped random mats (see the Section “Constituent Materials” in this Volume) may exhibit different macromechanical response. Thus, the computation of basic layer/lamina/ply-level elastic constants from its material constituents (fiber, matrix, and coatings) and the fiber architecture type (unidirectional roving, braids, braid angles, woven fabrics, fiber directions, and weave patterns) is an essential first step in any FEA of composite structures.

Homogenization

No real-life fibrous composite structure can be completely discretized at the microlevel, the level of its constituent fiber and matrix, in a single stress analysis. Even with the most sophisticated computers now available, it is not only computationally expensive, but also practically impossible to perform such a detailed microlevel discretization and analysis. Therefore, in practical applications of numerical analysis techniques such as FE methods, it becomes necessary to idealize and discretize a composite structure at the macrolevel. The important first step in this direction is to obtain the elastic constants of a ply/ lamina/single layer by homogenizing materials properties at the microlevel. The reinforcement- fiber architecture types, such as unidirectional roving, woven fabrics, and braids, influence the homogenized properties at the microlevel. Fiber architecture plays a dominant role in determining the mechanical response of textile composite materials. Inhomogeneous local displacement fields develop within textile composite laminates, even under uniform extension, as a result of the interweaving and interlacing of the yarn bundles.

A convenient way to analyze a textile composite is to consider a unit cell, or *representative/ repetitive volume element* (RVE), of the material. A unit cell is a unit of repeating fiber architecture that can be considered the building-block of the material. The size of the repeating unit cell is dependent on the tow size of the yarns, the angle at which they are intertwined or interwoven, and yarn spacing. Thus, for the textile composite material reinforcements, such as woven or braided composites, it is customary to obtain the 3-D on- axis material constants for a unit cell. (For more details on textile composite materials, see the article "Fabrics and Preforms" in this Volume.) Once the homogenized single-layer/lamina elastic constants are obtained, they are then used to derive the elemental constitutive laws at the macrolevel.

In a full *3-D analysis,* the fibrous composite structure is essentially discretized at the lamina level, rather than at the fiber-matrix level. Each ply is discretely modeled in space using 3-D solid elements. There are obvious variations to this approach, where all or some layers can be smeared into a single layer and modeled using effective 3-D anisotropic materials properties. As compared to the full microlevel analysis, a full 3-D analysis still does not greatly reduce the computational complexities, because the discretization of any real-life, multilayered composite structure at the ply (or single-layer/lamina) level is by no means an easy task.

While a full 3-D structural analysis may be possible in terms of computational power and resources, it is still prohibitively expensive and a waste of computational time and memory. It is prudent to analyze the real-life structures using 2-D shell or one-dimensional (1-D) beam-, bar-, or rod-type elements. One can always resort to a more detailed, global-local-type full 3-D analysis in highly stressed regions or regions of special interest, such as joints, ply drop-off, and areas where free-edge effects become prominent. In a typical 2-D analysis of multilayered composite structures, the layers are modeled as a smeared entity effective plate membrane, with bending and coupling stiffness constants derived from the classical laminated plate theory. In composite analysis, these stiffness constants are also known as the [**A**], [**B**], and [**D**] stiffness matrices relating plate-shell stress and moment resultants to the midsurface strains and curvatures.

One-dimensional beam elements are most often used in conjunction with 2-D plate-shell elements to model stiffeners and ribs attached to the skin in stiffened plates and shells. In civil engineering analysis applications, beam elements are independently used to model girders and frames. However, as compared to the metallic structures, the use of 1-D beam elements in the analysis of composite material structures is limited. In many structural analysis problems, 1-D beam elements fail to capture the anisotropy, the weakness in transverse shear direction, and the coupling effects associated with a typical composite material behavior. All these effects also complicate the mathematical theory involved in the derivation of composite beam section properties in stretching, bending, torsion, and warping. Thus, the use of beam elements in the analysis of composite structures should be evaluated on a case- by-case basis. One of the best uses of 1-D beam- element-based analysis is in the preliminary design of laminated composite beams and frames, where the analysis needs to be repeated a number of times in an optimization loop (Ref 18).

As in the case of metals, FEA of fibrous composite structure involves the use of various elements or combinations of elements:

- 3-D hexahedrons, bricks, tetrahedrons, and axisymmetric solids
- 2-D shells, plates, and plane stress-strain quadrilaterals
- 1-D beams, bars, rods, trusses, and springs

In case of composite FEA, it is of utmost importance to understand how the macrolevel homogenization is performed to obtain the material constitutive laws for the 3-, 2-, and 1-D finite elements. The types of assumptions and the mathematical theory used to derive the homogenized elemental material constitutive laws at different dimensional levels play an important role, because the subsequent recovery of strains and stresses after the analysis is very dependent on them. Furthermore, it is prudent to note that the mathematical problem of optimization of such a fibrous composite structure under applied loads is essentially an optimization of its constituent materials and the fiber architecture type through these homogenized material constitutive laws.
A general theoretical background for the displacement-based, linear elastic FEA of fibrous composite structures will be outlined, so that the elemental constitutive laws for 3-D solid, 2-D shell, and 1-D beam elements can be obtained through the homogenization process. An I-section beam structure, subjected to arbitrary static and kinematical boundary conditions, is considered as an example problem to demonstrate the relevance of obtaining material constitutive laws at various levels of FEA. This fibrous composite I-beam can be manufactured by pultrusion process using unidirectional roving, by laying up unidirectional fibers, by using fabric prepeg, or by using woven or braided perform consolidated in the resin transfer molding process. Irrespective of the type of constituents, the fiber architecture, or the manufacturing process, in order to proceed with the FEA of the I-beam under applied loads and constraints, it is essential to obtain an appropriate material constitutive law to generate the elemental and, subsequently, the global structural stiffness matrix. At each dimensional level, the fibrous composite constitutive laws are very different and more complex than the simple metallic isotropic constitutive laws.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

3-D Solid Elements

Consider an I-section beam with its web and flanges discretized by solid brick elements for a full 3-D analysis (Fig. 1). The generalized strain vector for a typical 3-D solid element, in the elemental Cartesian coordinate system, is:

$$\bar{\boldsymbol{\varepsilon}} = [\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{zz}, \gamma_{yz}, \gamma_{xz}, \gamma_{xy}]^T \quad \text{(Eq 1)}$$

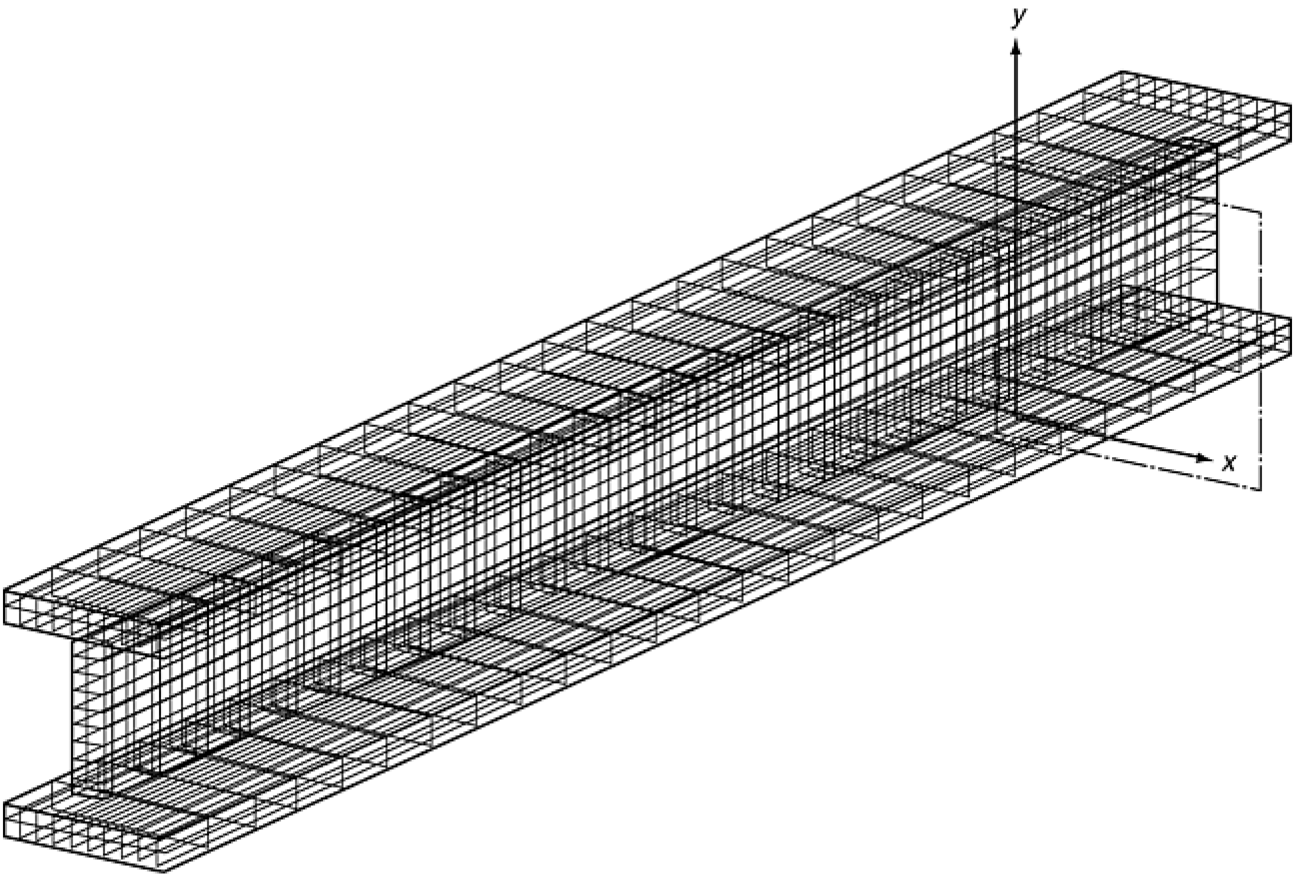

Fig. 1 An I-beam discretized with 3-D solid elements

Assuming small displacements and displacement gradients, the 3-D strain-displacement relations for the brick element are:

$$\varepsilon_{xx} = \frac{\partial U}{\partial x} \quad \varepsilon_{yy} = \frac{\partial V}{\partial y} \quad \varepsilon_{zz} = \frac{\partial W}{\partial z} \quad \gamma_{yz} = \frac{\partial V}{\partial z} + \frac{\partial W}{\partial y}$$
$$\gamma_{xz} = \frac{\partial U}{\partial z} + \frac{\partial W}{\partial x} \quad \gamma_{xy} = \frac{\partial U}{\partial y} + \frac{\partial V}{\partial x} \quad \text{(Eq 2)}$$

where $U=u(x,y,z)$, $V=v(x,y,z)$, and $W=w(x,y,z)$ are the element displacement fields in the three orthogonal coordinate directions.

Let the generalized stress vector for the brick element be:

$$\bar{\boldsymbol{\sigma}} = [\sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \tau_{yz}, \tau_{xz}, \tau_{xy}]^T \quad \text{(Eq 3)}$$

Also, let ΔT and Δm represent the change in temperature and moisture content, respectively, of the element from some datum values. The hygrothermal effects may be important to consider in the analysis of composite structures, due to certain service conditions. (See the article "Hygrothermal Behavior" in this Volume.) The constitutive law for the brick element, including hygrothermal effects, is:

$$\bar{\boldsymbol{\sigma}} = [\mathbf{C}]\bar{\boldsymbol{\varepsilon}} - \{\mathbf{a}\}\Delta T - \{\mathbf{b}\}\Delta m \quad \text{(Eq 4)}$$

where C_{ij} denote the off-axis stiffness coefficients, a_i the off-axis thermal constants, and b_i the off-axis moisture or swelling constants. The coefficients C_{ij}, a_i, and b_i are given by (Ref 19):

$$[\mathbf{C}]=[\mathbf{J}]^{-1}[\mathbf{S}']^{-1}[\mathbf{J}]^{-T}$$
$$\{\mathbf{a}\}=[\mathbf{J}]^{-1}[\mathbf{S}']^{-1}\{\boldsymbol{\alpha}'\} \quad \text{(Eq 5)}$$
$$\{\mathbf{b}\}=[\mathbf{J}]^{-1}[\mathbf{S}']^{-1}\{\boldsymbol{\beta}'\}$$

In Eq 5, the on-axis compliance matrix $[\mathbf{S}']$ for orthotropic materials, in terms of engineering constants, is (Ref 3):

$$[\mathbf{S}'] = \begin{bmatrix} \frac{1}{E'_1} & -\frac{\nu'_{12}}{E'_2} & -\frac{\nu'_{13}}{E'_3} & 0 & 0 & 0 \\ -\frac{\nu'_{21}}{E'_1} & \frac{1}{E'_2} & -\frac{\nu'_{23}}{E'_3} & 0 & 0 & 0 \\ -\frac{\nu'_{31}}{E'_1} & -\frac{\nu'_{32}}{E'_2} & \frac{1}{E'_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G'_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G'_{13}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G'_{12}} \end{bmatrix} \quad \text{(Eq 6)}$$

Here, the major Poisson's ratio is denoted ν'_{21}, and the minor Poisson's ratio is denoted ν'_{12}. The vectors representing the on-axis coefficients of thermal expansion and the on-axis coefficients of moisture expansion are:

$$\{\boldsymbol{\alpha}'\} = [\alpha'_1,\ \alpha'_2,\ \alpha'_3,\ 0,\ 0,\ 0]^T$$
$$\{\boldsymbol{\beta}'\} = [\beta'_1,\ \beta'_2,\ \beta'_3,\ 0,\ 0,\ 0]^T \quad \text{(Eq 7)}$$

In Eq 5, [**J**] is the transformation matrix relating the off-axis material constants to the on- axis material constants, and is given by:

$$[\mathbf{J}] = \begin{bmatrix} m^2 & n^2 & 0 & 0 & 0 & 2mn \\ n^2 & m^2 & 0 & 0 & 0 & -2mn \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & m & -n & 0 \\ 0 & 0 & 0 & n & m & 0 \\ -mn & mn & 0 & 0 & 0 & m^2 - n^2 \end{bmatrix} \quad \text{(Eq 8)}$$

where $m = \cos\theta$ and $n = \sin\theta$, and θ is the lamina/ply/layer orientation with respect to the elemental *x*-axis. Figure 1 in the article "Macromechanics Analysis of Laminate Properties" in this Volume shows the orientation.

As mentioned previously, for many woven and/or braided fiber architecture types, it is often easier to obtain the on-axis stiffness coefficients, C'_{ij}, directly as a result of the homogenization at microlevel using RVE concepts (Ref 20). However, the on-axis stiffness matrix [**C′**] may no longer be orthotropic. Also, when smearing some or all the layers into a single layer, the effective 3-D materials properties may not be orthotropic, thereby resulting in an anisotropic on- axis stiffness matrix [**C′**]. In all these cases, the off-axis coefficients in the constitutive law, Eq 4, can be alternatively given as:

$$[\mathbf{C}] = [\mathbf{J}]^{-1}[\mathbf{C}'][\mathbf{J}]^{-T} \quad \{\mathbf{a}\} = [\mathbf{J}]^{-1}[\mathbf{C}']\{\boldsymbol{\alpha}'\}$$
$$\{\mathbf{b}\} = [\mathbf{J}]^{-1}[\mathbf{C}']\{\boldsymbol{\beta}'\} \quad \text{(Eq 9)}$$

Once the elemental constitutive law given by Eq 4 is established, the statement of *internal virtual work* for the solid element, $\delta W^{int} = \int\int\int_V \delta\vec{\epsilon}^T \vec{\sigma} dV$, can be used to derive the elemental stiffness matrix in the usual manner (see Ref 2). Subsequently , the global stiffness matrix is assembled, and the numerical problem is solved to obtain the elemental and/or nodal displacements under applied static and/or kinematic boundary conditions The 3-D elemental strain-displacement relations in Eq 2 can then be used to obtain the strains. The 3-D element stresses are recovered using the constitutive law given by Eq 4. The element stress/strain vectors are further transformed into the material coordinate system using the transformation matrix, such as the one given by Eq 8. These stresses and strains can now be used in subsequent progressive damage and/or failure analysis.

Rastogi (Ref 21) developed variable-order 3-D solid elements using the formulations presented previously. Subsequently, a FORTRAN computer code called structural analysis using variable-order elements (SAVE) was written to perform 3-D analysis of laminated structures (Ref 22). Examples of some benchmark problems solved using the SAVE code and other commercially available FE codes are presented in the later part of this article.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

2-D Cylindrical Shell Elements

Figure 2 represents the I-section beam whose web and flanges are discretized by 2-D shell elements. A shell is actually a 3-D body that is thin in one dimension. The concepts, which are generally applicable to the 3-D analysis, are also applicable to the shells. Thus, while working with shell theories, one tries to exploit the thinness of the shell and reduce the theories to a 2-D analysis. However, each shell analysis needs to be performed on a case-by-case basis. For an accurate analysis of thick composite shells, either a higher-order shell theory with shear deformation effects, a layer-wise theory (Ref 23), or a quasi-three-dimensional theory may be required. Consider that G/E, the ratio of shearing to extensional stiffness, is fixed for an isotropic material at $1/(2 + 2\upsilon)$, or about 0.40 for most metals. By contrast, for a unidirectional lamina of high-modulus graphite-epoxy, the value of G/E can be as low as 0.01. Thus, it is apparent that the same loading will induce significantly more transverse shear deformation in composite structures than in their metal counterparts. Indeed, it is not difficult to find composite problems where transverse shear is the dominant response mode of the

structure. It is important, therefore, to consider the transverse shear deformation effects in analyzing composite structures using 2-D shell/ plate elements.

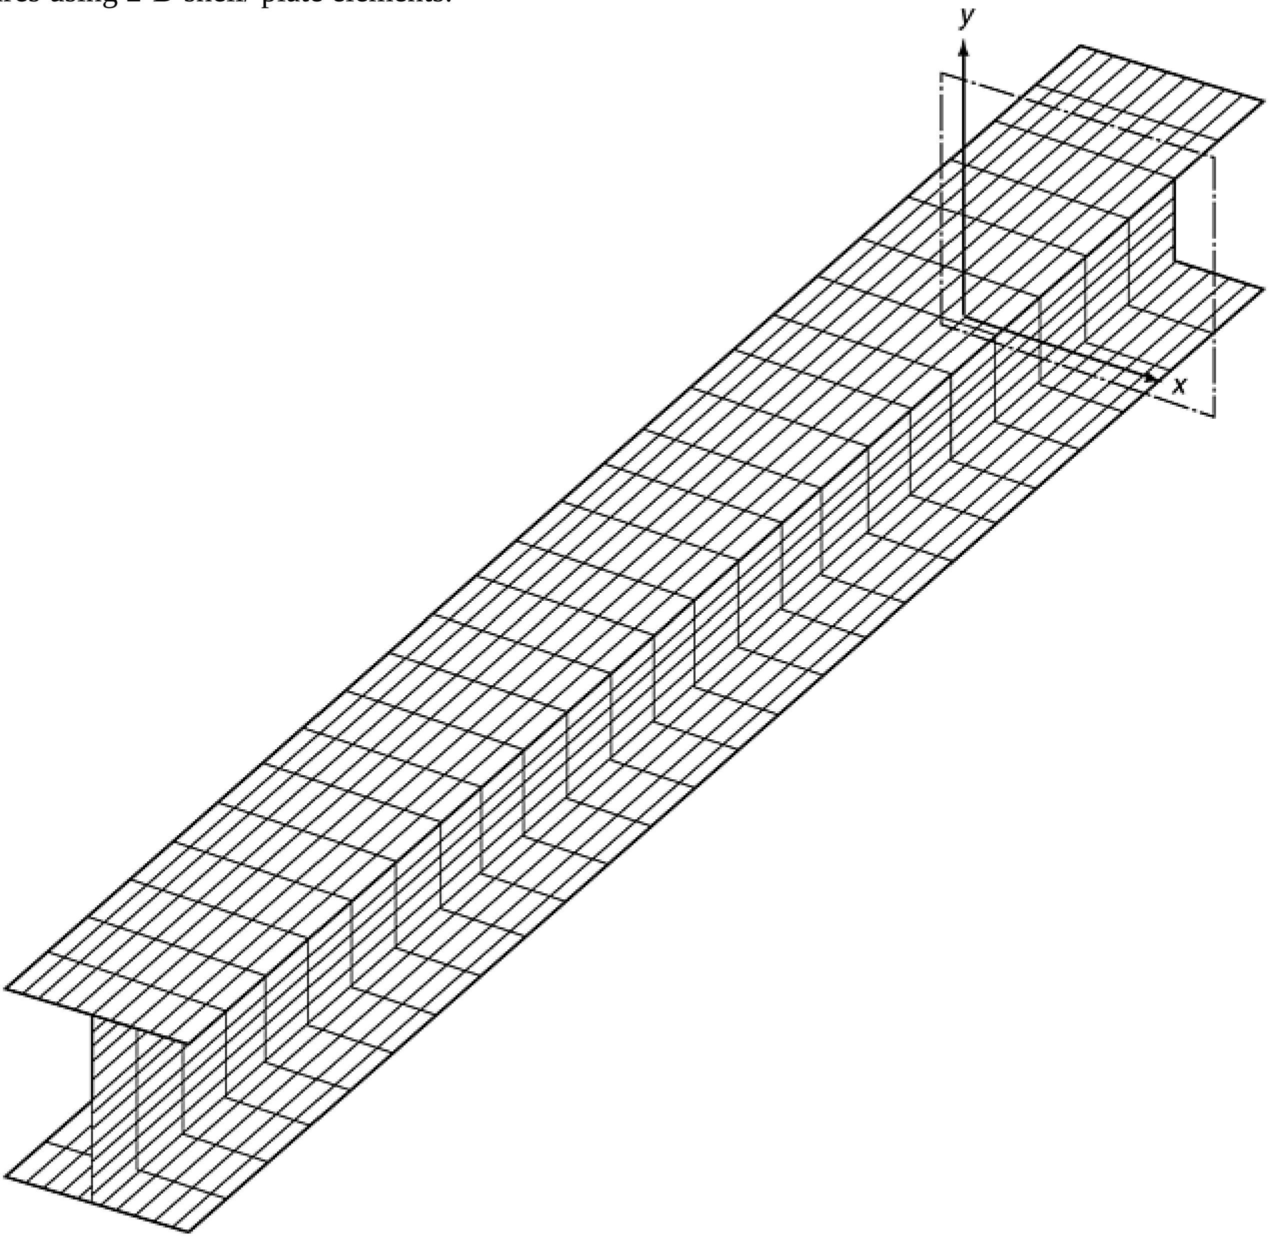

Fig. 2 An I-beam discretized with 2-D shell elements

In order to derive the material constitutive law of a typical shell element, a consistent first-order transverse shear deformation shell theory, developed by Rastogi and Johnson (Ref 24), is used. Based on the assumption that the shell thickness, *t*, is relatively small and hence, does not change during loading, the displacement at any arbitrary material point in the shell element is approximated by:

$$U(x,\theta,z) = u(x,\theta) + z\varphi_x(x,\theta)$$

$$V(x,\theta,z) = v(x,\theta) + z\varphi_\theta(x,\theta) \quad \text{(Eq 10)}$$

$$W(x,\theta,z) = w(x,\theta)$$

where $u(x,\theta)$, $v(x,\theta)$, and $w(x,\theta)$ are the displacements of the points of the reference (or middle) surface, and $\varphi_x(x,\theta)$ and $\varphi_\theta(x,\theta)$ are the rotations of the normal to the reference surface, as shown in Fig. 3. The 3-D engineering strains are related to the displacements by:

$$e_{xx} = \frac{\partial U}{\partial x} \quad e_{\theta\theta} = \frac{1}{(R+z)}\left[\frac{\partial V}{\partial \theta} + W\right]$$

$$e_{x\theta} = \frac{\partial V}{\partial x} + \frac{1}{(R+z)}\frac{\partial U}{\partial \theta}$$

$$e_{zz} = \frac{\partial W}{\partial z} \quad e_{xz} = \frac{\partial W}{\partial x} + \frac{\partial U}{\partial z} \qquad \text{(Eq 11)}$$

$$e_{\theta z} = \frac{\partial V}{\partial z} + \frac{1}{(R+z)}\left(\frac{\partial W}{\partial \theta} - V\right)$$

Substituting Eq 10 into Eq 11 and rearranging the terms results in the following expressions for the 3-D engineering strains:

$$e_{xx} = \varepsilon_{xx} + z\kappa_{xx} \quad e_{\theta\theta} = \frac{\varepsilon_{\theta\theta} + z\kappa_{\theta\theta}}{\left(1+\frac{z}{R}\right)} \quad e_{zz} = 0$$

$$e_{x\theta} = \frac{\gamma_{x\theta} + z\left(1+\frac{z}{2R}\right)\overline{\kappa}_{x\theta} + \frac{z^2}{2R}\tilde{\kappa}_{x\theta}}{\left(1+\frac{z}{R}\right)} \qquad \text{(Eq 12)}$$

$$e_{xz} = \gamma_{xz} \quad e_{\theta z} = \frac{\gamma_{\theta z}}{\left(1+\frac{z}{R}\right)}$$

in which ϵ_{xx}, κ_{xx}, $\epsilon_{\theta\theta}$, $\kappa_{\theta\theta}$, $\gamma_{x\theta}$, $\overline{\kappa}_{x\theta}$, $\tilde{\kappa}_{x\theta}$, γ_{xz}, and $\gamma_{\theta z}$ are the shell strains, independent of the *z*- coordinate. The transverse shear strains, e_{xz} and $e_{\theta z}$, given in Eq 12 were obtained through differentiation of Eq 10 with respect to *z*. However, Eq 10 is approximate in the *z*-coordinate, so differentiating with respect to *z* cannot capture the distribution of the transverse shear strains through the thickness of the shell. Since the material is assumed rigid in the *z*-direction (e_{zz}= 0), the distribution of the transverse shear strains, and consequently the distribution of the transverse shear stresses, does not influence the shell behavior. It is the integral of the transverse shear stresses through the thickness, or transverse shear resultants, that influences the shell behavior. Thus, the transverse shear strains in Eq 12 are the *average* values, evaluated at the reference surface (*z*= 0).

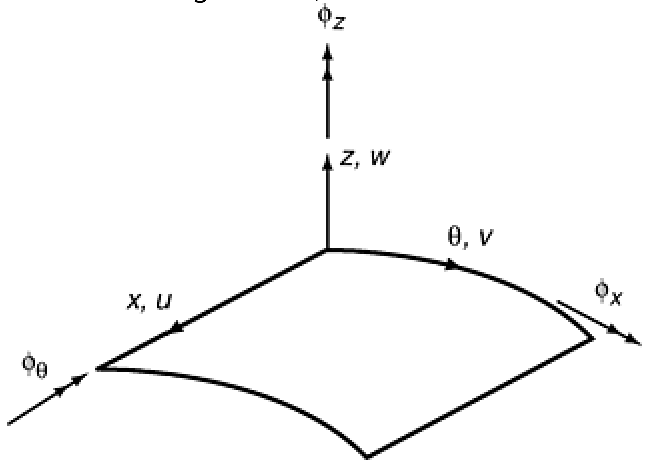

Fig. 3 Displacements and rotations for a shell element

Assuming small rotations, the 2-D, or shell strain measures, are defined as:

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} \quad \varepsilon_{\theta\theta} = \frac{1}{R}\frac{\partial v}{\partial \theta} + \frac{w}{R} \quad \gamma_{x\theta} = \frac{\partial v}{\partial x} + \frac{1}{R}\frac{\partial u}{\partial \theta}$$
$$\kappa_{xx} = \frac{\partial \phi_x}{\partial x} \quad \kappa_{\theta\theta} = \frac{1}{R}\frac{\partial \phi_\theta}{\partial \theta} \quad \bar{\kappa}_{x\theta} = \frac{\partial \phi_\theta}{\partial x} + \frac{1}{R}\frac{\partial \phi_x}{\partial \theta} + \frac{1}{R}\frac{\partial v}{\partial x}$$
$$\tilde{\kappa}_{x\theta} = \frac{\partial \phi_\theta}{\partial x} - \frac{1}{R}\frac{\partial \phi_x}{\partial \theta} - \frac{1}{R}\frac{\partial v}{\partial x} \quad \gamma_{xz} = \phi_x + \frac{\partial w}{\partial x}$$
$$\gamma_{\theta z} = \phi_\theta + \frac{1}{R}\frac{\partial w}{\partial \theta} - \frac{v}{R} \qquad \text{(Eq 13)}$$

If the average transverse shear strains in Eq 12 are set to zero, the rotations about the normal are:

$$\phi_x = -\frac{\partial w}{\partial x} \quad \phi_\theta = \frac{v}{R} - \frac{1}{R}\frac{\partial w}{\partial \theta} \qquad \text{(Eq 14)}$$

so that

$$\kappa_{x\theta} = \bar{\kappa}_{x\theta} = -\frac{2}{R}\frac{\partial^2 w}{\partial x \partial \theta} + \frac{2}{R}\frac{\partial v}{\partial x} \quad \tilde{\kappa}_{x\theta} = 0 \qquad \text{(Eq 15)}$$

Hence, the thickness distribution of the in- plane shear strain reduces to:

$$e_{x\theta} = \frac{\gamma_{x\theta} + z\left(1 + \frac{z}{2R}\right)\kappa_{x\theta}}{\left(1 + \frac{z}{R}\right)} \qquad \text{(Eq 16)}$$

which results in a classical shell theory with no transverse shear deformation effects. It is evident from Eq 12 that three shell strain measures are needed to represent the distribution of in-plane shear strain through the thickness in the transverse shear deformation shell theory; whereas only two shell strain measures are required in classical shell theory to represent the shearing strain distribution through the thickness (refer to Eq 16).

In the 3-D shell theory, the *internal virtual work* for the shell is:

$$\delta W_{\text{int}}^{\text{shell}} = \iiint_V [\sigma_{xx}\delta e_{xx} + \sigma_{\theta\theta}\delta e_{\theta\theta} + \sigma_{zz}\delta e_{zz} + \sigma_{x\theta}\delta e_{x\theta} + \sigma_{xz}\delta e_{xz} + \sigma_{\theta z}\delta e_{\theta z}]dV \qquad \text{(Eq 17)}$$

where V denotes the volume of shell and $dV = [1 + (z/R)]dxRd\theta dz$. Substitute the variation of Eq 12 into Eq 17, and note that the virtual strains are explicit functions of z. Integrals of the stresses with respect to z give force and moment resultants conjugate to the shell strains. Hence, the volume integral in Eq 17 reduces to an area integral, and the internal virtual work for the shell element becomes:

$$\delta W_{\text{int}}^{\text{shell}} = \iint_S \delta\bar{\varepsilon}_{\text{shell}}^T \bar{\sigma}_{\text{shell}} dS \qquad \text{(Eq 18)}$$

where S denotes the area of the reference surface, with $dS=dxRd\theta$. The generalized 9 × 1 stress vector of the shell in Eq 18 is:

$$\bar{\sigma}_{\text{shell}} = [N_{xx}, N_{\theta\theta}, N_{\theta x}, M_{xx}, M_{\theta\theta}, \bar{M}_{x\theta}, \tilde{M}_{x\theta}, Q_x, Q_\theta]^T \qquad \text{(Eq 19)}$$

and the generalized strain vector for the shell is:

$$\bar{\varepsilon}_{\text{shell}} = [\varepsilon_{xx}, \varepsilon_{\theta\theta}, \gamma_{x\theta}, \kappa_{xx}, \kappa_{\theta\theta}, \bar{\kappa}_{x\theta}, \tilde{\kappa}_{x\theta}, \gamma_{xz}, \gamma_{\theta z}]^T \qquad \text{(Eq 20)}$$

The physical stress resultants and stress couples for the shell, some of which appear in Eq 19, are:

$$(N_{xx}, M_{xx}) = \int_h (1, z)\sigma_{xx}\left(1+\frac{z}{R}\right)dz$$
$$(N_{\theta\theta}, M_{\theta\theta}) = \int_h (1, z)\sigma_{\theta\theta}dz$$
$$(N_{x\theta}, M_{x\theta}) = \int_h (1, z)\sigma_{x\theta}\left(1+\frac{z}{R}\right)dz \qquad \text{(Eq 21)}$$
$$(N_{\theta x}, M_{\theta x}) = \int_h (1, z)\sigma_{\theta x}dz$$
$$Q_x = \int_h \sigma_{xz}\left(1+\frac{z}{R}\right)dz \quad Q_\theta = \int_h \sigma_{\theta z}dz$$

In Eq 19, $\overline{M}_{x\theta}$and $\tilde{M}_{x\theta}$are the mathematical quantities conjugate to the modified twisting measures, $\overline{\kappa}_{x\theta}$and $\tilde{\kappa}_{x\theta}$, respectively, and are defined in terms of the physical stress couples by:

$$\bar{M}_{x\theta} = \frac{1}{2}(M_{x\theta} + M_{\theta x}) \quad \tilde{M}_{x\theta} = \frac{1}{2}(M_{x\theta} - M_{\theta x}) \qquad \text{(Eq 22)}$$

The nine elements of the stress vector in Eq 19 and the relations of Eq 22 determine all the stress resultants and stress couples listed in Eq 21, except for in-plane shear resultant, $N_{x\theta}$. The shear stress resultant, $N_{x\theta}$, is determined from the moment equilibrium about the normal for an element of the shell. This so-called sixth equilibrium equation is:

$$N_{x\theta} = N_{\theta x} + \frac{M_{\theta x}}{R} \qquad \text{(Eq 23)}$$

Written in full, the *internal virtual work* for the shell element is:

$$\begin{aligned}\delta W_{\text{int}}^{\text{shell}} = \iint_S [&N_{xx}\delta\varepsilon_{xx} + N_{\theta\theta}\delta\varepsilon_{\theta\theta} + N_{\theta x}\delta\gamma_{x\theta} \\ &+ M_{xx}\delta\kappa_{xx} + M_{\theta\theta}\delta\kappa_{\theta\theta} + \bar{M}_{x\theta}\delta\bar{\kappa}_{x\theta} \\ &+ \tilde{M}_{x\theta}\delta\tilde{\kappa}_{x\theta} + Q_x\delta\gamma_{xz} + Q_\theta\delta\gamma_{\theta z}]dS\end{aligned} \qquad \text{(Eq 24)}$$

The material law for a lamina with one material axis in the normal direction is:

$$\begin{Bmatrix}\sigma_{xx}\\ \sigma_{\theta\theta}\\ \sigma_{x\theta}\end{Bmatrix} = \begin{bmatrix}C_{11} & C_{12} & C_{16}\\ C_{12} & C_{22} & C_{26}\\ C_{16} & C_{26} & C_{66}\end{bmatrix}\begin{Bmatrix}e_{xx}\\ e_{\theta\theta}\\ e_{x\theta}\end{Bmatrix} - \begin{Bmatrix}a_1\\ a_2\\ a_6\end{Bmatrix}\Delta T(x, y, z) \qquad \text{(Eq 25)}$$

where the off-axis stiffness coefficients, C_{ij}, and the thermal constants, a_j, appearing in Eq 25 are given by Eq 5. Substitution of Eq 25 into Eq 21 in conjunction with Eq 22, and use of Eq 12 for the 3-D engineering strains, results in following *linear elastic constitutive law* for a laminated composite shell element:

$$\begin{Bmatrix} N_{xx} \\ N_{\theta\theta} \\ N_{\theta x} \\ M_{xx} \\ M_{\theta\theta} \\ \bar{M}_{x\theta} \\ \tilde{M}_{x\theta} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16}^{1} & B_{16}^{2} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26}^{1} & B_{26}^{2} \\ A_{16} & A_{26} & A_{66} & B_{61} & B_{62} & B_{66}^{1} & B_{66}^{2} \\ B_{11} & B_{12} & B_{61} & D_{11} & D_{12} & D_{16}^{1} & D_{16}^{2} \\ B_{12} & B_{22} & B_{62} & D_{12} & D_{22} & D_{26}^{1} & D_{26}^{2} \\ B_{16}^{1} & B_{26}^{1} & B_{66}^{1} & D_{16}^{1} & D_{26}^{1} & D_{66}^{11} & D_{66}^{12} \\ B_{16}^{2} & B_{26}^{2} & B_{66}^{2} & D_{16}^{2} & D_{26}^{2} & D_{66}^{12} & D_{66}^{22} \end{bmatrix} \times \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{\theta\theta} \\ \gamma_{x\theta} \\ \kappa_{xx} \\ \kappa_{\theta\theta} \\ \bar{\kappa}_{x\theta} \\ \tilde{\kappa}_{x\theta} \end{Bmatrix} - \begin{Bmatrix} N_{xx}^{T} \\ N_{\theta\theta}^{T} \\ N_{\theta x}^{T} \\ M_{xx}^{T} \\ M_{\theta\theta}^{T} \\ \bar{M}_{x\theta}^{T} \\ \tilde{M}_{x\theta}^{T} \end{Bmatrix} \qquad \text{(Eq 26)}$$

in which stiffnesses A_{ij}, B_{ij}, and C_{ij} are given in Table 1. Note that for the deep shells, large t/R ratios, the shell curvature can induce extension-bending and/or bending-twisting coupling even for balanced, symmetric laminated constructions, due to nonzero B_{ij} terms. Also, compare the expressions for A_{ij}, B_{ij}, and D_{ij} , as given in Table 1, with the simple membrane and bending stiffness expressions for metallic (isotropic material) shells. In Eq 26, the thermal stress resultants and stress couples, denoted by superscript T, are:

$$\begin{aligned} (N_{xx}^{T}, M_{xx}^{T}) &= \int_{h} (1, z) a_1 \Delta T(x, y, z) \left(1 + \frac{z}{R}\right) dz \\ (N_{\theta\theta}^{T}, M_{\theta\theta}^{T}) &= \int_{h} (1, z) a_2 \Delta T(x, y, z) dz \\ N_{\theta x}^{T} &= \int_{h} a_6 \Delta T(x, y, z) dz \\ \bar{M}_{x\theta}^{T} &= \int_{h} z\left(1 + \frac{z}{2R}\right) a_6 \Delta T(x, y, z) dz \\ \tilde{M}_{x\theta}^{T} &= \int_{h} \frac{z^2}{2R} a_6 \Delta T(x, y, z) dz \end{aligned} \qquad \text{(Eq 27)}$$

The lamina material law relating transverse shear stresses and strains is:

$$\begin{Bmatrix} \sigma_{\theta z} \\ \sigma_{xz} \end{Bmatrix} = \begin{bmatrix} C_{44} & C_{45} \\ C_{45} & Q_{55} \end{bmatrix} \begin{Bmatrix} e_{\theta z} \\ e_{xz} \end{Bmatrix} \qquad \text{(Eq 28)}$$

where the transverse shear stiffnesses, C_{44}, C_{45}, and C_{55}, are given by Eq 5. Substitution of Eq 28 into the last two equalities of Eq 21, in conjunction with Eq 12 for the transverse shear strains, results in the following linear elastic constitutive law for a laminated composite shell element relating transverse shear resultants and strains:

$$\begin{Bmatrix} Q_{\theta} \\ Q_{x} \end{Bmatrix} = \begin{bmatrix} A_{44} & A_{45} \\ A_{45} & A_{55} \end{bmatrix} \begin{Bmatrix} \gamma_{\theta z} \\ \gamma_{xz} \end{Bmatrix} \qquad \text{(Eq 29)}$$

The transverse shear stiffnesses, A_{44}, A_{45}, and A_{55}, in Eq 29 are given in Table 1. Because Eq 12 represents average values of the transverse shear strains, the constitutive law relating transverse shear resultants and strains, Eq 29, can be viewed as a Hooke's law, based on the assumption of constant transverse shear strain distribution through the thickness. Alternatively, one can obtain the constitutive law relating transverse shear resultants and strains, based on the assumption of constant transverse shear stress distribution through the thickness. A detailed discussion on the subject is given in Chapter 2 of the text by Vasiliev (Ref 25). However, both methods result in a shear correction factor of one (as compared to 5/6 for isotropic materials).

Table 1   Stiffness coefficients

$\{A_{11}, B_{11}, D_{11}\} = \int_t C_{11}\{1, z, z^2\}(1+\frac{z}{R})dz$
$\{A_{12}, B_{12}, D_{12}\} = \int_t C_{12}\{1, z, z^2\}dz$
$\{A_{22}, B_{22}, D_{22}\} = \int_t C_{22}\{1, z, z^2\}(1+\frac{z}{R})^{-1}dz$
$\{A_{16}, B_{61}\} = \int_t C_{16}\{1, z\}dz$
$B_{16} = B_{16}^1 = \int_t C_{16}z(1+\frac{z}{R})dz$
$B_{16}^2 = \int_t C_{16}\frac{z^2}{2R}dz$
$D_{16} = D_{16}^1 = \int_t C_{16}z^2(1+\frac{z}{R})dz$
$D_{16}^2 = \int_t C_{16}\frac{z^3}{2R}dz$
$\{A_{26}, B_{62}\} = \int_t C_{26}\{1, z\}(1+\frac{z}{R})^{-1}dz$
$B_{26} = B_{26}^1 = \int_t C_{26}z(1+\frac{z}{2R})(1+\frac{z}{R})^{-1}dz$
$B_{26}^2 = \int_t C_{26}\frac{z^2}{2R}(1+\frac{z}{R})^{-1}dz$
$D_{26} = D_{26}^1 = \int_t C_{26}z^2(1+\frac{z}{2R})(1+\frac{z}{R})^{-1}dz$
$D_{26}^2 = \int_t C_{26}\frac{z^3}{2R}(1+\frac{z}{R})^{-1}dz$
$A_{66} = \int_t C_{66}(1+\frac{z}{R})^{-1}dz$
$B_{66} = B_{66}^1 = \int_t C_{66}z(1+\frac{z}{2R})(1+\frac{z}{R})^{-1}dz$
$B_{66}^2 = \int_t C_{66}\frac{z}{2R}(1+\frac{z}{R})^{-1}dz$
$D_{66} = D_{66}^{11} = \int_t C_{66}z^2(1+\frac{z}{2R})^2(1+\frac{z}{R})^{-1}dz$

$$D_{66}^{12} = \int_t C_{66} \frac{z^3}{2R}(1+\frac{z}{2R})(1+\frac{z}{R})^{-1} dz$$

$$D_{66}^{22} = \int_t C_{66} \frac{z^4}{4R^2}(1+\frac{z}{R})^{-1} dz$$

$$A_{44} = \int_h C_{44} \left(1+\frac{z}{R}\right)^{-1} dz$$

$$A_{45} = \int_h C_{45} dz$$

$$A_{55} = \int_h C_{55} \left(1+\frac{z}{R}\right) dz$$

For classical shell theory, the linear elastic constitutive law for a laminated composite shell element is reduced to:

$$\begin{Bmatrix} N_{xx} \\ N_{\theta\theta} \\ N_{\theta x} \\ M_{xx} \\ M_{\theta\theta} \\ \bar{M}_{x\theta} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{61} & B_{62} & B_{66} \\ B_{11} & B_{12} & B_{61} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{62} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \times \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{\theta\theta} \\ \gamma_{x\theta} \\ \kappa_{xx} \\ \kappa_{\theta\theta} \\ \bar{\kappa}_{x\theta} \end{Bmatrix} - \begin{Bmatrix} N_{xx}^T \\ N_{\theta\theta}^T \\ N_{\theta x}^T \\ M_{xx}^T \\ M_{\theta\theta}^T \\ \bar{M}_{x\theta}^T \end{Bmatrix} \quad \text{(Eq 30)}$$

in which stiffnesses A_{ij}, B_{ij}, and D_{ij} are the same as given in Table 1, and thermal stress resultants and stress couples are given by Eq 27.

The transverse shear deformation formulations given in the preceding paragraphs for the composite cylindrical shell element can be readily reduced for a laminated flat plate element by first replacing $R\theta$ with y and letting $1/R$ approach 0 in Eq 10 through 24. Note that the thickness distribution of the in-plane engineering shear strain for the plate element reduces to:

$$e_{x\theta} = \gamma_{x\theta} + z\bar{\kappa}_{x\theta} \quad \text{(Eq 31)}$$

Thus, in the transverse shear deformation shell theory, three shell strain measures are needed to represent the distribution of in-plane shear strain through the thickness (see Eq 12); whereas, only two strain measures are required in transverse shear deformation plate theory to represent the shearing strain distribution through the thickness (refer to Eq 31). Furthermore, because $\tilde{M}_{x\theta} = 0$, the linear elastic constitutive law for the laminated plate element will have the usual 6 × 6 stiffness matrix, instead of a 7 × 7 matrix, as given by Eq 26 for the shell element. The A_{ij}, B_{ij}, and D_{ij} expressions given in Table 1 will now have $1/R$ terms eliminated, reducing them to the simplified stiffness coefficients based on the classical laminated plate theory (Ref 4).

Once the elemental constitutive law is established for transverse shear deformable shell theory (Eq 26 and 29), or for classical shell theory (Eq 30), the statement of internal virtual work for the shell element (Eq 24) can be

used to derive the shell element stiffness matrix in the usual manner. Subsequently, the global stiffness matrix for the structure is assembled, and the numerical problem is solved to obtain the shell element reference surface displacements and rotations as given by Eq 10. The element strain- displacement relations in Eq 11 can then be used to obtain the 3-D engineering strains. The stresses at any material point in the shell are then recovered, using the constitutive laws given by Eq 25 and 28. The stress/strain vectors may require further transformation in the material coordinate system for subsequent use in the progressive damage analysis and/or failure analysis. Johnson and Rastogi (Ref 26) successfully used the first-order shear deformable theory presented here to develop a shell superelement to analyze orthogonally stiffened composite cylindrical shells subjected to internal pressure loads.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

1-D Beam Elements

Beams, such as hat, blade, angle, I-, C-, L-, J-, or F-sections, and circular or rectangular tubes, are commonly used in various industrial applications. Generally, beams are either used as stand-alone structures, or in combination with skins as stiffening elements. If either the wall thickness of the beam is small as compared to its cross-sectional dimensions, or the beam cross-sectional dimensions are sufficiently small compared to its length, a 2-D branched shell analysis may be performed to analyze the beams. A full 3-D analysis with solid elements is warranted for all other cases.

In cases where a 2-D branched shell analysis would suffice, the computational resources required for the analysis can still be very large, thereby making it cumbersome for a design optimization process. This is especially true when these beam sections are made of composite materials and attached to a sheet or skin as stiffening elements. For the purpose of preliminary design and optimization of structures, it may be prudent to model and analyze the beams as 1-D beam elements.

Consider the open-section I-beam discretized by 1-D beam section elements in Fig. 4. In order to obtain the constitutive law for composite beam elements, a thin-walled, open-section, curved beam theory by Woodson, Johnson, and Haftka (Ref 27) is used. The development of a combined theory for torsion and flexure of thin-walled, open-section, curved beams is usually accredited to V.Z. Vlasov (Ref 28). Bauld and Tzeng (Ref 29) extended Vlasov's curved beam theory to straight beams having laminated composite material wall construction. Woodson, Johnson, and Haftka (Ref 27) contributed to further the work in this area by developing a Vlasov-type classical theory for laminated composite curved beams with thin-walled open sections. Later on, Johnson and Rastogi (Ref 26) added the effects of transverse shear deformation to this work. A brief description

of this thin-walled, open-section, laminated curved beam theory will acclimatize the reader with the complexities of homogenization at the 1-D level required to obtain an accurate laminated beam constitutive law.

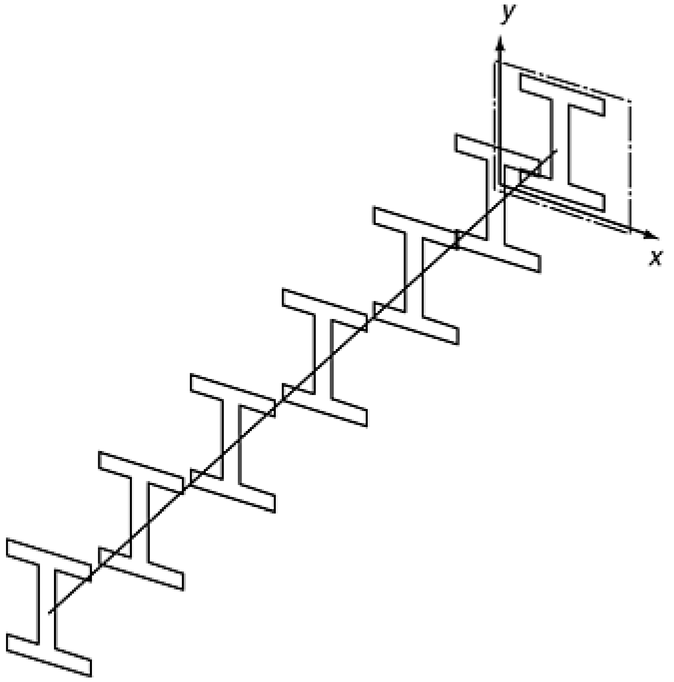

Fig. 4 An I-beam discretized with 1-D beam section elements

Let the coordinate system (x,θ,ζ) be located at the centroid of the curved beam, in accordance with the right-handed system shown in Fig. 5, in which ζ is the normal coordinate. Let the displacements of a material point on the beam reference axis in the x, θ, and ζ directions be denoted by $u(\theta)$, $v(\theta)$, and $w(\theta)$, respectively. Let the rotations about the x, θ, and ζ axes be denoted by $\varphi_x(\theta)$, $\varphi_\theta(\theta)$, and $\varphi_z(\theta)$, respectively. The displacement of a generic material point in the beam is related to the displacement and rotations of the point on the reference surface by approximations:

$$U(x,\theta,\zeta) = u(\theta) + \zeta\varphi_\theta(\theta)$$

$$V(x,\theta,\zeta) = v(\theta) + \zeta\varphi_x(\theta) + x\varphi_z(\theta) - \omega(x,\zeta)\tau(\theta) \qquad \text{(Eq 32)}$$

$$W(x,\theta,\zeta) = w(\theta) - x\varphi_\theta(\theta)$$

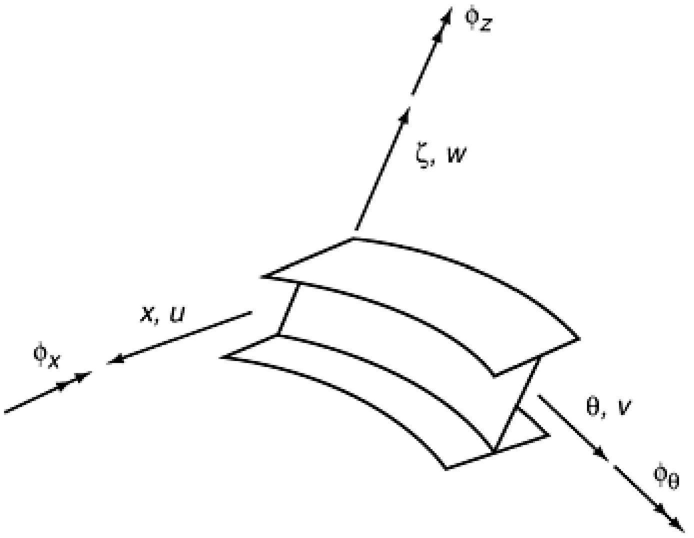

Fig. 5 Displacements and rotations for a curved beam element

The cross section of the beam is in the $x\zeta$ plane normal to the θ axis, so that U and W are interpreted as in-plane displacement components. V is the out-of-plane component. It is assumed that the beam cross section is rigid in its own plane. In Eq 32, $\omega(x,\zeta)$ is the warping function of the beam cross section, and $\tau(\theta)$ is the twist rate. For

laminated composite materials, $\omega(x,\zeta)$ not only depends upon the beam geometry, but also on the type, architecture, lay-up, and orientation of the composite material as well. The beam strains, curvatures, and twist rate are related to the displacements and rotations of the beam reference axis as:

$$\varepsilon_\theta = \frac{\dot{v}+w}{R_0} \quad \kappa_x = \frac{\dot{\phi}_x}{R_0} \quad \kappa_z = \frac{\dot{\phi}_z - \phi_\theta}{R_0} \quad \tau = \frac{\dot{\phi}_\theta + \phi_z}{R_0}$$
$$\gamma_z = \phi_x - \frac{(v-\dot{w})}{R_0} \quad \gamma_x = \phi_z + \frac{\dot{u}}{R_0} \qquad \text{(Eq 33)}$$

where the overdot denotes an ordinary derivative with respect to θ. In Eq 33, ϵ_θ is the circumferential normal strain of the centroidal arc, κ_x is the in-plane bending rotation gradient, κ_z is the out-of-plane bending rotation gradient, γ_x is the transverse shear strain in the $x\theta$ plane, γ_z is the transverse shear strain in the $\theta\zeta$ plane, and R_0 is the radius of the beam reference arc. The *internal virtual work* is:

$$\delta W_{\text{int}}^{\text{beam}} = \int [N_\theta \delta\varepsilon_\theta + M_x \delta\kappa_x + M_z \delta\kappa_z + T_s \delta\tau$$
$$+ M_\omega \delta(\dot{\tau}/R_0) + V_x \delta\gamma_x + V_z \delta\gamma_z] R_0 d\theta \qquad \text{(Eq 34)}$$

in which N_θ is the circumferential force, M_x is the in-plane bending moment, M_z is the out-of- plane bending moment, M_ω is the bimoment, T_s is the St. Venant's torque, V_x is the transverse shear force in the x-direction, and V_z is the transverse shear force in the ζ-direction. Due to the inherent assumption that the beam is a built-up shell structure, with shell branches representing various flanges and webs of the beam, the beam resultants in Eq 34 are fundamentally expressed as contour integrals of the shell resultants of each of its branch. The shell resultants for each branch are obtained in the usual way, by using an appropriate 2-D shell theory. For example, one can use the shell theory, such as the one presented earlier in this work, as the starting point to further develop the expressions for these beam resultants. Assuming that the transverse shear forces are decoupled from extension, bending, and torsional deformation, the Hooke's law for the composite material beam is:

$$\begin{Bmatrix} N_\theta \\ M_x \\ M_z \\ M_\omega \\ T_s \end{Bmatrix} = \begin{bmatrix} EA & ES_x & -ES_z & -ES_\omega & EH \\ ES_x & EI_{xx} & -EI_{zx} & -EI_{\omega x} & EH_c \\ -ES_z & -EI_{zx} & EI_{zz} & EI_{\omega z} & -EH_s \\ -ES_\omega & -EI_{\omega x} & EI_{\omega z} & EI_{\omega\omega} & -EH_q \\ EH & EH_c & -EH_s & -EH_q & GJ \end{bmatrix} \times \begin{Bmatrix} \varepsilon_\theta \\ \kappa_x \\ \kappa_z \\ \dot{\tau}/R_0 \\ \tau \end{Bmatrix} \qquad \text{(Eq 35)}$$

and

$$\begin{Bmatrix} V_x \\ V_z \end{Bmatrix} = \begin{bmatrix} GA_{x\theta} & GA_{zx} \\ GA_{zx} & GA_{\theta z} \end{bmatrix} \begin{Bmatrix} \gamma_x \\ \gamma_z \end{Bmatrix} \qquad \text{(Eq 36)}$$

The stiffness terms appearing in Eq 35 and 36 are commonly referred to as modulus-weighted section properties containing complex contour integrals and are given in Ref 26 and 27. However, a couple of brief comments are in order. First, the "*EH*" terms in Eq 35 are unique to the laminated thin-walled beams (Ref 29). Thus, the coupling between extension-bending and torsional deformation is unique to laminated composite beams. If the laminate construction for each branch, flanges and webs, of the beam is orthotropic, then "*EH*" terms are all equal to zero. Second, for the structural models in which the effect of warping of the beam cross section is excluded, the contribution of the bimoment, M_ω, to the virtual work of the beam in Eq 34 is neglected, and fourth row and column of the beam stiffness matrix, Eq 35, are ignored. Also, the warping function $\omega(x,\zeta)$ is taken as zero. In the limit as the radius of the beam reference arc, R_0, approaches infinity, the laminated, thin-walled curved beam theory presented here reduces for straight laminated beams. For further details on the laminated composite curved beam theory presented here, see Woodson's dissertation (Ref 18).

Reference 18 implemented the classical laminated, thin-walled curved beam theory via a displacement-based 1-D beam element having seven degrees of freedom (DOF) per node. The accuracy of the beam theory outlined here in isotropic and anisotropic beam analyses was demonstrated, and the practical usefulness of such an approach in preliminary design optimization process was established. Both Woodson (Ref 18) and Johnson and Rastogi (Ref 26) demonstrated the significance of modeling the restrained cross- sectional warping effects in accurately predicting the stresses in thin-walled open-section laminated beams. Warping is a distinctive feature of thin-walled open-section beams. Restraint of cross-sectional warping leads to additional longitudinal normal strains in beams subjected to torsion loads.

Once the elemental constitutive law (Eq 35 and 36) for transverse shear deformable curved beam theory is established, the statement of internal virtual work for the beam element (Eq 34) can be used to derive the beam element stiffness matrix in the usual manner. Subsequently, the global stiffness matrix for the complete structure is assembled, and the specified numerical problem is solved to obtain the beam element reference surface displacements and rotations given by Eq 32. The 3-D engineering strains can now be obtained by substituting the global beam displacements, Eq 32, into the 3-D elemental strain- displacement relations given by Eq 11. (Note that coordinate z is replaced by ζ, and R is replaced by R_0 in Eq 11.) The stresses at any material point in the beam webs and flanges, originally treated as the shell branches, are then computed using the lamina constitutive laws given for a shell element (Eq 25 and 28). Note that the stress/strain vectors may need to be further transformed into the material coordinate system for use in subsequent progressive damage and/or failure analysis.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

Commercial Finite Element Analyses Codes

As has been stated, the two most fundamental and important aspects of FEA of composite structures are:

- *Homogenization* of material properties to obtain the elemental constitutive law at an appropriate level of analysis

- *Post-processing* of numerical results to recover strains and stresses in the principal material directions for subsequent failure prediction analysis

Note that an efficient postprocessing of numerical result is inherently tied with an accurate preprocessing of composite-material-related input information. Thus, a good commercial code for composite FEA is one that incorporates the homogenization process at appropriate level of analysis, as well as supports pre- and postprocessing of composite-material-related information in an efficient and user-friendly manner.
Table 2 lists some of the commercially available FE codes that can analyze composite structures under various loading conditions. All these codes fully support 3-D solid elements with complete anisotropic material constitutive law. They also support 2-D plate and shell elements, including transverse shear deformation effects with simplified laminated-plate-theory-based constitutive laws (Ref 4). However, this author is not familiar with any commercial FE code that supports the correct form of constitutive laws for 1-D, composite material beam elements.

The pre- and postprocessors of most of the commercial codes listed in Table 2 support the key aspects related to the analysis of fibrous composite materials. These include:

- Input of ply properties based on unidirectional as well as 2-D woven fiber architecture
- Ply lay-ups
- Vector orientations used to define ply orientation in space
- Computation of 3-D effective properties
- Computation of [**A**], [**B**], and [**D**] stiffness matrices for plate and shell elements
- Recovery of strains and stresses in various coordinate systems, such as global axis, local element axis, laminate axis, and lamina axis
- First ply failure based on either point stress/ strain (maximum strain/stress) or quadratic failure (Tsai-Wu, Hill, Hashin) criterion

Some of the explicit analysis codes, such as LS-DYNA, MSC-DYTRAN, PAM-CRASH, and ABAQUS also provide progressive damage material models for ultimate failure load prediction. However, these computational progressive damage models have not been experimentally verified for a wide variety of structural applications. Based on the author's personal experience, ESI-SYSPLY is perhaps the most comprehensive and user-friendly pre- and postprocessor program currently available for composite FEA. However, in the current form, it does not have the interface with most widely used FEA solvers, such as NASTRAN and ABAQUS, thereby severely limiting its utility. Over the years pre- and postprocessing tools have been highly optimized for the FEA of metallic structures. These tools now need significant enhancement in their capabilities to accurately and efficiently analyze and design complex structures manufactured from advanced composite materials.

Finite Element Analysis

Naveen Rastogi, Visteon Chassis Systems

Numerical Examples

The continuity of transverse stresses at the layer interfaces and the free-edge effects are unique aspects in the analysis of multilayered composite structures. Finite element analysis of two classical examples from the mechanics of composite materials illustrates these aspects of multilayered composite structures. The first example is a problem of transverse bending of a simply supported $[0/90/0]_T$ laminated plate, the benchmark solution of which was obtained by Pagano (Ref 30). The second numerical example is of a $[0/90]_s$ laminated plate under uniform extension (Pagano, Ref 31, 32), illustrating the free-edge effects in multilayered composite structures.

Example 1: Transverse Bending of a Laminated Plate. A simply supported $[0/90/0]_T$ laminated plate is subjected to sinusoidal loading on the top surface. Laminated plates with two different aspect ratios are considered. For a/h= 4, the plate represents a thick multilayered structure. For a/h= 50, a thin-walled structure is represented. All layers are assumed to be of equal thickness. The material properties for the orthotropic lamina are (Ref 30): E_1/E_2= 25, E_2=E_3, G_{12}/E_2=G_{13}/E_3= 0.5, G_{23}/E_2= 0.2, ν_{12}=ν_{13}=ν_{23}= 0.25. The origin of the right- handed coordinate system is chosen at the corner of the middle surface of the plate, that is, $0 \le x \le a$, $0 \le y \le b$, and $-(h/2) \le z \le (h/2)$ (see Fig. 6).

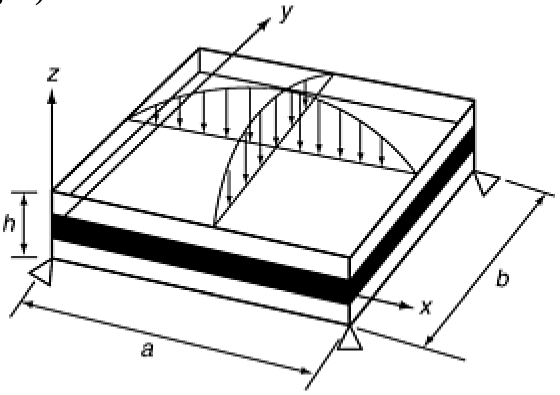

Fig. 6 A simply supported $[0/90/0]_T$ laminate subjected to sinusoidal loading on the top surface

This problem is analyzed by using the novel 3-D FEA tool SAVE, developed by the author (Ref 21, 22). For the laminated plate problem described previously, a quick comparison between 3-D elasticity solution of Pagano (Ref 30) and the 3-D structural analysis code SAVE is presented in Table 3 for various a/h ratios. The normalized quantities used in Table 3 are described as: $\overline{\sigma_{xx}} = \sigma_{xx}/\left(q_0 s^2\right)$, $\overline{\sigma_{yy}} = \sigma_{yy}/\left(q_0 s^2\right)$, $\overline{\sigma_{zz}} = \sigma_{zz}/q_0$, $\overline{\tau_{xy}} = \tau_{xy}/\left(q_0 s^2\right)$, $\overline{\tau_{xz}} = \tau_{xz}/\left(q_0 s\right)$, $\overline{\tau_{yz}} = \tau_{yz}/\left(q_0 s\right)$, where s=a/h and q_0 is the peak magnitude of the applied sinusoidal pressure load at the center of the laminated plate at the top surface. The results presented in Table 3 demonstrate the accuracy of SAVE analysis code in the 3-D analysis of multi-layered structures. Results from SAVE analysis can now be used as a basis to compare with the results obtained from commercial FEA codes.

(a) (a) From the SAVE analysis (Ref 21, 22). (b) By Pagano (Ref 30)

Next, the example problem is analyzed using commercial FEA codes such as ABAQUS (Ref 33), NASTRAN (Ref 34), and I-DEAS (Ref 35). The solid elements—C3D8 and C3D20 in ABAQUS, and CHEXA and CHEXA20 in NASTRAN—and linear and parabolic brick in I- DEAS are used in the analyses. Results from the commercial FEA codes and the SAVE analysis are compared in Table 4 for a/h= 4. The mesh description shown in Table 4 represents the number of elements that are used to represent each composite layer in the three orthogonal coordinate directions. For example, a 12 × 12 × 2 finite element mesh represents 12 solid elements in *x*- and *y*-direction each, and 2 solid elements in the *z*-direction, in every single composite layer. As is shown in Table 4, the numerical values of the six stress components as obtained from the 3-D FEA using solid elements with quadratic shape functions (parabolic in I-DEAS, CHEXA20 in NASTRAN, and C3D20 in ABAQUS) are within 5% of the exact values. Only the transverse shear stress component, τ_{yz}, shows some significant difference (about 12 %) from the exact solution. However, as is shown in Table 4, the accuracy in the solution of this stress component is increased significantly by refining the FE mesh. In Table 4, compare the results obtained from I-DEAS and ABAQUS analyses with progressive mesh refinement (6 × 6 × 2, 12 × 12 × 2, and 20 × 20 × 4 meshes of parabolic solid elements). It is also worth noting that a sufficiently accurate solution to the problem being analyzed could be obtained by using parabolic brick elements in a coarse mesh (6 × 6 × 2 per layer) with 2916 DOF only. However, in spite of using a more refined mesh (12 × 12 × 2 per layer), solid elements with linear shape functions (linear brick in I-DEAS and C3D8 in ABAQUS) do not provide an accurate solution. For the numerical problem analyzed here, solid elements with linear shape functions, also known as constant strain elements, can be erroneous in the bending stress values by as much as 30%.

DOF, degrees of freedom; *M*, degree of polynomial

The through-the-thickness distributions of six stress components, as shown in Fig. 7, demonstrate many unique features of the 3-D stress state in multilayered laminated composite structures. Note the jump in the in-plane normal stress components σ_{xx} and σ_{yy} at the layer interfaces (see Fig. 7a and b). In multilayered laminated structures, in-plane stresses σ_{xx}, σ_{yy}, and τ_{xy} are discontinuous (hence, the in-plane strains ϵ_{xx}, ϵ_{yy}, and γ_{xy} are continuous) at the layer interfaces. On the other hand, the transverse stresses σ_{zz}, τ_{yz}, and τ_{xz} are continuous at the material interfaces, as shown in Fig. 7(c)–(e). However, the out-of-plane strains ϵ_{zz}, γ_{yz}, and γ_{xz} are now discontinuous (or jump) at these interfaces.

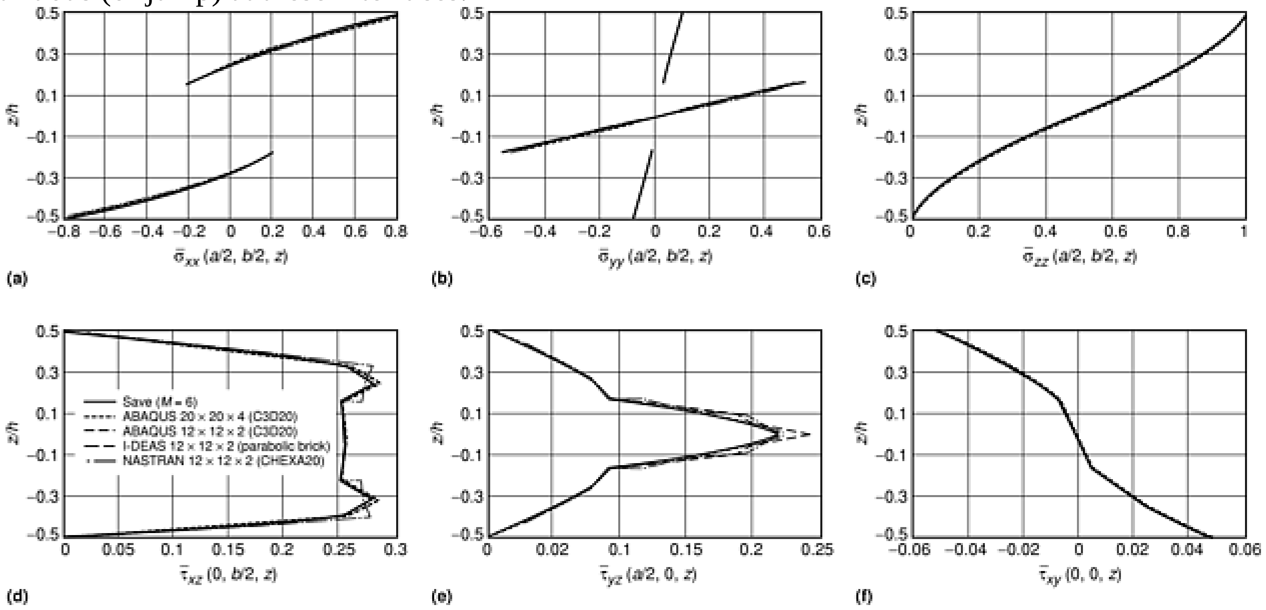

Fig. 7 Through-the-thickness distributions for *a*/*h*= 4. (a) σ_{xx}. (b) σ_{yy}. (c) σ_{zz}. (d) τ_{xz}. (e) τ_{yz}. (f) τ_{xy}. In the legend for these curves, *M* is the degree of the polynomial.

Continuity of the transverse normal and shear stresses at the layer interface, is a unique and important aspect in the analysis of multilayered laminated structures. Table 5 presents the actual numerical values of transverse stress components σ_{zz}, τ_{yz}, and τ_{xz} at the layer interfaces, thereby providing a deeper insight into the continuity of these interlaminar stresses. The notation “T” represents values computed at the interface approaching from the top; similarly, “B” represents values computed at the interface approaching from the bottom. While the SAVE analysis code is almost perfect in satisfying the continuity of interlaminar stresses at the interfaces, ABAQUS analysis with a very refined mesh (20 × 20 × 4 per layer with 61,200 DOF) is also reasonably good in achieving that goal. However, as the mesh size becomes coarser, the commercial FE analyses results tend to become more distinct as well as less accurate at the interface (refer to Table 5). Once again, in all the commercial FE analyses, the transverse shear stress component, τ_{yz}, shows the most significant differences. As is shown in Table 5, the continuity of interlaminar stresses at the layer interfaces is the worst from the FEA with constant strain elements, thereby making them unsuitable for transverse bending analysis of multilayered composite structures.

Table 5 Interlaminar stresses as obtained at the ply interfaces from various 3-D analyses of a $[0/90/0]_T$ simply supported laminated plate (a/*h*= 4) subjected to sinusoidal loading on the top surface

In general, a 3-D analysis using discrete layer- by-layer representation of the laminate can be performed with reasonable accuracy, using solid elements with quadratic shape functions in any of the commercial FE codes evaluated here. However, due to limitations in the available computational resources, many times it may not be possible to discretize a complex, practical structure completely with 3-D solid elements. In addition, most of the real-life structures are thin- walled, so as to justify the use of 2-D shell elements in their analyses. However, the limitations, or bounds, of using 2-D shell elements to accurately analyze multi-layered composite structures needs to be well understood.

The thick laminated plate problem (a/h= 4) described previously is now analyzed using 2-D shell elements available in the commercial FE codes, namely, ABAQUS (S4R), NASTRAN (CQUAD4), I-DEAS (linear shell), and MECHANICA (p-type shell) (Ref 36). The type of shell element used in each analysis is mentioned in parentheses. The stress solutions obtained from various 2-D shell analyses are compared with the exact 3-D solution, as shown in Table 6. The 2-D shell analysis does not provide the transverse normal stress component, σ_{zz}. Note the very high numerical discrepancy among the stress values as obtained from exact 3-D solution and various 2-D analyses using shell elements. The largest discrepancy is in the magnitude of stress in the fiber direction in 0° layer, where the stress values from the 2-D analysis are almost 50% lower than the exact 3-D values. At the same time, the similarity among the 2-D analyses solutions is remarkable. Except for the values of transverse shear stress, τ_{yz}, as obtained from MECHANICA, the numerical results for the stresses obtained from the 2-D shell analyses are essentially the same. A systematic attempt was made to check the convergence of the 2-D solutions by increasing the order of shell elements (e.g., S4R to S8R in ABAQUS, CQUAD4 to CQUAD8 in NASTRAN, and linear shell to parabolic shell in I-DEAS), as well as by refining the FE mesh in the model. No further improvement in the numerical solution of the problem was observed.

DOF, degrees of freedom; *M* or *p*, degree of polynomial

Further insight into this subject is gained by analyzing the laminated plate problem described previously with a/h= 50. The same 2-D shell elements and FE mesh are used during the analysis. Numerical results from a typical 2-D shell analysis using SDRC I-DEAS and the 3-D exact analysis SAVE are presented both in tabular form (Table 7) and as plots of stress distributions through the thickness of the laminate (Fig. 8). Except for the

transverse shear stress component, τ_{yz}, numerical solutions obtained from the 2-D and 3-D analyses for this problem compare very well with each other. The numerical examples discussed here emphasize the need to understand the limits of 2-D shell elements in the analysis of anisotropic, multi-layered composite structures.

Example 2: Uniaxial Extension of a Laminated Plate. This example focuses on the free- edge effects in a $[0/90]_s$ laminated plate subjected to uniaxial extension (see Fig. 9). Pagano (Ref 31) presented the closed-form solution to this classical problem in 1974. Later on, Pagano and Soni (Ref 32) also solved this problem using a global-local variational model. Here, the results from the SAVE FE analysis program, performed using a 1 × 20 × 12 mesh of *variable- order* rectangular solid elements (Ref 21, 22), are presented.

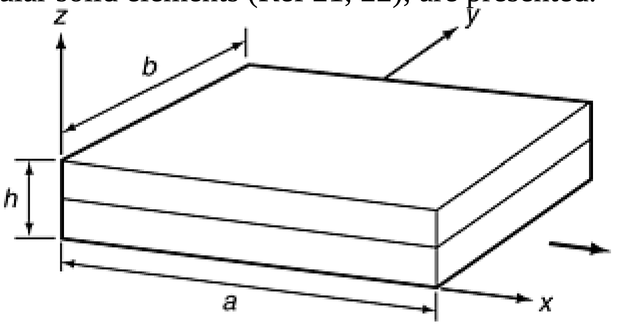

Fig. 9 A $[0/90]_S$ laminate subjected to uniform axial extension

Due to the symmetry of geometrical and materials properties and the applied loading, only one-eighth of the configuration of the $[0/90]_s$ laminated plate (a=b= 4 h; see Fig. 9) need be analyzed. The uniform extension of the laminated plate is achieved by applying a uniform axial displacement at the ends x=a. For the purpose of analyses, the following lamina elastic constants are taken (Ref 31):

E_1= 138 GPa (20 × 10^6 psi)

E_2=E_3= 14.5 GPa (2.1 × 10^6 psi)

G_{12}=G_{13}=G_{23}= 5.9 GPa (0.85 × 10^6 psi)

ν_{12}=ν_{13}=ν_{23}= 0.21

The distributions of interlaminar stresses as obtained from the analysis are plotted along the y-direction at x/a= 0.5. All the stress components are normalized by the applied axial strain. The distributions of the transverse normal stress, σ_{zz}, as obtained from the analysis at the midsurface of the $[0/90]_s$ laminate in the 90° layer, are shown in Fig. 10. The normalized peak value of 2.0 GPa (0.29 × 10^6 psi) for this stress component, which occurs at the free edge y/b= 1, compares very well with those obtained by Pagano (Ref 31) and Pagano and Soni (Ref 32). Next, the distributions of the normalized transverse normal stress component, σ_{zz}, as obtained from the analysis at the interface of the 0/90 layers, are shown in Fig. 11. Note that in Fig. 11 the numerical results from both 0° layer and 90° layer are plotted separately but appear superimposed. As is shown in Fig. 11, the continuity of the transverse normal stress component, σ_{zz}, is satisfied extremely well. Similar observations are made regarding the distributions of the transverse shear stress component, τ_{yz}, as shown in Fig. 12. Note the high gradients of interlaminar stresses that occur in the vicinity of the free-edge at y/b= 1 (see Fig. 11 and 12). These stresses are normally the primary cause of delamination failure in multilayered laminated structures.

Computer Programs

Barry J. Berenberg, Caldera Composites

Introduction

TRADITIONAL ENGINEERING MATERIALS are isotropic. Common engineering analyses can be performed with little more than a standard reference such as *Roark's Formulas for Stress and Strain* (Ref 1) and a scientific calculator. Laminated composites, on the other hand, are generally anisotropic. Performing a simple stiffness calculation, even for the case of an orthotropic laminate, is too complex for hand calculations.

Although somewhat lengthy, laminate calculations are relatively simple. They can be programmed into a spreadsheet with little difficulty. The challenge in this approach is verifying the calculations. The large number of variables involved, coupled with the anisotropic nature of composites, makes it difficult to prove the accuracy of the program for all types of laminates.

Fortunately, there are now a good number of high-quality commercial programs available for laminate calculations. Capabilities range from simple stiffness calculations and point-stress analysis to micromechanical modeling to shell buckling and other structural considerations. The problem now becomes one of finding a program that meets the user's needs.

Computer Programs

Barry J. Berenberg, Caldera Composites

Evaluation Criteria

Criteria for evaluating computer programs for composites structural analysis include database capabilities, types of engineering calculations supported, user, interface and operating systems, and technical support.

Databases

All composite programs, even the simplest ones for laminate stiffness calculations, deal with a large amount of data. Any program should therefore provide a means for storing and reusing this data. Database implementations can range from a simple text file that can be edited by hand to a fully relational database implemented in a commercial engine such as Microsoft Jet. Even when text files are used, the program can provide a graphical means of adding, editing, or deleting records.

The exact data to be stored depend on the calculations performed by the program, but usually include:

- Constituent material properties (engineering constants for reinforcements and matrices)
- Ply properties (engineering constants for individual lamina)
- Laminate definitions (lay-up sequences including material, orientation, and ply thickness)
- Results of calculations

If legacy databases exist, consideration must be given to importing old data into the new databases. Text files are the easiest to manipulate; commercial engines probably require a special utility, if conversion is even possible.

Engineering Calculations. For the purpose of selecting software, composite engineering calculations can be classified into three broad classes: micromechanics or material modeling, macromechanics or laminated plate theory, and structural analysis such as beam bending or joint failure. Some programs offer functions in only one of these classes, but it is becoming more common to offer all classes of calculations within a single package. If a needed function is not offered within the program, consideration must be given to how output from one program can be used as input to another program. For example, if a specialized program is used for buckling analysis, it must be able to read laminate properties (usually **ABD** matrices) from another program. Likewise, a laminate stiffness program might need to read ply properties generated by a micromechanics program.

Micromechanics programs take constituent material properties and generate ply properties. Calculations can be performed for different types of reinforcements (particulate, platelet, short fiber, long fiber, unidirectional, woven fabrics) and different types of matrices (polymeric, metallic, ceramic). For each material combination, there are several theories to choose from. Most general-purpose composite codes support only a subset of these materials and theories. To cover a more complete range of options, as well as user-defined theories, a specialized micromechanics program may be needed.

Macromechanics programs calculate laminate properties from ply or lamina properties using laminated plate theory. Inputs usually consist of engineering constants, obtained either from written sources—manufacturer's datasheets, open literature, *MIL-HDBK-17* (Ref 2)—or from micromechanics calculations. Outputs consist of, at a minimum, laminate engineering constants, including flexural constants. Most programs can also output constitutive equations such as the **ABD** and **Q** matrices.

Laminates are usually analyzed for both stiffness and strength, so these programs typically offer a point-stress capability. Loads are input as stress resultants or laminate strains; results are shown as ply stresses and strains in both ply and laminate coordinate systems. Failure criteria such as maximum stress or Tsai-Wu are used to calculate stress ratios or safety factors.

Temperature changes and moisture absorption can have a significant impact on composite behavior, so laminate programs should be able to handle environmental loads. Engineering constants should include laminate expansion coefficients, and stress/strain calculations should include temperature and moisture components.

Structural Analysis. Calculation of laminate properties and point-stress ratios is just the start of composite analysis. Once these preliminary screenings are complete, it is necessary to see how the laminate behaves under structural loads. Although finite-element analyses are often relied on for detailed design work, closed analytical solutions can be a powerful tool. Many types of structures can be analyzed this way, including beams, plates, shells, and pressure vessels. Solutions exist for stiffness, strength, stability, and dynamic conditions. Programs may also offer solutions for structural components, such as bolted or bonded joints, ply drop-offs, and stresses around cutouts.

Optimization. The goal of most design programs is to maximize strength or stiffness for a given set of loads while minimizing weight. This is an iterative process even for isotropic materials and is made more difficult by the large number of design variables available to the composites engineer. Some laminate and structural programs have tools to aid in the optimization process. In the simplest case, laminate properties and point-stress safety factors can be generated for a family of laminates. For example, a program might create a plot of modulus versus ply angle for the $[0/\pm\theta]_S$ family, where θ may vary from 0° to 90° in increments of 5°. In more complex cases, the program may be given a design goal and use an optimization algorithm to determine optimal materials, stacking sequence, and structural geometric parameters.

User Interface and Operating Systems

A good number of composite programs are now written for use under Microsoft Windows and sport a familiar graphical user interface (GUI). Graphic user interfaces are also common on programs written for UNIX systems, but some still use text-based interfaces. Macintosh programs are always GUI-based, but there are few composite programs written for that platform. It is important not to pick a program based solely on its interface: a slick cover may disguise a lack of capabilities.

Care must be taken to ensure programs are compatible with different versions of the operating system. UNIX programs should, of course, match the flavor of UNIX being run on the workstation. Most Windows 98

programs can run on Windows 95 systems, and vice-versa, but engineering programs especially often require Windows NT or 2000. Programs written for Windows 3.x may or may not run on Windows 9x or NT/2000 systems. Likewise, DOS-based programs may not run under any version of Windows, even a 9x version in DOS mode.

Support

Technical support should always be included with a software package, whether as part of the purchase price or for a maintenance fee. Support may be required not only for technical issues related to the calculations, but also for installation, system maintenance, and upgrades (software or hardware). If at all possible, arrange for a time-limited trial of the software before purchasing. Run some sample problems to test the features and make some support calls to determine the level of response that can be expected.

Few programs provide printed manuals anymore. On-line manuals should document all capabilities of the software, should be easy to navigate, and should have index and search functions. Theory manuals are not always included in the documentation, but are an important component. Some company standards require a specific theory to be used: in these cases there must be some way to determine what the software uses. Also, when comparing software results to the literature, discrepancies might be explained by differences in the theories used for the calculations. If theory manuals are not provided, this information should be available as part of the support agreement.

Reviews of Available Programs

Early programs for composite analysis tended to perform only one or a select few functions. Using ply properties from a micromechanics calculation in a laminate analysis, or laminate properties from a macromechanics calculation in a shell analysis, often required manually transferring the results from one program to another. Interfaces were text-based and linear: errors could not be corrected by backing up a step, and modifications to variables required an entirely new analysis. Storage of properties, if at all available, required the editing of a text file, often in a cryptic format.

Modern programs sport a graphical interface, built-in databases, and integrated modules for different types of analyses. Some programs even make it easy to add analysis modules, for those times when a specific type of calculation is not included in the program. Three of these comprehensive packages are reviewed in this section. Table 1 summarizes the capabilities of these programs.

Table 1 Capabilities of three programs for composites analysis

Program	Interface	Database	Micromechanics	Macromechanics	Structures	Design
CompositePro Version: 3.0 Beta OS: Windows 3.*x*, 9*x*, NT*x*, W2K Publisher: Peak Composite Innovations URL: http://www.compositepro.com	MDI, printed report of all analyses (to printer only, no file option), English or SI units, on-line demo, no help files, no theory manuals	Simple text format. Store fiber (6), matrix (3), lamina (9), core (6) properties; laminate sequences. No references for included properties. Edit files or use program GUI.	Stiffness, thermal, strength, density. Theory not specified. Store results in database. Volume-fraction/weight-fraction converter; winding, fabric thickness (based on areal weight); roving converter; fabric properties (random, woven, stitched, based on weave style)	Stiffness, thermal properties; constitutive matrices; stresses, strains (top, middle, bottom); curvatures; FPF, LPF (max stress, max strain, quadratic); FPF failure mode survey; stress, strain, resultant, temperature, moisture loads	Plate (bending, stability, frequency); sandwich plate (bending, local and global stability); tubes/beams (bending, torsion, frequency; shell and Euler stability; thin- and thick-wall pressure vessels)	Thermal curvature; laminate surveys (tabular form of carpet plots); laminate parametric analysis (family studies)
Name: ESA CompVersion: 1.5 OS: Windows 9X, NT4, W2K; UNIX Publisher: Helsinki University of Technology URL: http://www.componeering.com	SDI (unlimited windows); screen, file, printed reports and plots; SI units; extensive help files (HTML format); full theory manual (PDF format and hard copy); Quick Start guide; built-in browser;	Text format (not designed for simple editing). Adhesives; fibers; honeycomb and homogeneous cores; reinforced and homogeneous plies; matrix. Supports process	Unidirectional plies: thickness, engineering constants, thermal and moisture expansion from rule of mixtures. Save ply results into database	Ply: List and plot all constants and matrices. Laminates: All constants and matrices; FPF, LPF (8 failure criteria for composite plies; 4 each for homogeneous and core plies); sandwich wrinkling; laminate and layer stress and strain.FEA: Export laminate properties to	Notched laminates; ply drop-offs; free-edge effects (built-in finite-element model)	Micromechanics: plot constants versus volume/weight fraction, fiber direction; multiple materials.Laminates: carpet plots; family studies; θ-laminates (variable angles); failure envelopes; strength and stiffness sensitivity studies (ply properties, orientation);

	API (documented on-line); fully customizable	specifications. Large database included		ABAQUS, ANSYS, ASKA, I-DEAS, MSC/NASTRAN		multiobjective design (specify desired laminate properties, constraints, and objectives)
Name: V-LabVersion: 2.0 OS: Windows 9X, NT4, W2K Publisher: Applied Research Associates URL: http://www.techpub.com	Outlook icon bar for selecting modules; tabbed dialogs within each module. Three-dimensional plots show failure envelopes. Extensive help files; minimal theory background. API, no documentation. Printed reports of individual analyses. SI or English units	MS Jet (access through program only). Fiber, matrix, lamina (8), and other materials (3); subcategories; temperature dependence; laminate sequences (4). Includes complete MIL-17 database	None, but database supports fiber and matrix properties	Lamina: constitutive matrices, stress/strain, failure (max stress, max strain, Tsai-Wu); no engineering constants.Laminate: constitutive matrices, stress/strain, moisture diffusion, free edge effects, plate with hole	Bonded joints (composite-composite, metal-composite).	Laminate carpet plots as part of lamina module.

CompositePro

CompositePro is one of the earliest comprehensive programs developed for the Windows operating system. First released in 1996, it is one of the few programs that will still run under any Windows version from 3.x to 2000.

The program has a multiple-document interface (MDI). The main window has a menu for accessing all of the analysis functions, a toolbar for quick access to the most common functions, and a window area for holding the individual analysis forms. There does not seem to be a built-in limit to the number of analysis forms that can be visible at once. Any single form can be printed as a graphical image, and a summary report can be generated for all analyses that have been run within a session.

The database uses a simple text format to store fiber, matrix, lamina, and core properties, as well as laminate sequences. One file stores properties for a single material, so a database of 50 materials requires 50 files. The files can be edited by hand, but it is easier to use the forms built into the program.

The only documentation for CompositePro is an on-line demo, which basically steps through the forms one at a time and explains how each works. The demo is similar to a help file, but it must be run sequentially, and there is no way to go directly to the guide for a specific form. Fortunately, the forms require little explanation, so the lack of printed or on-line help should not be missed. The theories used for the calculations are not specified, but the program author has been willing to provide this information via e-mail in the past.

Lamina and Laminate Analysis. Laminate properties can be generated using simple micromechanics calculations. Fiber and matrix materials are selected from the database, and lamina properties are calculated based on either volume or weight percent. The theory used is not specified. Resulting lamina properties can be saved in the lamina database for use in laminate calculations.

Lay-ups are entered in a tabular format, and special functions are available for creating symmetric laminates or rotating the entire laminate by some angle. These functions operate by simply copying plies, so it is not possible to undo a symmetry operation. Loads are entered as stresses, strains, or stress resultants (bending loads can only be entered as moment resultants, not as curvatures). The program also supports uniform temperature and moisture changes.

Output consists of constitutive matrices ($\overline{Q}$, **ABD**, **ABD** $^{-1}$) and engineering constants (both in-plane and flexural, for two-dimensional thin laminates and three-dimensional thick laminates). Moduli and coefficients of thermal expansion in the principal directions can be shown in a bar graph. A complete set of stress analysis results are available, including: midplane laminate strains; stresses and strains in laminate and ply coordinates, at ply top, middle, and bottom surfaces; first-ply-failure (FPF) analysis; first- ply-failure survey; and progressive-ply-failure (PPF) analysis. All stresses and strains can be plotted.

The program provides three failure criteria: maximum stress, maximum strain, and quadratic or Tsai-Wu. The FPF analysis simply reports the first ply to fail under the applied load, including the failure mode (such as fiber tension or resin shear) and the factor of safety. The failure survey determines which ply will fail first under five basic loads (inplane tension and compression in the laminate *X* and *Y* directions, plus in-plane shear). Figure 1 shows the results of a failure survey on a simple laminate. Failure loads for each ply are listed in a table and plotted in a bar chart for comparison.

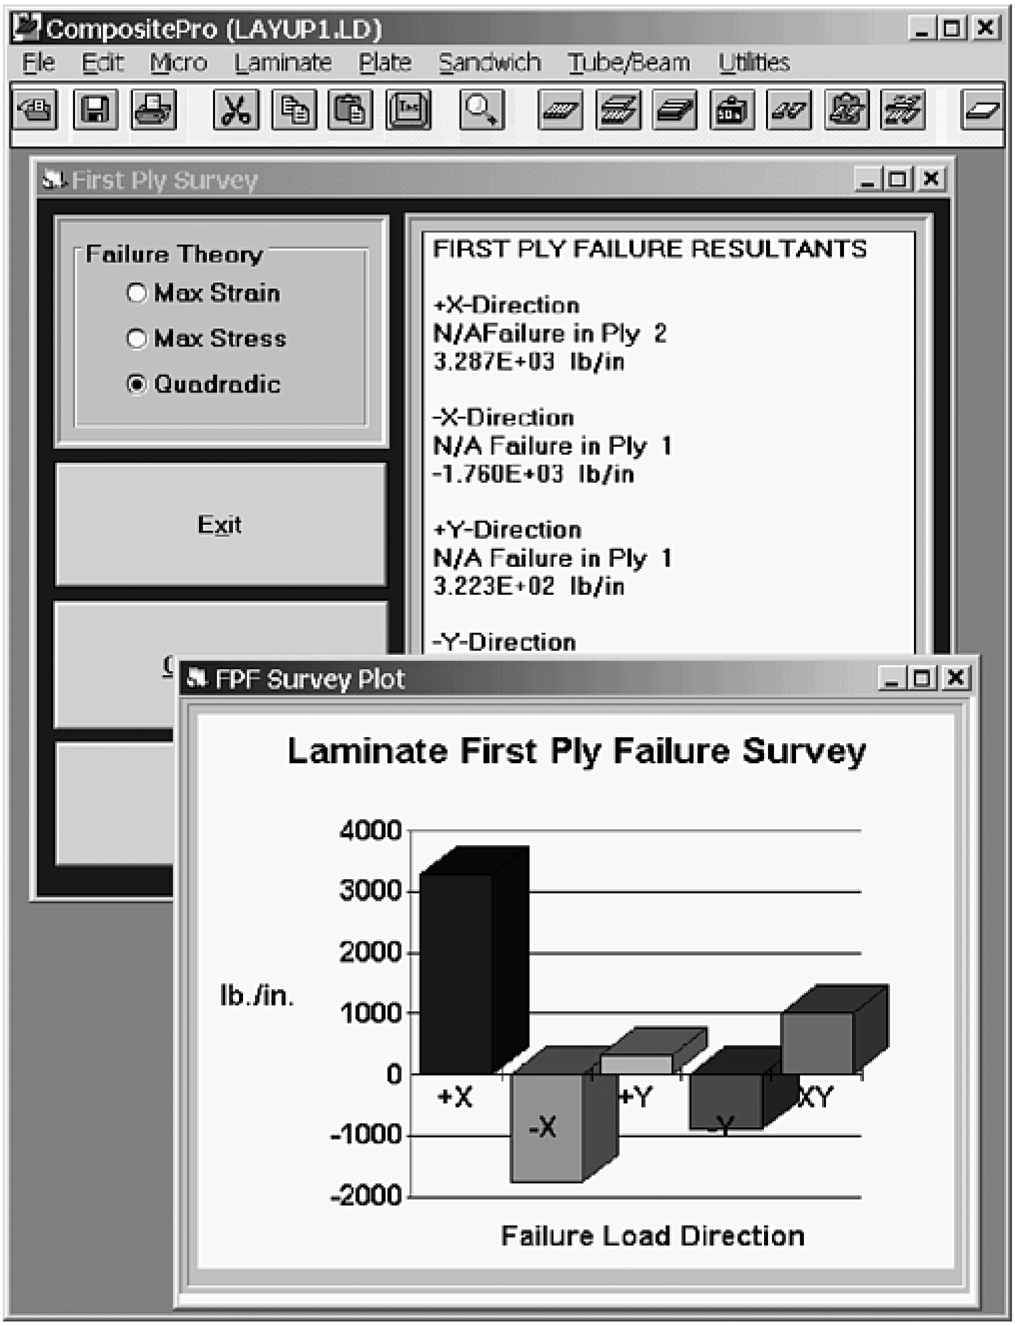

Fig. 1 Example of a laminate failure survey in the CompositePro software program

The PPF analysis is similar to a last-ply-failure (LPF) analysis, except that it reports the failure of each ply up to the last ply. The termination criterion can be either the first occurrence of fiber failure in a ply or failure of a specified number of plies in any mode. Degradation factors are specified individually for Young's modulus, E_{11} and E_{22}; shear modulus, G_{12}; and Poisson's ratio, v_{12}. The report lists the plies in the order they fail and includes the reduced moduli, the safety factor, and the failure mode.

Structural Analysis. CompositePro provides functions for analyzing some simple types of structures: plates, sandwich plates, beams (with eight standard cross sections), shells, and pressure vessels.

All structural analyses begin with the definition of the geometry. For plates, this is length and width; for sandwiches, it also includes core thickness and material; for beams and shells, it is the dimensions of the cross section (radius, width, and height, as appropriate). Plate, facesheet, and wall thicknesses are all set by the laminate definition. Figure 2 shows an example of a hat-section definition. Dimensions are entered in a form, and section properties can be viewed in a separate window.

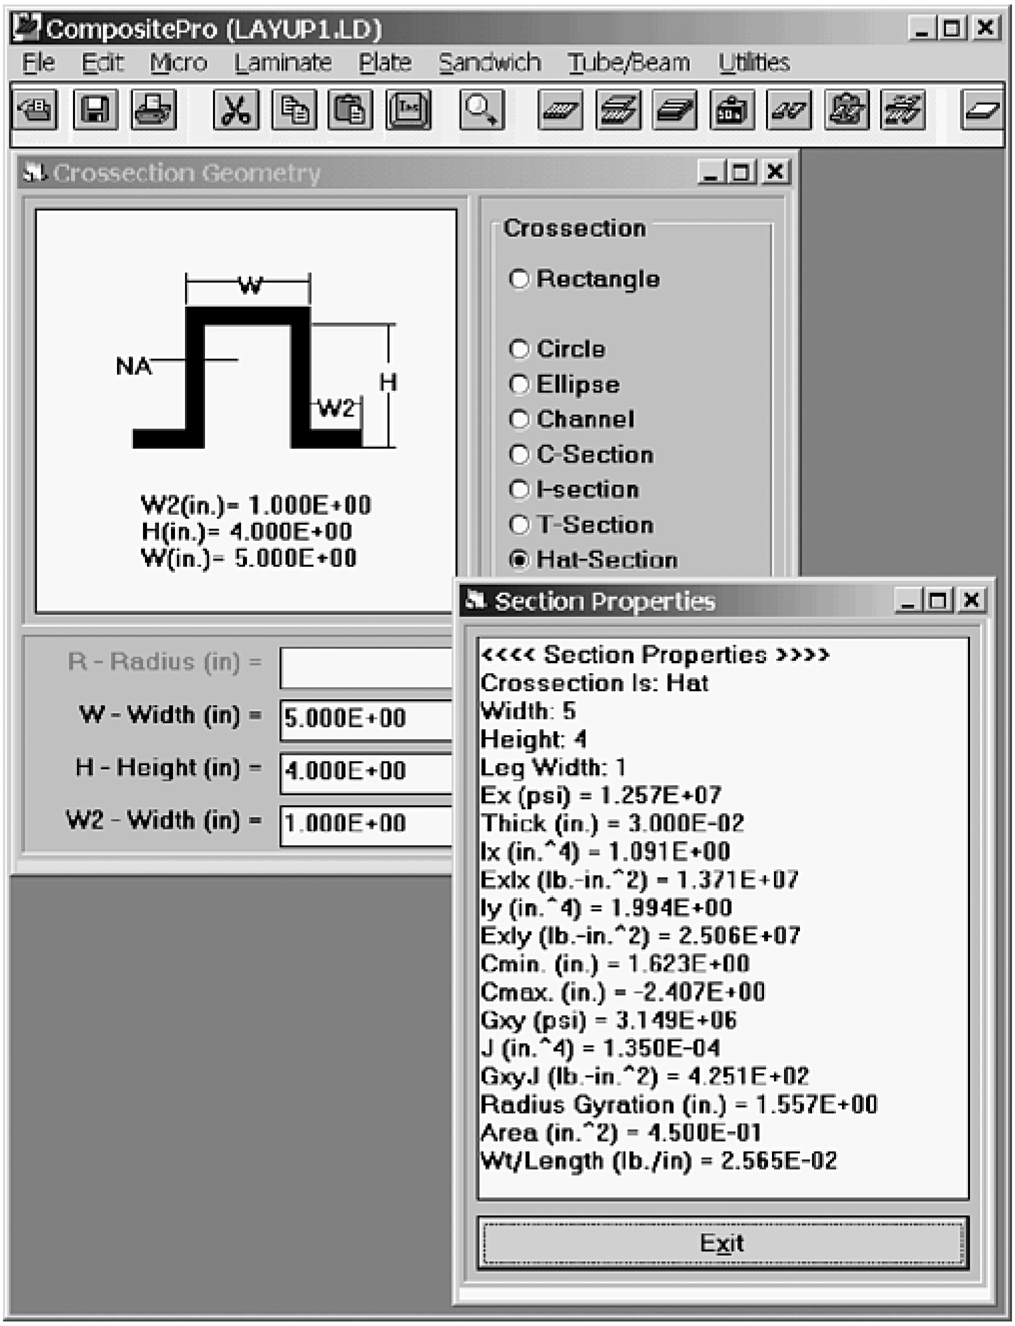

Fig. 2 Example of a beam definition in the CompositePro software program

The structural results are somewhat limited, but cover the most common situations:

- *Plates:* Analyses include bending under a uniform pressure or concentrated load, buckling under uniaxial or biaxial compression, and fundamental vibration frequency. Three types of boundary conditions are supported for each type of analysis. The bending analysis gives moments (*X*, *Y*, and *XY*) and maximum deflection at a user-specified point.
- *Sandwich plates:* Analyses include bending of a simply supported plate under uniform pressure and plate buckling under uniaxial compression. Both calculations include the local stability failure modes of face wrinkling and face dimpling. Maximum deflection only is given for the bending analysis.
- *Tubes and beams:* This section has the largest number of calculations. A full set of section properties can be displayed for the cross-section geometry. Beam calculations include bending, torsion, and vibration. Bending allows twelve boundary conditions and load- type combinations, with section *EI*, end-point reactions, rotations and moments, stresses (maximum and at a specified point), and maximum deflection included in the results. The torsion solution is for a free-clamped beam with an end torque and calculates beam properties (such as *GJ*), angle of twist, and shear stresses. Vibration allows eight boundary conditions (two with an end mass) and shows the frequencies of the first three modes.

Stability analyses include shell buckling for cylindrical shells and column or Euler buckling for any cross section.

- *Pressure vessels:* Two modules provide solutions for thin-wall and thick-wall pressure vessels. The thin-wall module can analyze open or closed-end vessels with an internal pressure, axial load, and applied torque. The thick-wall module can analyze vessels under combined internal and external pressure, with an applied axial load and temperature change (no distinction is made between open and closed-end vessels). In both cases, ply stresses and strains are tabulated and plotted in the hoop, axial, shear (thin vessels only), and radial (thick vessels only) directions. The thin-wall module also calculates strength ratios and failure modes. The program gives no criteria for determining whether the vessel qualifies as thick or thin.

Several of the structural solutions use an *m, n* factor, such as plate bending (for iteration) or shell buckling (for buckle waves in the axial and circumferential direction). The user must specify maximum values for these factors. The results must be manually checked and, if the solution occurs at one or both of the maxima, the factors must be increased and the solution run again.
Utilities. CompositePro has several utility functions, most of which could be classified under micromechanics. The utilities include:

- *Converter* for volume fraction/weight-fraction conversions
- *Winding calculator:* Given a mandrel diameter and winding schedule, it calculates individual ply thicknesses. Results can be copied to the laminate definition form.
- *Fabric thickness:* Calculates layer thickness based on fiber volume, void volume, and areal weight
- *Roving converter:* Converts among various linear density units, such as cross-sectional area, yield, denier, and tex
- *Radius of curvature calculator:* Determines warping of a nonsymmetric laminate under a uniform temperature change
- *Fabric builder:* Calculates lamina properties for broadgoods (random continuous mat, woven fabric, stitched fabric) based on weave style (if appropriate), fiber volume, areal weight, fiber weight percent, and void volume percent. Resultant properties include lamina thickness, engineering constants, and strengths. The lamina properties can be saved in the database for use in laminate and structural analyses.

Design Utilities. Two design utilities were not yet available in the beta version supplied for this review: Laminate Surveys and Laminate Parametric Studies. The laminate survey form is basically a carpet plot in tabular form. Engineering properties and FPF strengths are calculated for $\theta_1/\theta_2/\theta_3$ laminates and tabulated at 10% ply-content increments (0%/0%/100%, 10%/0%/ 90%, 10%/10%/80%, etc.). The parametric study is similar to a carpet plot, but instead of adjusting ply content the ply angles are rotated. For example, applying a +5/0/+5 rotation to a 0/90/ 0 laminate would generate results for 0/90/0, 5/ 90/5, 10/90/10, …, 90/90/90 laminates.

ESAComp

Of the comprehensive programs reviewed here, ESAComp is the only one available on both Windows and UNIX systems. The standard UNIX distribution is for SGI platforms. Other UNIX platforms can be delivered on request, and a Linux version was in development at the time of this writing. ESAComp's focus is primarily on micromechanics and laminate analysis. Within those categories, it offers more features and analysis options than the other programs. An extensive set of design and optimization tools is provided. Version 2.0, scheduled for release in late 2000, will expand the design tools; add structural elements such as beams, plates, and shells; and include an improved interface for user extensions.
Because of its UNIX heritage, ESAComp uses a single-document interface (SDI) rather than a MDI. Most commands bring up a new window, which can be placed anywhere on the desktop. The program is fully documented on-line. Help files are in HTML format. They can be viewed in a standard browser or from within the program using the built-in, proprietary browser. A theory manual in portable document file (PDF) and printed format is also included. It details the theory used in all ESAComp analyses and even serves as a good stand-alone reference.

The interface is not as intuitive as other programs, making it difficult to use ESAComp without first reading the documentation. A Quick Start Guide (PDF and printed) is provided; working through it provides sufficient experience to run most analyses. The help documentation is comprehensive, but tends to describe the software more from a programmer's point of view than from a user's. This approach is probably necessary to show the full power of the program, but it does make the learning curve a bit steep.

Interface. ESAComp sessions work with a single case. Each case contains information about materials, plies, laminates, and loads. A case is set up by selecting one of those categories, defining the items for that category (selecting them from the database or entering new items into the database), and establishing the analysis options. Case setups are also saved in the database.

The main window also provides access to global program options. Options can be set for analysis, display, help, and units:

- *Analysis:* Failure criteria (eight for composite plies, four for isotropic plies, four for cores), factors of safety, sandwich wrinkling factor, stress/strain recovery plane
- *Display:* General; header; footer; line, bar, and layer charts (size, grid, scale); failure margins (expressed as margin or failure ratios)
- *Help:* Default to User Manual or Design Manual
- *Units:* Select default unit, format, and precision for all measurements (displacement, length, stress, coefficient of thermal expansion, pressure, etc.). Only SI units provided

Results of all analyses are displayed using the built-in HTML browser. The HTML pages are generated on the fly using a macro language. The global Display and Units options affect the results displays, and each results window has several options for altering the display. Users may also create their own macros for custom displays.

Database. ESAComp has been developed with the corporate user in mind, and nowhere is that more evident than in the database. Whether working with constituent materials, plies, laminates, or loads, three data levels are always available: User, Company, and ESAComp. The User level is for properties and analyses used by a single person, the Company level is for data shared by many, and the ESAComp level is for the extensive built-in collection of properties.

The database has also been developed with the manufacturer in mind. Each material is allowed six data categories, only one of which is mechanical data. The other categories are: Composition (physical properties), Operating Environment (temperature and pressure), Processing Data (cure cycle and applicable manufacturing processes), Product Data (manufacturer, type, specification, and price), and Comment. Keywords can be associated with each material, ply, or laminate; the list of built-in keywords includes categories, material types, and manufacturers. Items are referred to by an identification string, which can be built up from keywords. For example, a ply from one of the demonstrations is identified as “T300;Epoxy;UD-.200/210/60” with the keywords “Fiber;Carbon;Toray;Matrix;Epoxy;”.

The ESAComp Data Bank is divided into seven categories: Adhesives, Fibers, Honeycomb Cores, Homogeneous Cores, Homogeneous Plies, Matrices, and Reinforced Plies. Each of those categories is further divided by material type. For example, fibers are categorized as Aramid, Carbon, or Glass. Material types are categorized by manufacturer, such as Akzo, DuPont, and Teijin for Aramid.

Constituent Materials. All analyses start by defining materials and loads. In the case of micromechanics, this means getting fiber and matrix properties from the database or defining new material properties.

The micromechanics analysis simply creates a ply property based on the selected fiber and matrix properties. Results include engineering constants, expansion constants, and strengths. If a mass per unit area of fibers is entered, the ply thickness will be calculated. The generated properties can automatically be entered into the database as a new ply material. Identification keywords are combined from the two materials, giving a default identifier; all processing and other information from the two materials is also included in the new ply definition.

The effects of volume or weight fractions and fiber directionality can be studied by specifying a range for one or both of these values. Any or all of the material constants can be plotted and tabulated against the selected variable. If both variables are chosen, the result is similar to a carpet plot with, for example, volume fraction on the *X*-axis and individual curves for the discrete angles.

Plies. The basic ply analysis simply calculates ply properties, engineering and expansion coefficients, stiffness and compliance matrices (two- dimensional and three-dimensional), invariants, and transformation matrices.

The basic analysis is made more powerful by specifying a ply angle. If a single value is specified, the results show the transformed properties. If a range of angles is specified, then all properties (including constitutive matrix components) can be plotted and tabulated against ply angle. In addition to the standard *X*-*Y* plots of property versus angle, ESAComp also offers a polar plot. The radial coordinate represents ply angle, and the circumferential coordinate represents the property. The *X*-component of the plot corresponds to the property in the 1-direction; the *Y*-component corresponds to the property in the 2-direction. For example, the polar modulus plot in Figure 3 shows E_1 on the horizontal axis and E_2 on the vertical axis.

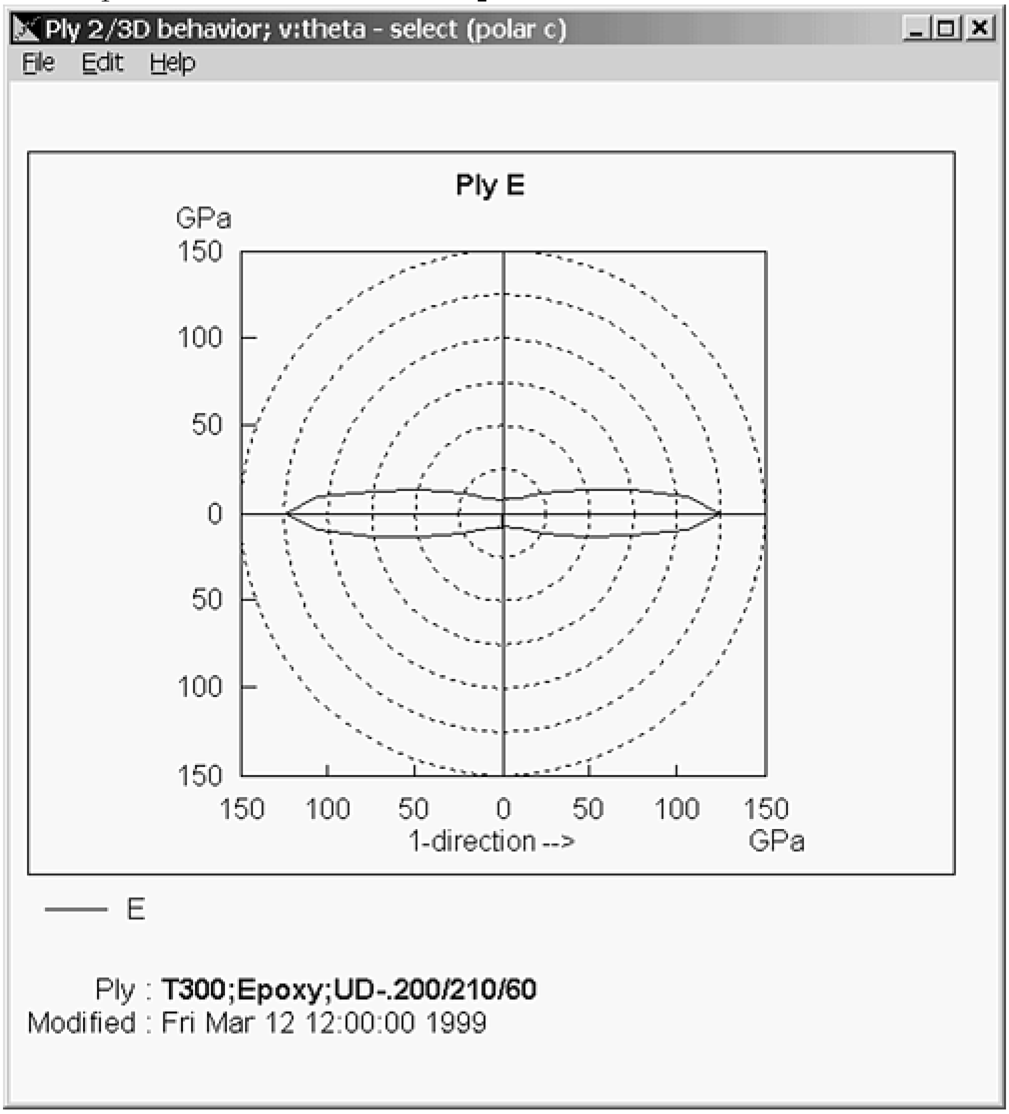

Fig. 3 Example of a polar modulus plot in the ESAComp software program

Multiple materials can also be analyzed at once. Selecting more than one ply allows comparison bar charts and tables of properties to be generated. Comparison results can include all standard constants as well as specific moduli. An angle-range analysis can be combined with a multiple-material analysis to generate overlay plots showing the variation of properties versus angle for all materials simultaneously.

Finally, the carpet plots can be generated for one material at a time. The laminate is of the format $[0/\pm\theta/90]_S$, where θ is specified by the user. Plot parameters (line spacing by percent for each angle) can be customized to generate dense or sparse plots. Any engineering, expansion, or strength constant can be plotted. For strength properties, any of the eight failure criteria may be used.

Laminates. As with other portions of the program, analysis of laminates starts by importing a laminate definition from the database or by defining a new laminate.

ESAComp has a rather unique but powerful method for defining laminates. The program uses standard laminate notation, with each ply entered as a single line in the laminate view. The line shows the material (designated by a letter) and the ply angle. Sublaminate delimiters and modifiers (such as “S” for symmetric) appear on their own lines. The laminate builder automatically recognizes special types of laminates, allowing the program to expand a lay-up, showing one ply per line. It can also contract a laminate, automatically inserting delimiters and

modifiers as appropriate. Modifiers can be edited, so a symmetric laminate, for example, can be changed to an antisymmetric laminate with a single mouse click.

Figure 4 shows a sample laminate definition. It is a sandwich laminate with $[0/(\pm30)_2]$ facesheets. The entire laminate is defined as Symmetric Odd (SO), which means that it is symmetric about the midplane of the core. The form shows the total number of plies (n), the total thickness (h), and the mass per unit area (m/A).

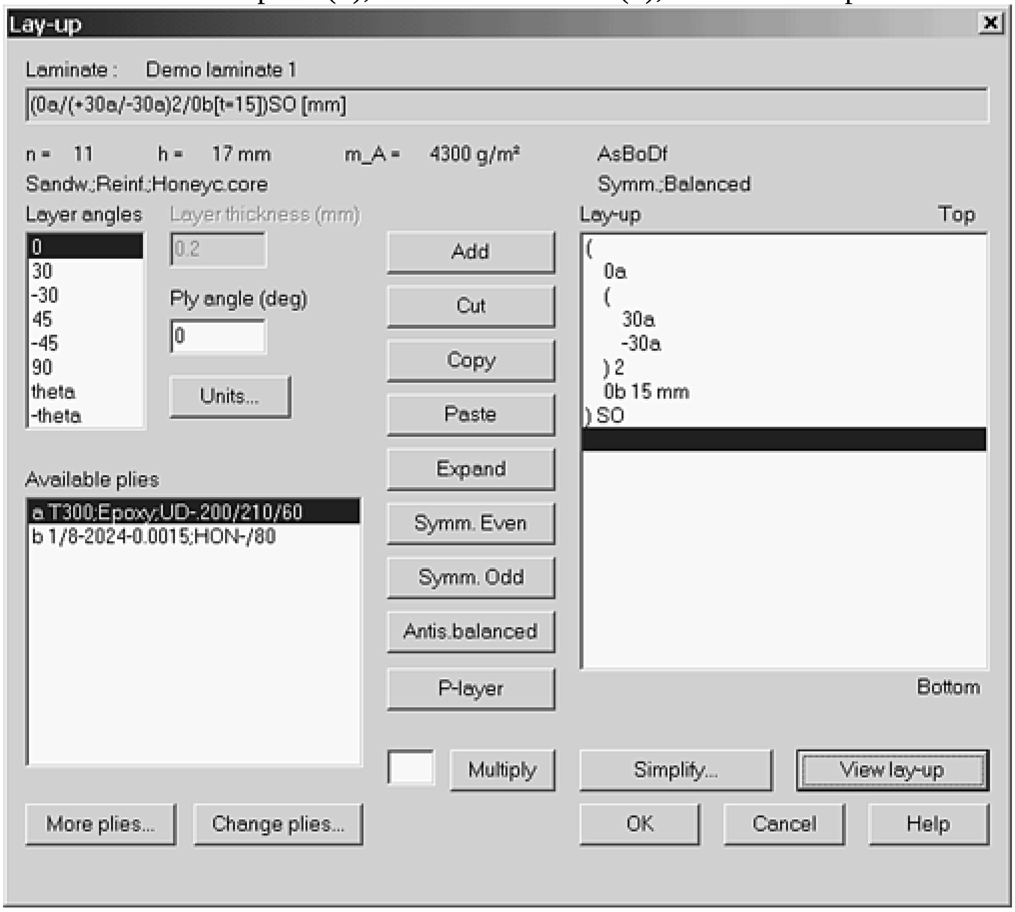

Fig. 4 Example of a laminate definition in the ESAComp software program

The basic laminate analysis is similar to the ply analysis, except that laminate properties are displayed. Multiple angles and multiple laminates can be analyzed at once. Results include the standard constants and matrices, plus normalized matrices, out-of-plane shear stiffnesses, layer (individual ply) properties, free-edge-effect estimates, and sandwich facesheet properties (if appropriate). Figure 5 shows a typical multiple analysis. In this case, two laminates are compared at four different angles. The longitudinal laminate modulus is plotted and tabulated for each laminate at each angle.

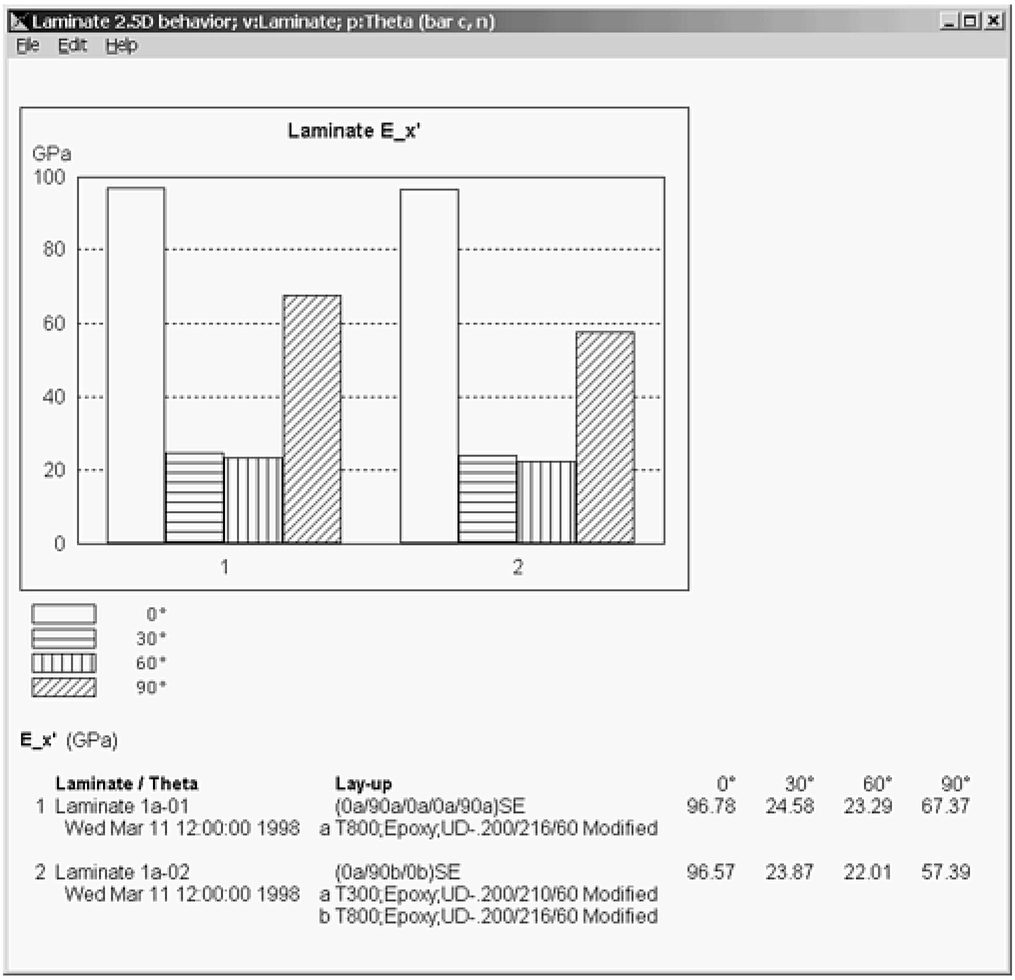

Fig. 5 Example of multi-laminate analysis in the ESAComp software program

Strength analyses can be either FPF or degraded laminate failure (DLF), sometimes called last ply or ultimate failure. Strength results can be generated for a single laminate or for multiple laminates. Comparison results are plotted and tabulated for one property at a time. Failure envelope graphs show the failure region for a combination of any two load components and can be plotted for FPF, DLF, or both. The load types are the same as are available for load definitions (described later in this section). The plots can be generated for the entire laminate, for each layer, for a range of loads in one direction, or for multiple failure criteria.

If loads are defined, load-response results can be generated. Loads are stored in the database along with the case. They can be entered as forces and moments, normalized stresses, forces with zero curvature, or strains and curvatures. Loads can include external (physical) loads, temperature loads (constant through thickness or top and bottom surface temperatures), and moisture loads (constant or variable, as with temperatures). Tabulated and plotted load responses include layer stresses, layer strains, and margins of safety. Results can be generated for multiple laminates, multiple loads, and angle ranges.

Materials and laminates are never perfect, so ESAComp provides two types of sensitivity studies. The first shows the sensitivity of laminate properties to changes in ply properties. One ply property, such as E_1, is selected for the study and a ± tolerance is specified. Nominal, maximum, and minimum laminate properties (engineering constants, thermal and moisture constants, or strengths) are then tabulated and plotted. The second study shows the sensitivity to layer orientations. An orientation tolerance is entered for each ply (each can have a different tolerance); nominal, maximum, and minimum properties are then shown as for the ply properties study.

The laminate analysis includes three specialized solutions: notched laminate, layer drop-off, and free-edge stresses. The notched laminate solution can use either a defined load or a load ratio; notches can be circular or elliptical. The layer drop-off solver shows stresses where a ply is dropped from the middle of a laminate. Finally, the free-edge analysis is performed using a built-in finite-element solver and shows layer stresses at the free edge of a laminate.

Finally, laminate properties can be output to any one of five finite-element programs (ABAQUS, ANSYS, ASKA, I-DEAS, and MSC/ NASTRAN). Output consists of a material definition in the appropriate input deck

format. For example, the NASTRAN output is a PCOMP or PSHELL definition, and the I-DEAS output is a Universal File.

Design Features. ESAComp has several features to aid in the design and optimization of laminates. The easiest to use are the multiple- analysis options, described previously in the sections on materials, plies, and laminates.

Two special types of laminates can be defined: θ-laminates and *p*-laminates. Theta-laminates can have any number of plies specified as a variable angle, or "θ." In other words, θ-laminates define a family of laminates, such as $[0/\pm\theta / 90]_S$. When running a basic laminate analysis, θ is automatically varied over a range, similar to a multiple-angle analysis.

For *p*-laminates, the total thickness of the laminate is assumed to stay constant, but the proportion of layers defined as *p*-layers is varied over a range. For example, if the nominal thickness of a $[0P/\pm30]_T$ laminate is 0.015 in. (each ply with a thickness of 0.005 in.), a *p*-laminate study might set the 0° ply thickness to (0, 0.005, 0.010, 0.015). The corresponding thicknesses of the 30° layers would then be (0.0075, 0.005, 0.0025, 0). The basic laminate analysis then shows results over the range of *p*-values.

User Extensions. Although ESAComp does not emphasize program customization, interfaces are provided for extensive customization of the program. As described earlier, all results displays are created using a macro language. The macro files are in plain text format, allowing the macros for all built-in results to be used as examples (though they should not be modified). The macro language is capable of displaying any numerical result generated by ESAComp and of creating line, bar, and polar plots of the results. Simple calculations can also be performed. Users can therefore customize the look of the results displays, combine results in ways not offered by the built-in macros, and even generate new results. The language is not fully documented, but the help file provides a fairly complex example of custom macro for combining the results from a basic laminate analysis and an FPF analysis.

For more complex analyses, user-defined procedures can be added. Procedures are written in the C Language Integrated Production System (CLIPS) designed at NASA/Johnson (National Aeronautics and Space Administration). Although few users are likely to be familiar with this language, the syntax seems rather simple. CLIPS documentation is available from a NASA Web site. The help file includes an example procedure that adds a failure criterion to the program. Although users could create other procedures by following this example, the lack of documentation specific to the ESAComp constructs would make this a difficult task. The next release is supposed to improve upon user extensions: if it does, this will become a much more useful feature.

V-Lab

A major shortcoming of most composite analysis programs is that they cannot perform all calculations. If the program does not support a type of analysis or specific theory, the only option is to use another program. With each program, though, comes the overhead of basic calculations such as laminate properties. If the analysis is highly specialized, it may not be available in a commercial package, forcing the user to write a customized program. To avoid the effort of developing an entire laminate program, it is common to export basic laminate properties (such as constitutive matrices) from a commercial package and import them into the user-written program.

V-Lab attempts to overcome this limitation by providing an interface for user-written calculations (called modules or Labs). The program ships with three Labs that provide standard functionality: ply or material analysis, laminate analysis, and bonded joint analysis. A Developer's Kit provides database documentation and an API, allowing the addition of user-created Labs. Unlike ESAComp, which mentions extensibility almost as an afterthought, V-Lab emphasizes user extensions as a selling point.

The program runs under Windows and has an Outlook-style MDI. The main program menu gives access to the Labs, program settings, and standard Windows functions. A simple toolbar provides open, save, print, and help functions, plus a switch between English and SI units. An Outlook-style icon bar on the left shows icons for each of the Labs. Each Lab has its own form; individual analyses are accessed through a tabbed interface on the Lab form. A report can be printed for each form showing any tabulated data and plots. Reports cover only the active tab and the active plot: several reports must be printed to cover all analyses in a Lab.

Full documentation is available in the on-line help files, with links to the appropriate sections from each form. The help files include theoretical overviews, but lack details of the specific implementations.

Databases are central to the functioning of V- Lab. The program supports multiple databases, but only a single database can be active or accessible at any one time. Each database stores both material properties and laminate definitions.

The view of a material within the database is called a data sheet. Although materials are classified by type (fiber, matrix, composite, coating, or isotropic), all data sheets hold the same set of properties. Each material can have multiple data sheets, representing properties at different temperature and moisture conditions, and the program can even create new data sheets by interpolating between existing environmental data sets.

V-Lab comes with two databases. The Sample database has a small number of materials and laminates, mainly for use in demonstrating V- Lab features. Of more use is the MIL-17 database. This database contains most (but not all) of the carbon composite properties from revision E of the handbook; it contains none of the glass, quartz, or other composite properties. Care must be taken when using the MIL-17 properties: the data sheets show normalized mean values, even when B-basis allowables are available. The MIL-17 file ships as a read-only database, but the data can be included in new databases by selecting an option in the New Session dialog.

Figure 6 shows a typical material datasheet from the MIL-17 database. The tabs across the bottom of the datasheet show that properties are defined at three or more temperature and moisture conditions. The MIL-17 properties have been imported into a new analysis, making them available for editing. Properties not already defined can be added to the datasheet, as shown in the Select Properties to Add window.

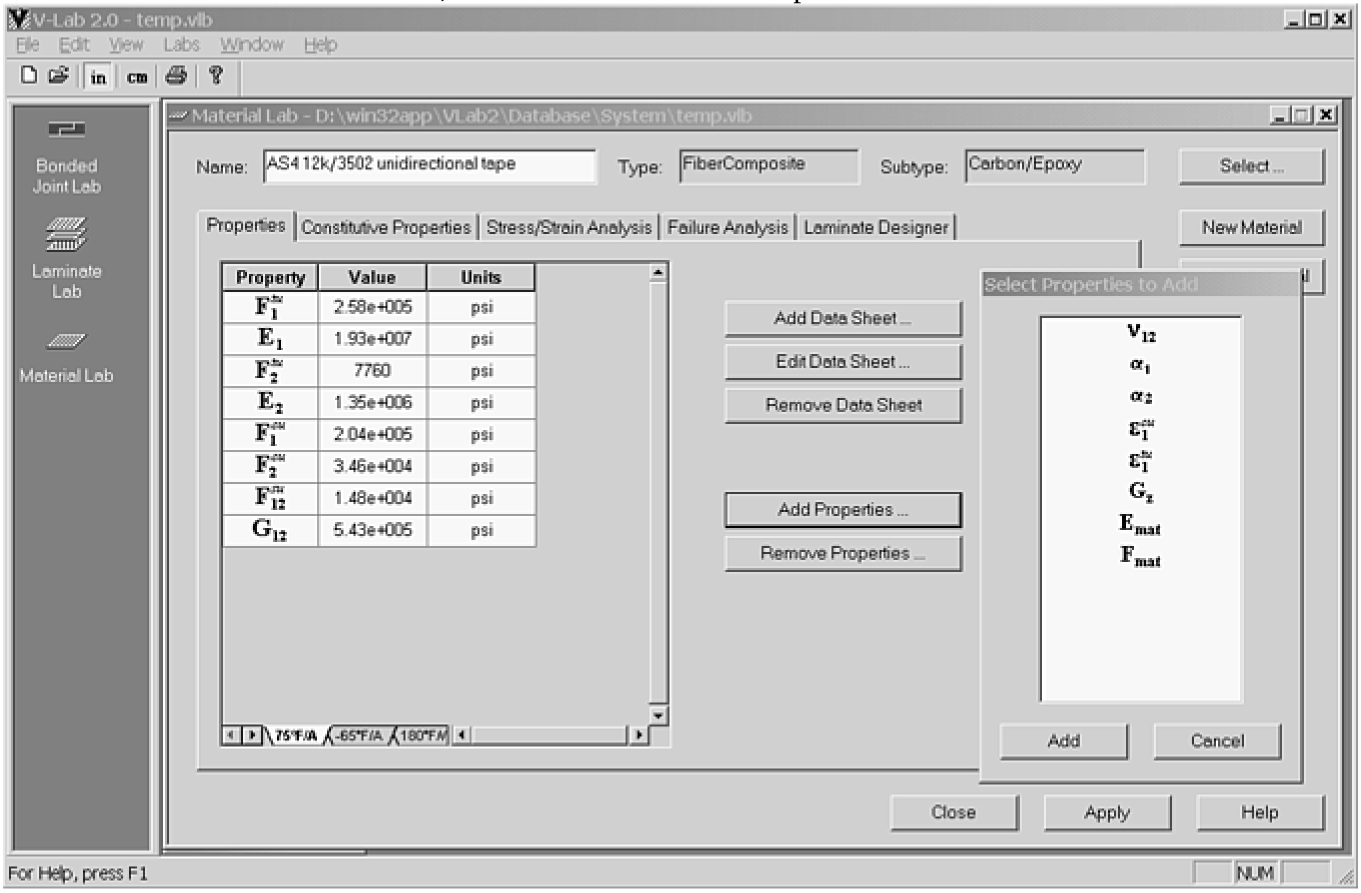

Fig. 6 Example of a material datasheet in the V-Lab software program

Material Lab. Although the V-Lab database defines categories for fibers and matrices, the program provides no micromechanics capabilities. The name of this Lab is a bit misleading: it is more for lamina analysis than for material analysis.

The Material Lab is used for creating or editing material data sheets, calculating constitutive properties (stiffness or compliance matrices), calculating strains from stresses or stresses from strains, performing a failure analysis (maximum stress, maximum strain, or Tsai-Wu), and generating carpet plots.

All analyses are performed on a single, unidirectional ply. The ply orientation can be rotated arbitrarily, but results cannot be plotted or tabulated versus ply angle. Carpet plots are generated for 0/90/±45 laminates only; properties that can be plotted are Young's modulus (E_{11} only), Poisson's ratio, shear modulus, thermal expansion coefficient, and open-hole tensile and compressive strength.

A major deficiency of many V-Lab analyses is a lack of numerical results. For example, the constitutive properties tab shows only stiffness and compliance matrices, not engineering constants. Also, the failure analysis tab provides only a qualitative result: the failure envelope is plotted in a graphics window, and the point- stress location is drawn in relation to that envelope. If the point is green, the applied loads are below the failure loads. If the point is red, the applied loads are above the failure loads. No stress ratios, safety factors, or margins are shown, nor are they available in any reports or printouts.

The Laminate Lab is used to calculate laminate properties, perform point-stress analysis, run moisture-diffusion calculations, estimate free-edge effects, and determine strains in a plate with a hole.

Analysis starts with definition of the lay-up. Plies are entered in a grid, with buttons for adding and removing layers, and moving layers up and down in the sequence. Layers can only be added in the last row: there is no insert function. Laminate types include Symmetric, Antisymmetric, Symmetric/Midply, and Total. Stacking sequences can be stored in the database. Surprisingly, the database categorizes laminates differently than the definition form, allowing Any, Angle-Ply, Cross-Ply, and General.

Constitutive properties are given as **ABD** or $\mathbf{ABD}^{-1}$ matrices only: laminate engineering constants are available nowhere in the program. Furthermore, laminate thermal and moisture expansion properties are not shown at all, either as matrices or as engineering constants.

As in the Material Lab, stress, strain, and failure results are only shown graphically. Loads are input as stress and bending resultants or as laminate strains. Failure analysis results are shown using the same type of plot as in the Material Lab. As seen in Fig. 7, only one stress component can be viewed at a time. The thick horizontal line shows the location of the failure criterion calculation, plotted in the graph to the right. The box in the failure plot represents the failure envelope; the sphere represents the calculation point. In this particular case the ball is green, indicating no failure, even though it appears to be outside the envelope. The envelope plot indicates failure for these loads if the calculation line is moved up one more increment in the line chart. The lack of numerical results for laminate constitutive properties and stress/strain analyses, or even a quick "yes-no" flag for an entire laminate, severely limits the usefulness of V-Lab in engineering applications, where these numbers are usually required.

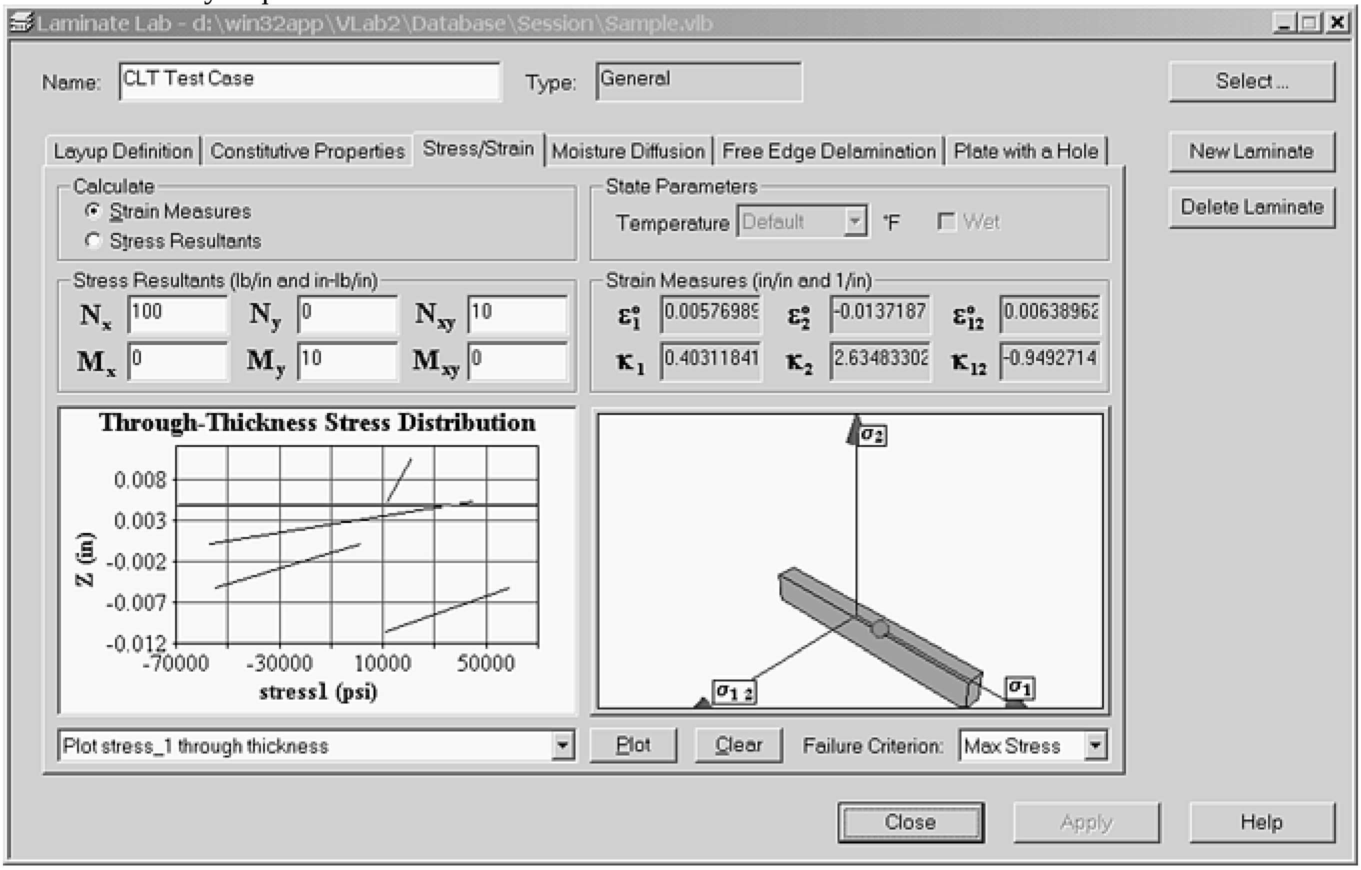

Fig. 7 Example of a stress analysis and failure plot in the V-Lab software program

The moisture diffusion solution can be a useful tool for examining environmental effects. It depends on the laminate definition only for total thickness. Given an initial condition, a boundary condition (expressed as

percent moisture concentration) and a laminate diffusivity, this module plots either a through-thickness moisture concentration profile or an average mass gain versus time curve.

The free-edge delamination module calculates the strain energy release rate (*G* value) for a crack extending from the free edge of a laminate. Inputs consist of a temperature change and an applied strain. Five different *G* values can be calculated (strain energy, virtual work, I, II, III). Results are shown in a bar graph, with one bar for each ply. Again, numerical results are not available, and no assistance is given in interpreting the results.

Finally, the Laminate Lab provides a module for calculating maximum strains in a plate with a hole. Input consists of the hole diameter, stress and bending resultants (which are independent of the stress/strain analysis), and optional bolt loads. The results are presented as maximum compressive and tensile strains and minimum margin of safety. Unlike the other analyses, this one gives a numerical result.

The Bonded Joint Lab shows the potential for the wide range of analyses that can potentially be performed with V-Lab. The Material and Laminate Labs provide the standard capabilities of a composites program; the Joint Lab is an added analysis type.

Using the Joint Lab can be a bit confusing and so is one case where it pays to first read the Help file. The analysis starts by defining joint materials. The module can examine composite-to- composite or composite-to-metal joints. For composite-to-composite joints, the parent material and the patch material must be the same (to simplify the terminology, all joints are treated as repairs). The laminate consists of 0°, 90°, and off-axis (user-defined angle) layers. All layers can be the same material, or each set of angles can be a different material. The laminate definitions are not linked at all to the Laminate Lab or the laminate database (but the database can store joint definitions).

The Lab supports only one joint geometry: a stepped double-lap joint, which is similar to a scarf joint. Steps are entered into a table. Each step definition consists of the number of 0°, 90°, and off-axis plies. The parent laminate and repair section can have a different number of layers of each angle in each step. Step lengths are defined in the parent laminate table.

Once the joint is fully defined, two analyses can be performed: joint strength analysis and applied loads analysis. The strength analysis view shows the allowables in each step plus the amount of the load carried by the repair. Results are given for axial loads and shear loads, with the joint loaded in either tension or compression. A factor of safety and a uniform temperature change can be specified. Three failure criteria are used to determine the strengths, as outlined in the Help file. The program will reset the step lengths during the strength analysis to meet minimum length requirements, but the criteria for setting minimum length are not given. With the allowables determined, the applied loads analysis calculates the margin of safety, critical step, and critical section (parent, adhesive, or patch) for a specified load expressed as axial and shear stress resultants.

Program Customization. One of the most appealing features of V-Lab is its expandability. The application programmer's interface (API) gives users access to the database, to the functions within existing Labs, and to V-Lab's user interface. If V-Lab does not provide a needed function or analysis type, users should be able to add their own routines without worrying about the standard overhead functions.

End users add functions through a Developer's Kit. The Kit includes definitions of the API functions and necessary header files for writing Labs. The calculation portion of user Labs can be contained in a dynamic link library (DLL). Any language that supports compilation to a DLL can be used, or existing DLLs from other programs or libraries can be reused. The actual interface to V-Lab must be handled through C++. This can make adding interfaces somewhat difficult because C++ is not an easy language to learn. The source file for a sample Lab that simply displays the current units in a window takes up 7K or 235 lines of code.

Unfortunately, after more than one year since the release of V-Lab, the Developer's Kit has not yet been made available. No schedule has been set for its release, and no pricing has been set.

Other Programs

The programs reviewed above— CompositePro, ESAComp, and V-Lab—are only three of the many available. These three are the main comprehensive programs in use. Sometimes, though, a simpler program will do, or a specialized analysis must be performed. In that case, one of the programs listed in this section may provide an appropriate solution.

ASCA ASCA is a commercial Windows program published by AdTech System Research. Limited information about the program is available from http://www.adtechsystems.com/asca.html. The Web site also describes some additional programs available from AdTech.

ASCA has three modules: Composite Laminate Analysis (CLA), Free Edge Stress Analysis (FESA), and Transverse Crack Analysis (ALTRAC). The program includes a lamina material database system. The CLA module supports hygrothermoelastic point-stress analysis of laminates. Results can be viewed in tabular or graphical format.

CADEC is a program to accompany *Introduction to Composite Materials Design* (Ref 3). The license requires the user to own the textbook or to use it in a university course (either as an instructor or a student). The program runs on Windows systems. It may be downloaded from http:/ /www.cemr.wvu.edu/~ejb/cadec.html.

Although organized around the book, the program can be used on its own. Calculations are divided into five chapters: micromechanics, ply mechanics, macromechanics, failure theory, and thin-walled beams. Each chapter has a contents page with links to individual calculation pages. In general, each calculation page carries out a single calculation. For example, the micromechanics chapter has 22 calculation pages, each covering a single material property. Alternate theories are covered on different pages: E_2 can be calculated using the rule of mixtures or Halpin-Tsai theory, but the results cannot be viewed simultaneously.

Because the program is meant to be a teaching tool, applicable formulas are shown on each page. In the case of E_2 mentioned above, the Halpin-Tsai formula is shown next to the calculations. Many pages also have graphs that are automatically generated. Most micromechanics pages, for example, plot the property versus fiber volume fraction.

Material properties and laminate definitions can be stored in files for later use. Properties generated from micromechanics analyses can be stored as ply materials. All ply and laminate constants, matrices, and results (stresses and strains) can be printed and plotted. The thin-walled beam chapter can handle arbitrarily shaped cross sections.

Help is available on a per-page basis—the entire help file cannot be browsed. The help tends to be terse, with many references to the textbook. In some cases, such as the thin-walled beam definition, reference to the text would be necessary in order to use the program.

CoDA is a commercial, modular program from the National Physical Laboratory (NPL) in Teddington, United Kingdom. Modules can be purchased and run separately or in any combination. CoDA runs under Windows 3.1 or higher. A multimedia demonstration file may be downloaded from http://www.anaglyph.co.uk/coda.htm.

The program consists of four modules: Material Synthesizer, Laminate, Panel, and Beam. The Material Synthesizer module performs full three-dimensional micromechanics calculations for unidirectional, random, continuous, and discontinuous fiber composites. Elastic, temperature, and moisture constants are calculated. Resulting ply properties can be used in the other modules.

The Laminate module is used to determine elastic, hygrothermal, and strength properties of laminated panels. The Panel module is used for the analysis of rectangular and circular panels under load. Panels are of arbitrary lay-up and may include rib stiffeners. The supported load types are point, line, and pressure. Results include stresses, deflections, and creep behavior. The Beam module is similar to the Panel module and supports several standard cross sections, load types, and boundary conditions.

COMPASS is a specialized program developed by The George Washington University and NASA Goddard. Executable binaries are freely available for HP, IBM, Sun, and SGI UNIX systems. The binaries and the User's Manual can be downloaded from http://mscweb.gsfc.nasa.gov/ 543web/compass/compass.html.

COMPASS performs a three-dimensional failure analysis of composite laminates. It uses a finite-element solution based on eight-node solid isoparametric elements. Layers may be composed of fiber reinforced composites or isotropic materials. Two solution approaches are available: (1) a nonlinear progressive failure analysis using the Von Mises criterion for isotropic plies and the Hashin criterion for composite plies and (2) delamination growth analysis using Griffith's criterion for the fracture mechanics approach.

ESDU International. Unlike the other products reviewed here, ESDU does not provide a single software package, but collections of engineering design data, methods, and software. The information is packaged in more than 1200 design guides that are grouped by Series. Most of the Series are related to mechanical and aerospace engineering. In addition to composites, other Series topics include dynamics, mechanisms, structures, and acoustics.

Each Series is further divided into Volumes, and Volumes are subdivided into Data Items. Each Data Item contains documentation in PDF format, FORTRAN source code for the calculations described in the document,

a compiled DOS executable, and sample input and output files. The PDF documents provide the full theory for the Data Item, not just a description of the program. Thus, the Data Items also make a good basic reference.

The ESDU Web site at http://www.esdu.com provides a full listing of all Series, Volumes, and Data Items. Abstracts for each Data Item can be viewed at no charge; subscribers can download Data Items after logging in.

The Composites Series contains seven Volumes with 38 Data Items. Topics covered include basic laminate analysis, buckling of balanced and unbalanced plates, bonded joints, failure criteria, damping and acoustic loading, and natural vibration. Many special cases are covered, such as plates with holes, through-thickness shear stiffness, sandwich panels, edge delamination, and more.

The Laminator is a Windows shareware program for calculating laminate properties and performing point-stress analyses. It is available for download from http://tni.net/~mlindell/laminator.html.

The Laminator is a simple program, which makes it the right choice for a quick laminate analysis. Ply properties (engineering constants, thermal and moisture expansion coefficients, and strengths) are entered in a simple table. Up to ten properties may be stored in a file. The laminate is likewise entered in a table, with arbitrary materials, angles, and thicknesses for each ply. Loads include mechanical (forces and moments or strains and curvatures), temperature, and moisture components. Results are displayed in a plain text file and include all constants, matrices, stresses, strains, and load factors.

LAP is a commercial program from anaglyph Ltd., running on Windows 95 or higher. A program overview and a multimedia demo are available at http://www.anaglyph.co.uk/lap.htm.

LAP is used to perform point-stress analysis on laminates. It includes a database for storing ply properties and laminate definitions. Full hygrothermoelastic load conditions and results are supported, including residual curing strains. Two unique features of the program are calculation of the effects of deviation from nominal fiber volume and stiffness reduction factors based on layer failure. In the latter case, an iterative solution is used to give a nonlinear laminate stiffness response past the failure point. In addition to tabular and graphical output, interfaces are provided for export to text files, CoDA, and NASTRAN.

PROMAL. Like CADEC, PROMAL is a teaching program. It accompanies *Mechanics of Composite Materials* (Ref 4). PROMAL is distributed with the textbook, or course licenses are available directly from the author. Information about the book and the program can be found at http://www.eng.usf.edu/~kaw/promal/ book.html.

PROMAL includes five separate programs, accessible from the master menu. The first program is a matrix calculator, mainly intended to aid in solving homework problems. The second is a database for holding lamina properties. Up to 100 materials are supported. Properties include engineering constants, lamina thickness, strengths, and thermal and moisture expansion coefficients. The third program is simply a utility for fixing database problems.

The fourth program performs micromechanical analyses. Elastic and hygrothermal properties are calculated; properties can be plotted against fiber volume fraction. The fifth and sixth programs perform macromechanical analyses of laminas and laminates, respectively. Results include all laminate constants, matrices, stresses, strains, and failure envelopes, in both tabular and graphical format.

SACL. The Stanford Structures and Composites Lab maintains a large collection of programs related to composites and structures. A full list of the programs, as well as contact information for the collections, is available from http://structure.stanford.edu/CodeDesc.html.

The general areas covered by the programs are Manufacturing, Impact, Joints, Delamination, Design, Smart Structures, and Environment. Most programs are distributed as FORTRAN 77 source code. A few are available in other languages or as Macintosh executables.

The Think Composites software package, developed by Dr. Stephen Tsai, includes the Mic- Mac spreadsheet, GenLam, and LamRank. Information about the package, plus a “lite” version of Mic-Mac, is available from http:// www.thinkComp.com. That site also includes a downloadable version of *Theory of Composites Design* (Ref 5) in PDF format. Documentation for the Think Composites software is in the textbook.

Mic-Mac is a Microsoft Excel spreadsheet for performing point-stress laminate analysis. The spreadsheet is not protected, allowing it to be modified for additional calculations, but the lack of program documentation makes customization difficult. GenLam is a simple program for point- stress analysis, using simple text files as a database and for input. Finally, LamRank is a laminate-optimization program using the ranking method.

Computer Programs

Barry J. Berenberg, Caldera Composites

Internet Resources

Over the past few years, the Internet has become an invaluable source of both business and technical information. Its usefulness spans many industries, including composites. Within the composites industry, the Internet can be used for obtaining material data sheets, locating a manufacturer, and even researching and purchasing software.

On-line Programs

A few Web sites have started offering on-line programs. These are run directly from the remote site, usually as a Java applet. Although the current programs are of limited functionality, more capable programs should be expected in the future as the offerings of application service providers (ASPs) increases. Even now, major engineering tools such as Alibre Design (Ref 6) for three-dimensional computer-aided design (CAD) and e.VisualNastran 4D (Ref 7) for finite- element analysis are offered on-line on a subscription basis.

Classical Laminate Theory with Java (http://mlbf01.fbm.hs-bremen.de/java/applets/javalam.html). This is a little Java applet that calculates laminate stiffnesses, laminate strains, and ply stresses. Ply properties are calculated from a selection of five fibers and three matrices. Laminates can contain up to 20 plies. Loads are entered as stress and bending resultants, plus change in temperature. Results are printed in a tabular format. The program is very simple, with a promise of future extensions. A more powerful stand-alone version is available for download.

Think Composites (http://www.thinkComp.com). Dr. Stephen Tsai offers an on-line, interactive tutorial covering stress, strain, and ply properties transformations; failure criteria for plies and laminates; and laminated plate theory. There are 18 pages in all, each with a brief discussion of a single topic; some pages include a Java applet to demonstrate the principles. The Java applets run in the main browser window, so they cannot be viewed simultaneously with the text. The applets range from a Mohr's circle calculator to a laminate calculator showing constitutive matrices, engineering constants and failure envelopes (limited to the 11 materials from *Theory of Composites Design* and a four-θ laminate family). The site also offers *Theory of Composites Design* in PDF format, plus the lite version of the Mic-Mac spreadsheet. Free registration is required.

The University of Delaware's Center for Composite Materials (http://www.ccm.udel.edu/) offers eight on-line programs for analysis and learning. The programs are written in Java and are provided through an ASP server; the learning modules require Shockwave. The topics covered by the programs are composite properties analysis, preform properties analysis, cure-cycle design, mold-filling design, permeability analysis and laminate properties analysis. Each module has a descriptive overview, a theoretical overview with references and an applet. The modules load and run fairly quickly. Results are displayed in tabular or graphical format. A limited on-line database of material properties is available for each module, or users can enter their own properties. Inputs cannot be saved.

On-Line Resources

Software no longer has to be ordered through print catalogs; most publishers offer direct on- line sales. Some third-party sites offer downloads of engineering freeware, shareware, and demo programs; others provide

summary or detailed reviews and categorized links to program home pages. A few on-line stores specialize in engineering and even composite programs. Some of the more useful sites are:

- About Composite Materials (http://composite.about.com/cs/software/): Comprehensive listing of composite and related engineering programs with links to publisher home pages and brief reviews. Offers detailed reviews of some programs.
- ASME Engineering Software Database (http:/ /www.mecheng.asme.org): A large collection of engineering shareware and freeware. Browse by category or search by keyword.
- E-Composites.com (http://www.e-composites.com/software_store.htm): On-line composite software store divided into two categories: Analysis and Design, and Manufacturing.
- ER-Online (http://www.er-online.co.uk/software.htm) Brief reviews of engineering programs with links to publisher home pages.
- Lycos Directory, Software for Engineering (http://dir.lycos.com/Science/Technology/ Software_for_Engineering/): Links to engineering software companies and download pages organized by category.
- NetComposites (http://www.netcomposites.com): On-line composite software and bookstore. Offers brief reviews of software and international ordering.
- Sector Systems Company (http://www.marblehead.com/business/034/mech.htm): CD-ROM of mechanical engineering shareware. On-line listing of programs only; no downloads.
- Simtel.net (http://www.simtel.net/simtel.net/ win95/engin.html): Engineering section of this large, general archive.
- Softseek.com (http://www.softseek.com/Education_and_Science/Science_and_Engineering/): Engineering and science section of this large, general archive.

Testing and Analysis Correlation

Adam J. Sawicki, The Boeing Company

Introduction

COMPOSITE STRUCTURAL STRENGTH is primarily driven by various forms of discontinuities. During design development, rigorous analyses are needed to predict load distribution and local stress concentrations. Many of the same structural details that cause fatigue concerns with metals require ultimate strength assessment for composites (e.g., cutouts and attachments). Finite element models with sufficient mesh refinement may be needed to predict composite stress concentrations, and reliable failure criteria must be in place for accurate sizing. Ideally, the latter should accurately predict the failure level and dominant failure mechanisms.

Many past composite design allowables approaches have used tension and compression data from uniaxially loaded small-notch coupons (e.g., open hole compression and filled hole tension) to write margins of safety for points in a structure. These approaches are only rigorously applicable to small notches in near-uniform stress fields. Alternative sizing methods, involving design values derived from analysis and test correlation, are likely needed for combined stress states and stress concentrations associated with local structural detail or significant damage. For example, test results have shown that the allowed local stresses near an access hole will likely exceed those for near-uniform stress fields. The associated concentrated stress fields for an access hole can result in localized damage formation and material softening without catastrophic failure.

Composite materials have complicated failure mechanisms; strain softening behavior is often involved in the local failure process. Accurate prediction of composite structural detail strength requires a detailed understanding of the significant failure mechanisms. For example, efforts to model composite interlaminar stresses, progressive damage growth, and other nonlinear effects require advanced modeling tools and accurate structural representation. It is typically not enough to develop good correlation for small coupons. Advanced analyses must be correlated with sub-component-level tests before they can be considered validated.

Detailed analyses and test correlations are typically required to support design development, structural sizing, and certification. The supporting test program should focus on design details, load cases, environmental conditions, damage types, and damage locations judged to be most critical or difficult to analyze. The test results should be used to scrutinize analytical predictions of deflections and strains up to and including the point of failure, as well as the actual failure sequence and mode. For most purposes, sufficient analytical validation is not achieved by merely obtaining test results that are greater than the required design load.

Critical local details (e.g., cutout, pad-up lay- ups, mechanical attachment areas, curved laminate radii, transversely loaded stiffener details, and post-buckled panels) should be evaluated at test scales large enough to address structural load paths and specific processes and material forms early in a program. The sizing analysis tools should be updated as required based on these test results. This approach should help support the design by eliminating “poor structural details” that could result in expensive, premature full- scale test failures.

The best available analyses should be performed to support definition of the test plan (e.g., loading sequence, gage placement, and instrumentation). Some differences between configured subcomponent test data and pretest predictions are likely. Possible sources of differences may occur near panel boundaries (load introduction points and edge effects), joints, damage, and other areas of load redistribution. It is important to understand these differences to:

- Ensure sufficient testing is performed to overcome analysis limitations
- Improve structural analysis schemes
- Develop scaling relationships with building block test results
- Ensure structural test parts have sufficient gage section
- Improve failure mode resolution and failure criteria accuracy

Final analysis schemes for configured composite structure should be aimed at predicting specific failure modes. For example, analytical methods should be able to distinguish between the following bolted-joint failure modes:

net section, shear-out, end splitting, or pure bearing (compression). The methods development process is likely to involve several test and analysis iterations.

Testing and Analysis Correlation

Adam J. Sawicki, The Boeing Company

The “Building Block” Approach to Structural Qualification

In the design of aerospace composite structures, “building block” qualification programs are frequently conducted to verify the capability of the structure under design loads. This method utilizes a combination of tests and supporting analyses to minimize developmental risk, cost, and weight. A fundamental understanding of the purpose of the various levels of a building block program, along with the type and complexity of analyses used in interpreting test data at the various levels, is critical in achieving risk mitigation and cost minimization objectives.

Figure 1 presents a simplified overview of the building block method of structural qualification (Ref 1). The approach involves a testing sequence of progressively more complex structural coupons, elements, subcomponents, and so forth, throughout the design development process (Ref 2). Tests and supporting analyses of varying complexity are performed to fulfill four primary requirements:

- Generate strength and stiffness data to be used in structural analysis of the design
- Substantiate the load-carrying capability of the design
- Mitigate risk by testing specific design details prior to full-scale evaluation
- Verify accuracy of analysis predictions used in the design process

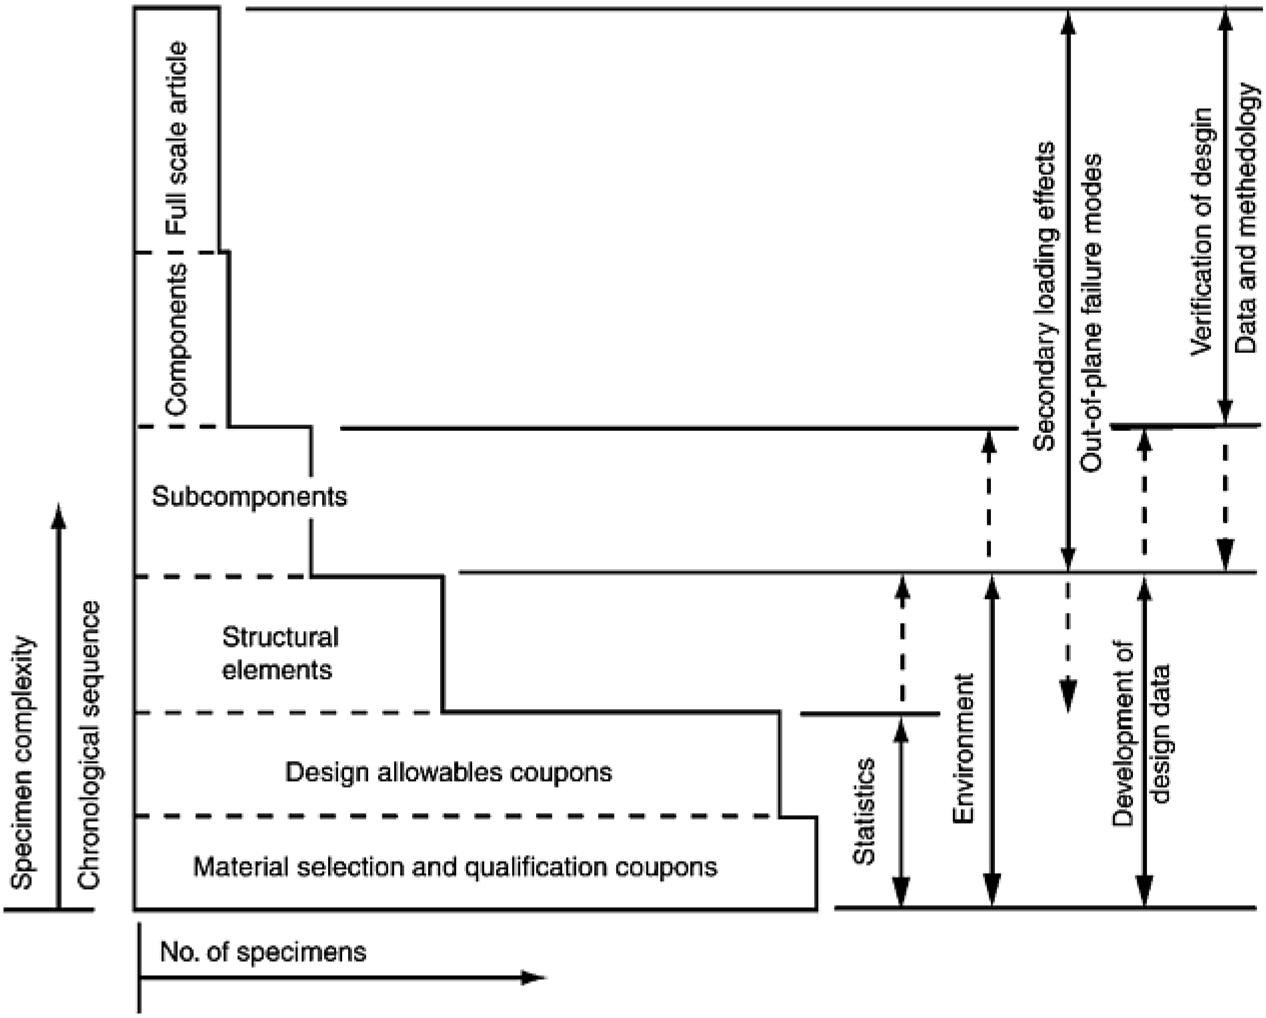

Fig. 1 Outline of the building-block methodology for qualification of composite structure. Source: Ref 1

Tests and Analyses Vary with Building Block Level. The types of tests performed at each of the levels vary due to the different requirements and issues addressed at each level of the building block plan. At the material qualification level, tests are conducted to establish strength and stiffness data, verify environmental resistance, and generate specifications for procurement and quality control. Test specimens are primarily small coupons (notched and unnotched) with limited variation in lay-up (typically unidirectional, 0°; cross-ply, ±45°; and limited multidirectional lay-ups). Consequently, supporting analysis is generally limited to strength and stiffness calculation, along with general sizing analysis to promote the onset of a desired mode of failure.

At the other extreme of the building block plan, components and full scale articles are used to verify load distribution predictions (typically generated using a global finite element analysis), demonstrate load-carrying capability under a variety of design conditions, and assess failure modes for complex structures. Specimen boundary and load introduction conditions are more representative of the actual structure than in lower-level tests. The level of complexity permits incorporation of representative details (shear clips, cutouts, etc.) and thus allows examination of secondary loading effects. As verification of load path modeling is of primary importance, the effects of factors such as environment, damage, and defects are often not assessed at this level (Ref 1). It should be noted that tests performed at the structural element level and above produce data in support of a particular program or structure. Data produced in the material qualification and allowables phases are material related and are not, on their own, sufficient for structural qualification.

This article addresses issues concerning building block levels ranging from design-allowables coupons up through subcomponents, as these levels exhibit a wide variety of test-analysis correlation objectives. At these levels, enhanced analysis capability can be used most effectively in minimizing test complexity and cost while also reducing design weight and risk (Ref 3). Examples of tests for which good correlative capability has shown significant benefit are discussed. Additional information about the building-block approach is provided in the article "Overview of Testing and Certification" in this Volume.

Testing and Analysis Correlation

Adam J. Sawicki, The Boeing Company

Design Allowables Coupons

The primary purpose of tests conducted at the design allowables level is to generate strength data used for predicting the in-plane and out-of- plane strength capability of the structure. Consequently, analysis correlation work in this area centers on strength and failure-mode prediction. Examples of tests conducted at this level include notched (open and/or filled hole) tension and compression, inter/intralaminar shear and tension, and pin bearing. While many specimen details remain fairly generic, the lay-ups, stress concentrations, environmental effects, and failure modes tested are more representative of the actual structure than they are at the material qualification level.

Notched Laminate Strength Prediction Methods

The generation of notched strength allowables provides an excellent example of the benefits of good analytical correlation with test data. As these are generated as a generic design property, the data obtained must cover the envelope of permissible lay-ups utilized throughout the design. Unlike metals, little relief of the elastic stress concentration arising at an open or filled hole due to plastic deformation is observed in composites, resulting in a strong relationship between lay-up, failure mode, and associated strength (Ref 1, 2). An example of this is shown in Fig. 2, which exhibits the relationship between failure mode and the angle minus loaded (AML) plies laminate-configuration parameter (% ± 45° plies–% 0° plies) observed in open hole compression testing of several materials (Ref 4). Statistical testing across the complete laminate family to assess strength properties would be exorbitantly expensive. Therefore, an analytical method for relating strength to laminate-configuration is necessary to reduce the cost of generating these design data.

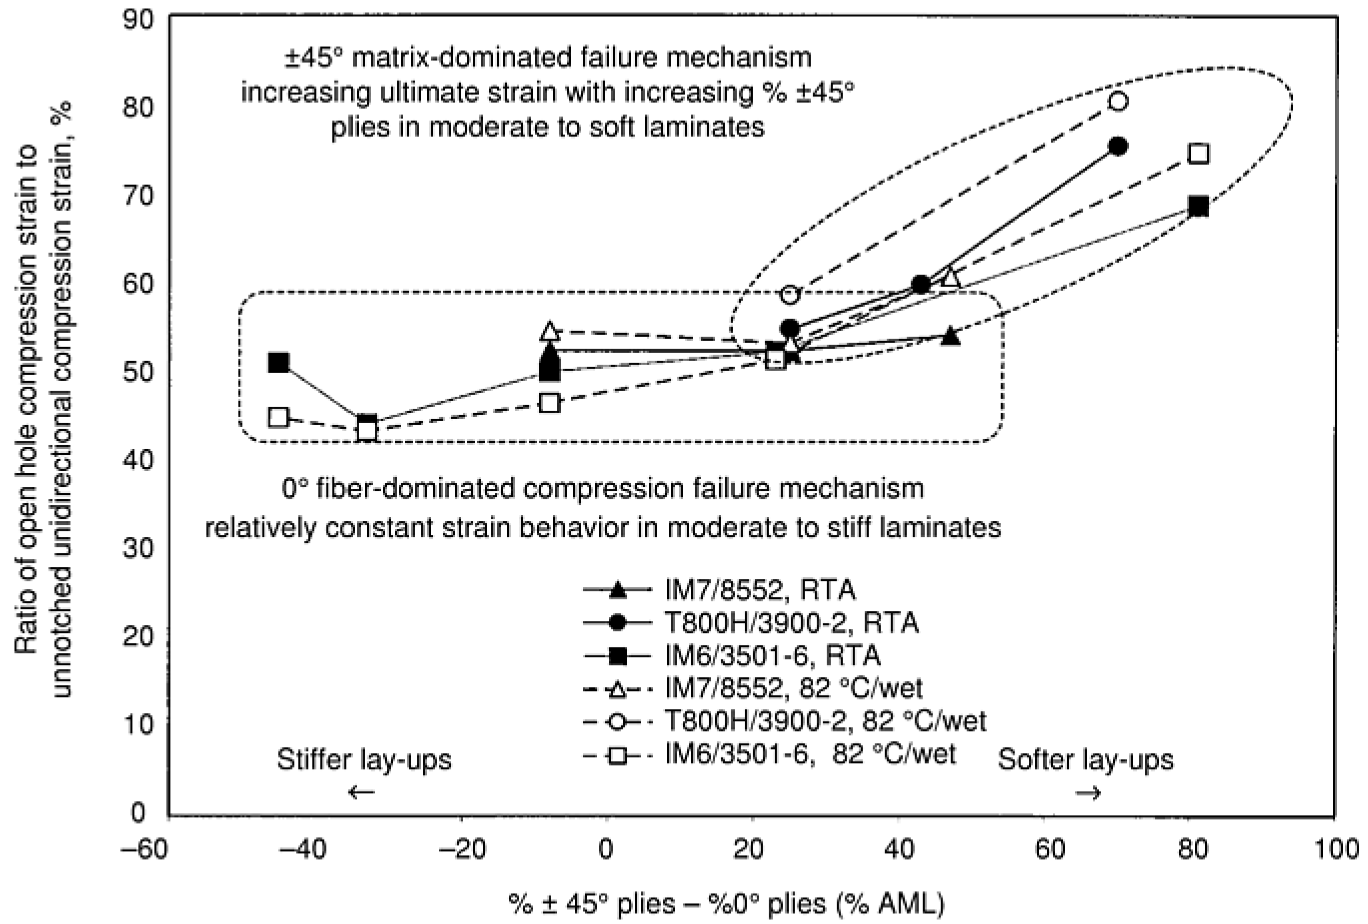

Fig. 2 Variation in failure modes for open hole compression specimens due to lay-up. RTA is Room Temperature ambient. Source: Ref 4

Stress and strain fields for notched anisotropic materials such as composite laminates can be determined using close-formed solutions such as those used by Lekhnitskii (Ref 5) or by finite element and finite difference techniques. Strength prediction is more complex due to the "hole-size effect," in which the ratio of notched to unnotched strength varies with hole diameter. This effect results from a number of factors, including greater localized stress gradients that promote stress-relieving subcritical damage formation near small holes, as well as the greater probability of defects and low strength material in the highly stressed region of a large hole (Ref 6).

Notched strength prediction has received much attention in the literature, and several predictive methods have been developed. Extensive reviews of models for predicting notched stress fields and strength for composites were documented in the mid-1980s by Crews (Ref 6), Curtis and Grant (Ref 7), and Awerbuch and Madhukar (Ref 8). Methods utilized up to that time included linear elastic fracture mechanics (Ref 9), two-parameter approaches including point and average stress criteria (Ref 10), and critical stress gradient (Ref 11). While successful in predicting the effect of hole size on strength for a given laminate configuration, such models are less effective in predicting the strength of lay- ups exhibiting significant stress-strain nonlinearity and subcritical damage formation.

Since the mid-1980s, additional notched strength predictive models utilizing progressive damage, finite element analysis (Ref 12, 13) and the spline variational technique (Ref 14) have been developed. These have utilized experimental data documenting subcritical damage formation to calibrate models for progressive damage formation and growth, as exemplified in Fig. 3 (Ref 13). Such models have been useful in predicting relationships between lay-up, failure mode, and far field failure strain semiempirically. Figure 4 shows an example of this provided by Bau (Ref 4), who used Chang's two- dimensional progressive damage methodology (Ref 12) to predict open hole compression failure of tape laminates.

Prediction of Strain Fields and Damage Formation

For notched laminates, test-analysis correlation is most frequently performed for prediction of strain fields and subcritical damage formation.

Strain Correlation. Localized strain data is most frequently obtained using strain gages; for notched coupons, axial strain gages are most commonly used. Gages are typically used in obtaining strain data local to the notch or hole at the location of peak axial stress concentration, in far-field locations, and in strain-gradient locations.

Gradients can also be assessed using photoelastic and shadow-moiré techniques, in which photoelastic sheets of material are bonded to the test specimen. As the specimen is strained, bands of differing color appear (as observed using an optical device). The bands correspond to the difference in principal strains within the specimen. An example of such an evaluation is Fig. 5, in which the shape and magnitude of photoelastic bands are compared to analysis predictions for the difference in principal strains in a uniaxially loaded coupon specimen containing a slit (Ref 15).

test result. (b) Computer-enhanced image of test result. (c) Analysis prediction for photoelastic patterns. Source: Ref 15

Test analysis correlation for local strains is influenced by several factors, among which are strain gradients, stress-strain nonlinearity, fastener-hole contact, and subcritical damage formation. Examples of how these factors influence test analysis correlation are provided by examining Fig. 6, which compares test data to finite-element-based predictions for strain at the edge of an open or filled hole under compressive loading (Ref 16). In strain fields with high gradients, correlation of predictions for specific strain levels with test data can be difficult due to the averaging effect of strain measurement under the area covered by the gage element. This accounts for the difference between measured and predicted strain seen in Fig. 6; despite the relatively small size of the gage element utilized in these experiments, there remains a finite distance from the hole over which strains are averaged in the gage measurement. Better correlation between predicted and measured strains can be achieved when the size of the elements used at the stress concentration approximates the size of the strain- gage element.

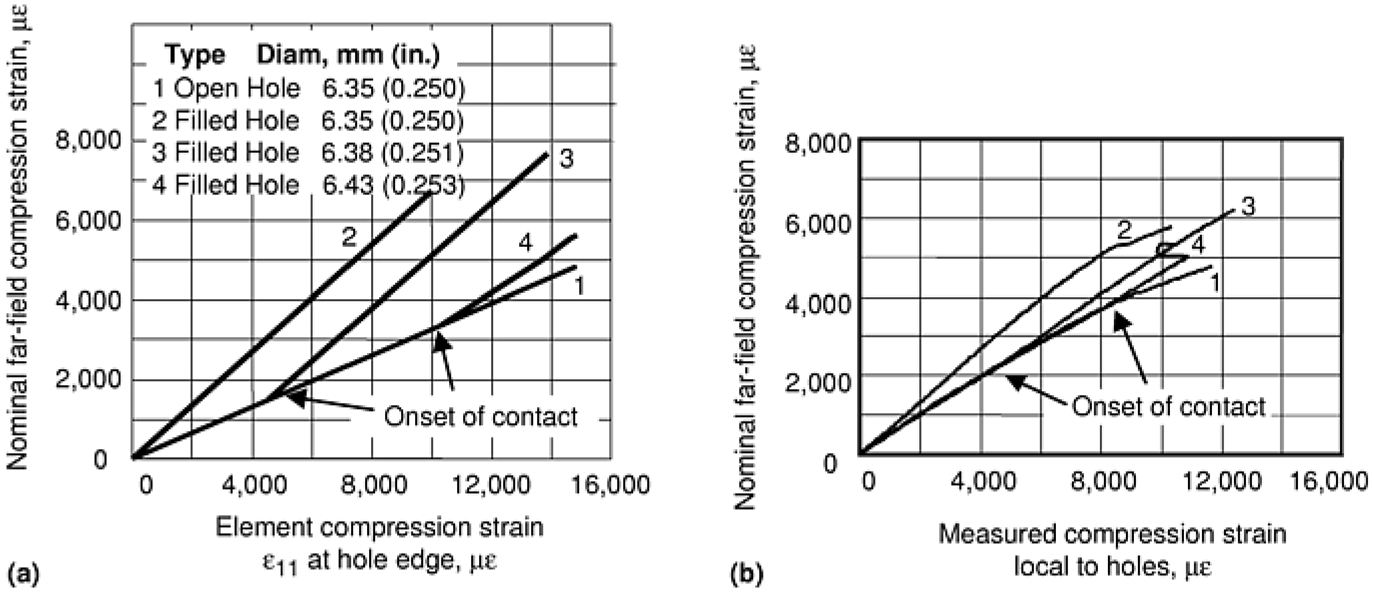

Fig. 6 Comparison of (a) predicted and (b) experimental load versus strain behavior for T800/3900-2 tape (angle minus loaded plies, AML, parameter =-8) open-hole and filled-hole compression specimens. Source: Ref 16

Nonlinearity in material stiffness properties results in the nonlinear strain measurement trend shown in Fig. 6 for both the open and filled hole cases. Such trends are not accounted for in analysis predictions when averaged stiffness properties are utilized; however, modern finite element codes can account for such nonlinear stiffness properties. The analyst must be aware of modeling assumptions regarding stiffness properties when assessing such nonlinearities.

Fastener-hole contact is evidenced by the sudden change in load-strain slope exhibited by the filled hole specimens shown in Fig. 6. If a finite clearance is present in the specimen on manufacture, initially filled hole compression specimens will exhibit load strain behavior equivalent to that of open-hole compression specimens. When the laminate deforms such that the hole surface contacts the fastener, an alternative load path is formed (see Fig. 7). The onset of fastener- hole contact changes the strain and stress distribution about the hole, as shown in Fig. 8, as the peak stress concentration decreases and bearing stresses arise at the contact surfaces. This phenomenon occurred at different load levels for the Fig. 6 specimens due to differences in initial clearance. After fastener-hole contact was achieved, the rate of increase of strain with load decreased at the measured location, resulting in a steeper load-strain trend.

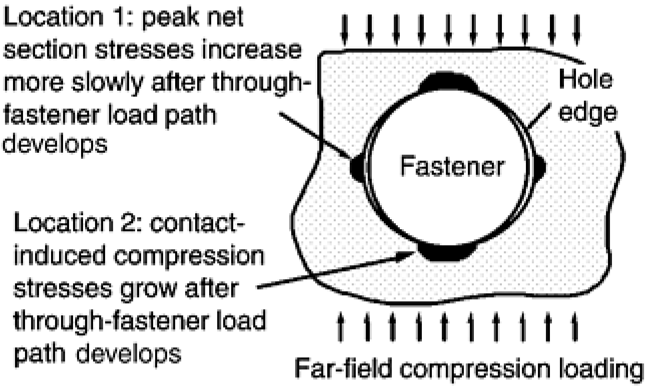

Fig. 7 Development of through-fastener load path at a filled hole under compression loading. Source: Ref 16

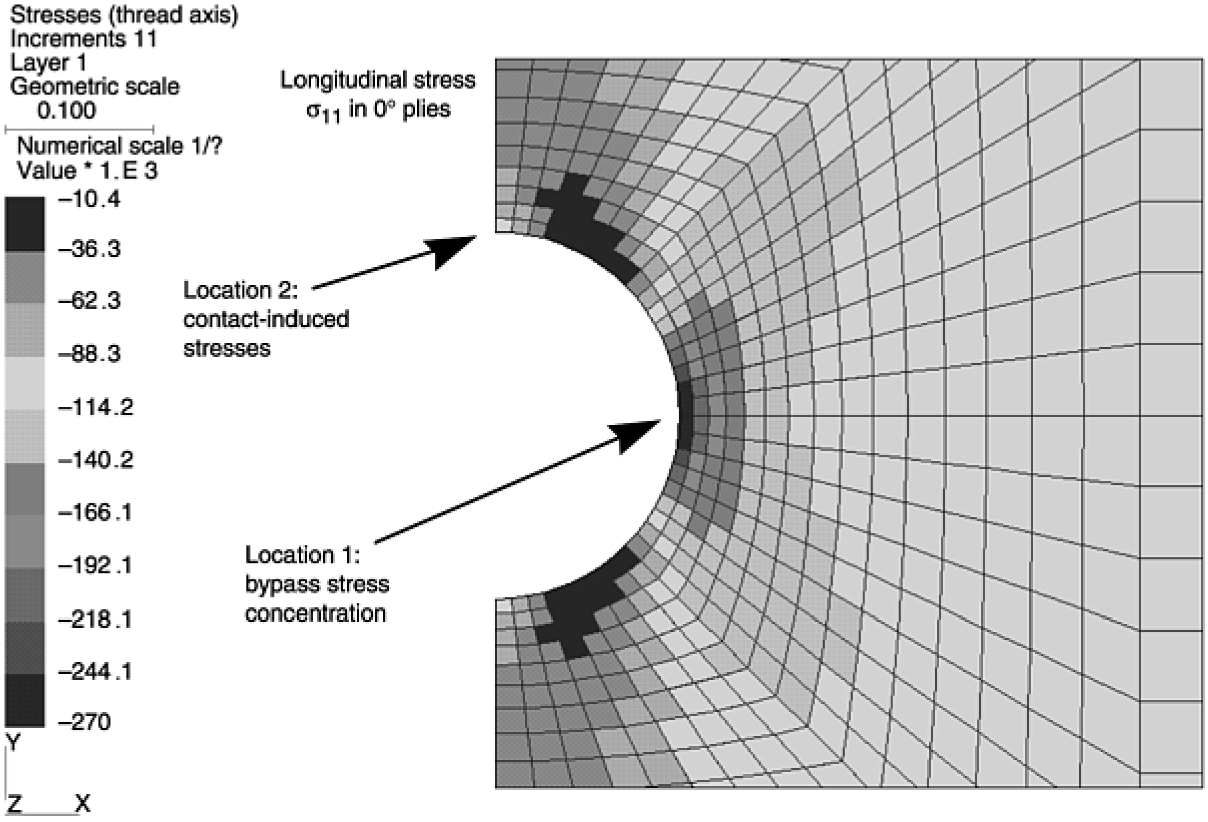

Fig. 8 Typical post-contact stress distribution in filled-hole compression specimen, demonstrating onset of contact- induced bearing stresses. Source: Ref 16

Subcritical, or noncatastrophic, damage formation is evidenced by sharp, sudden changes (most often decreases) in measured strain. In notched laminates, measurement of such subcritical failures is infrequently recorded by strain gages, because the relevant failure mechanisms (splits and delaminations) tend to change the measured strain gradients only slightly prior to final, catastrophic failure. This is especially true for notched compression failure, as the onset of subcritical damage tends to precipitate catastrophic failure. It should be noted that one set (curve 4) of filled-hole compression data in Fig. 6 did detect the onset of noncatastrophic damage, however.

Damage Correlation. Subcritical damage formation (fiber-matrix splits and delaminations) can be detected using destructive and nondestructive techniques. In both cases, tests are stopped at specified load levels such that the relative state and size of damage can be assessed incrementally. Destructive assessment is generally performed through sectioning of the laminate specimen at highly strained locations, followed by microscopic observation. Nondestructive assessment can be performed using x- radiographs (for splits and delaminations) and ultrasonic methods (most effective for delaminations). Nondestructive methods provide greater information on the overall state of damage than does destructive assessment but are less accurate in providing size and through-thickness location information than is destructive assessment. Such data are particularly useful in

comparing progressive damage-analysis predictions using finite-element and cubic-spline techniques, as shown in Fig. 3.

Bolted Joints

Depending on the type of specimens, bolted joint tests can be conducted at either the design allowables level (for generation of design data) or the element level (for verification of joint sizing methodology). As with notched-strength coupons, analysis correlation work centers on strength and failure-mode prediction but also involves fastener-load distribution calculation. Specimen details are generally more representative of the actual structure than basic notched allowable coupons, as fastener type, clamp-up torque, and three-dimensional loading effects must be accounted for.

Bearing Strength Correlation

As with notched strength, bearing design data must cover the envelope of lay-ups used throughout the design. However, bearing deformation and damage are generally less sensitive to lay-up effects than is notched strength. Consequently, geometry-influenced failure modes are more sensitive to the laminate configuration than is bearing damage (Ref 1). This is due to the significant amount of subcritical damage that forms as the fastener hole elongates. Final failure results from the onset of a geometry-influenced failure mode (shown in Fig. 1 of the article “Element and Subcomponent Testing” in this Volume), such as shear-out, cleavage, or net tension (Ref 17). Significant variations in bearing strength will tend to occur at extreme laminate configurations, due to the premature onset of a geometry-influenced mode of failure.

Bearing stress fields are not as easily determined as notched specimen stress fields. As discussed by Crews, this results from the need to model fastener-hole contact, friction, three-dimensional geometrical constraints, and through- thickness stress gradients (Ref 6). As with notched-strength prediction, bearing damage and strength prediction have been studied extensively. Early methods used several simplifying assumptions, such as a two-dimensional cosine distribution of bearing stress on the hole boundary (Ref 6); strength prediction methods included linear elastic fracture mechanics (Ref 18) and two-parameter approaches (Ref 19). Subsequently, progressive-damage finite-element analysis (Ref 13) and spline variational methods (Ref 20) have been developed.

Bearing strain field data can be obtained using strain gages, and correlation is influenced by factors such as strain gradients, stress-strain nonlinearity, fastener-hole contact, subcritical damage formation, and fastener deformation. However, subcritical damage formation (hole elongation) and fastener deformation are by far the greatest contributors to inelastic behavior, and correlation is most frequently performed using crosshead deflection or extensometer data. An example of this is provided in Fig. 9, which compares three-dimensional-finite element- based deformation predictions to load-deflection data (Ref 13). Subcritical damage formation is evidenced by gradual changes in the load-deflection curve slope. It should be noted that nonlinear load-deflection behavior of this type can also be caused by bending and plastic deformation of the fastener and that extraction of separate composite bearing and fastener load-deflection nonlinearities from such data is quite difficult.

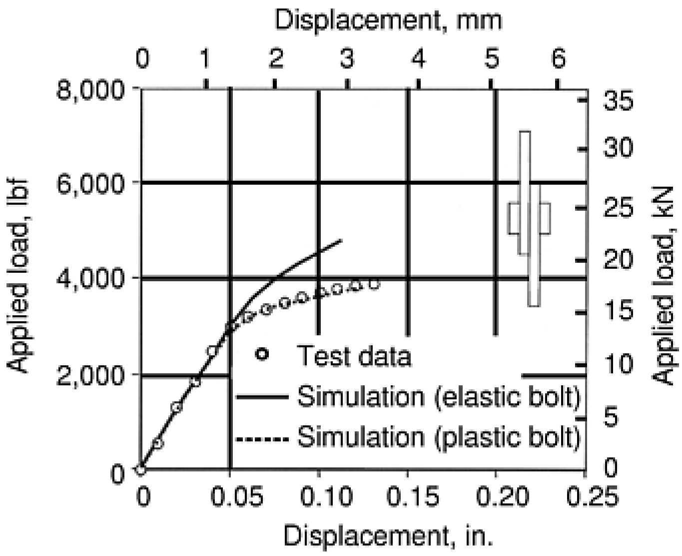

Fig. 9 Comparison of predicted and experimental load- displacement behavior for tension bearing specimen, single-lap joint. Source: Ref 13

Bearing-Bypass Analysis

Multi-fastener joint specimens require a two- step analysis process. First, the load distribution between fasteners must be determined. Once this has been accomplished, the interaction of bypass and bearing stress fields, and its influence upon strength, can be determined.

Fastener Load Distribution. For composites, fastener load distributions are calculated using methods similar to those developed for metal joint structures, namely compatibility/equilibrium and finite-element-based solutions dependent upon adherend (plate) stiffness and fastener flexibility (21, 22). Such models are developed through semiempirical calibration with test data to determine fastener flexibilities. Test analysis correlation is most frequently performed using axial strain gages located between fasteners. Due to the gradient nature of the strain field in these regions, calibration is often performed by testing the instrumented adherends with one or more of the joint fasteners removed, such that relationships between measured strain and load introduced through fasteners “ahead” of the gage can be obtained. Using the calibration data, the load distribution among joint fasteners can be monitored throughout the test (frequently, the load distribution changes as subcritical damage forms at the fastener holes).

Bearing-Bypass Strength. Stress distributions near a fastener hole can be approximated by the superposition of stresses for the unloaded hole (bypass) and loaded hole (bearing) cases. Once stresses have been calculated, they can be used with the various failure models for unloaded and loaded holes to calculate failure mode and strength (Ref 6), among these being those of Eisenmann (Ref 18), Garbo (Ref 19), Crews and Naik (23, 24), and Hung and Chang (Ref 25). Predictions are usually presented in a graphical nature, providing an envelope of permissible bearing stresses and bypass strains (see Fig. 10). As would be expected, test- analysis correlation issues are a combination of those relevant for unloaded-hole (notched) coupons and bearing coupons. An additional source of variation in load-deflection nonlinearity is caused by load transfer; as shown in Fig. 11, the greater the amount of load transfer, the greater is the degree of load-deflection nonlinearity observed for the specimen due to greater subcritical bearing damage formation.

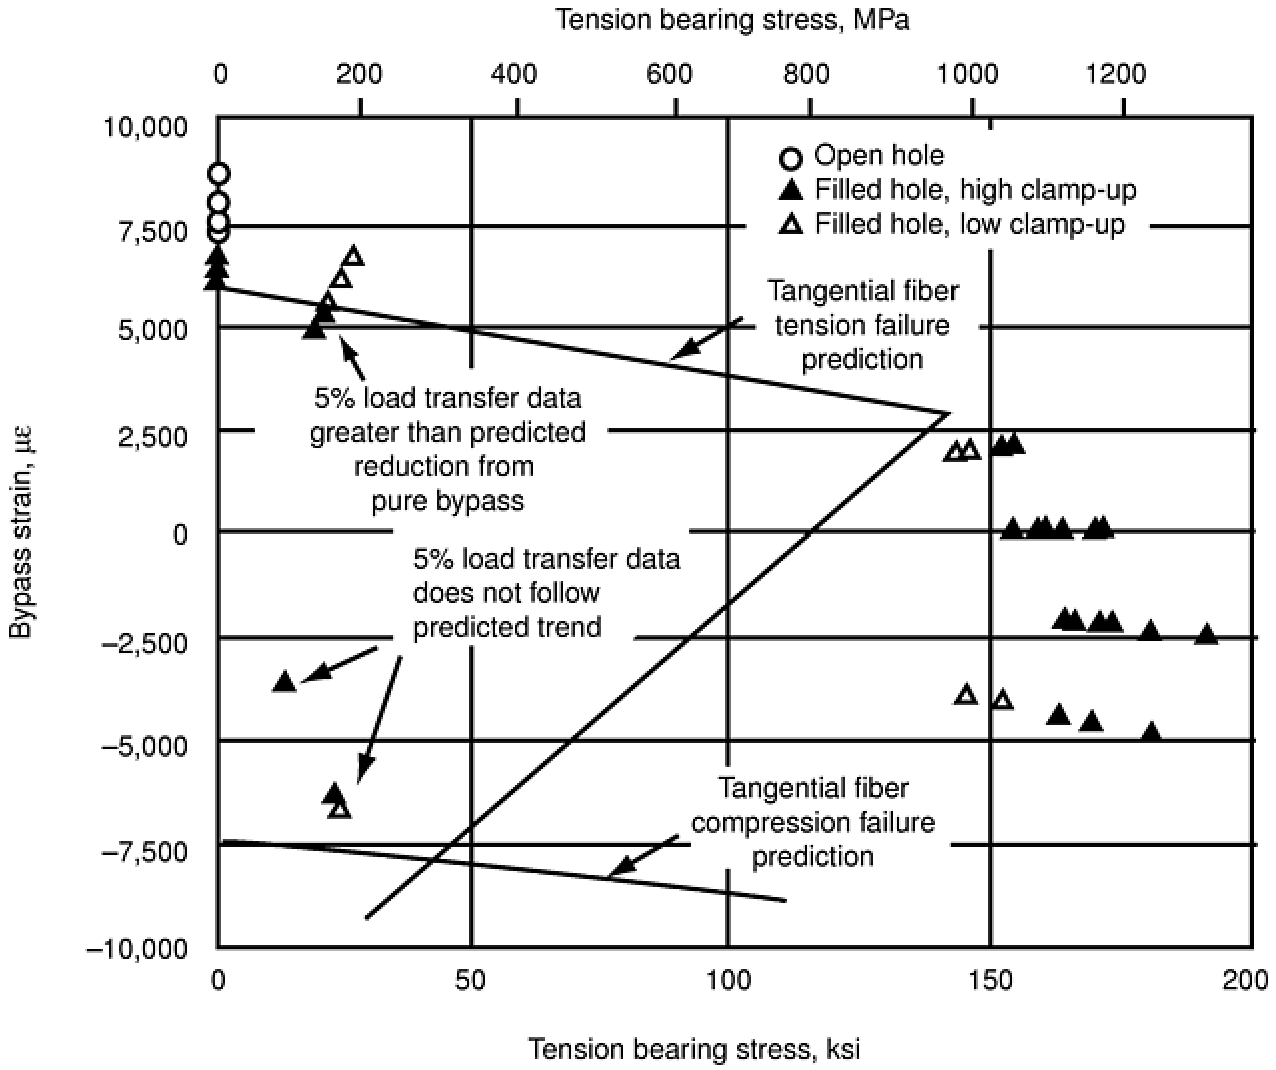

Fig. 10 Typical bearing-bypass interaction envelope and supporting test data for IM6/3501-6 tape laminates. Source: Ref 1

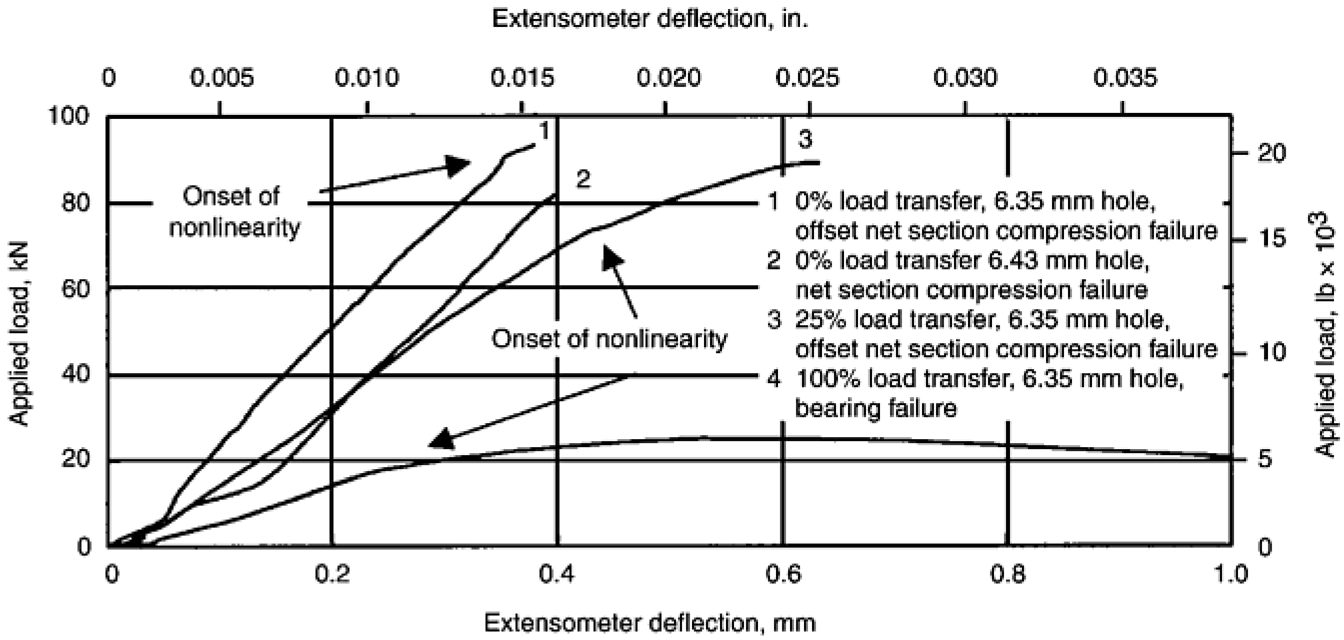

Fig. 11 Change in load-displacement nonlinearity for bolted joints with varying degrees of load transfer. Source: Ref 26

As with unloaded filled hole compression, fastener-hole clearance and contact can affect response, as evidenced by the test data shown in Fig. 12. As discussed by Crews and Naik (Ref 23) and Sawicki and Minguet (Ref 26),

differences in clearance can affect both the failure mode and the strength of bearing-bypass specimens loaded in compression. The compression bearing-bypass "envelope" is characterized by a net-section compression-critical region (low bearing stresses) within which dual-sided fastener-hole contact occurs, and a bearing-critical region (high bearing stresses) within which dual- sided contact is lost (Ref 26). Proper measurement of hole and fastener diameters is necessary for accurate compression failure mode and strength prediction. It should be noted that this effect is of lesser importance for tension bearing- bypass failure.

Testing and Analysis Correlation

Adam J. Sawicki, The Boeing Company

Elements and Subcomponents

At the elements and subcomponents levels of testing, data representative of typical structural geometries are obtained (see the article “Element and Subcomponent Testing” in this Volume). Examples of the types of specimens tested are complex bolted and bonded joints, stiffened panels, beams, and sandwich panels. For elements, the data generated may be closely linked to an analysis methodology, enabling the development of design values. Frequently, the specimens are used to assess load and strain distributions near damage and defects (Ref 1). For subcomponent tests, verification of analysis and strength prediction is achieved, and critical design details (which cannot be addressed with confidence in a lower level test) are assessed (Ref 2). Statistical scatter and environmental effects may be derived from coupon and element-level test data.

Correlation Issues

Analysis correlation work for these types of specimens centers on strain distribution, strength prediction, and failure-mode prediction. Stress and strain distributions are commonly calculated using finite-element-based methods. However, the level of modeling detail is typically coarser than that in coupon-level tests. For example, rather than assessing the local strain level near a stress concentration at which failure will occur, comparisons will be made to notched far-field strain allowables obtained in the coupon-level tests. Similarly, failure mode prediction will be performed at a macro level (bearing or bypass failure) rather than at a coupon level (shear-out, fiber-dominated notched tension, etc.).

Strain and Damage Prediction. Localized strain data is most frequently obtained using strain gages; rosette strain gages are more frequently used than in simpler tests due to the need to quantify shear strains. Gages are typically used in obtaining basic section strain data, as well as in gradient locations and near stress concentrations and damage/defect locations. Gradients and damage growth can also be assessed using photoelastic coatings and shadow-moiré techniques.

Correlation issues for elements and subcomponents are similar to those for simpler specimens and include strain gradients, stress-strain nonlinearity, and subcritical damage formation/ growth. It is at these levels,

however, that nonlinearities related to stability are also assessed. For compression-loaded specimens (see Fig. 13), the onset of buckling frequently precipitates catastrophic failure, and strain correlation is centered on detecting and predicting the onset of buckling. Conversely, in stiffened shear panels (see Fig. 14), skins can effectively carry load through diagonal tension well past the onset of web buckling (Ref 27). For these specimens, strain correlation involves prediction of buckling as well as diagonal tension response. Stability-related strain nonlinearities are most frequently manifested through sudden changes in bending strain measurements.

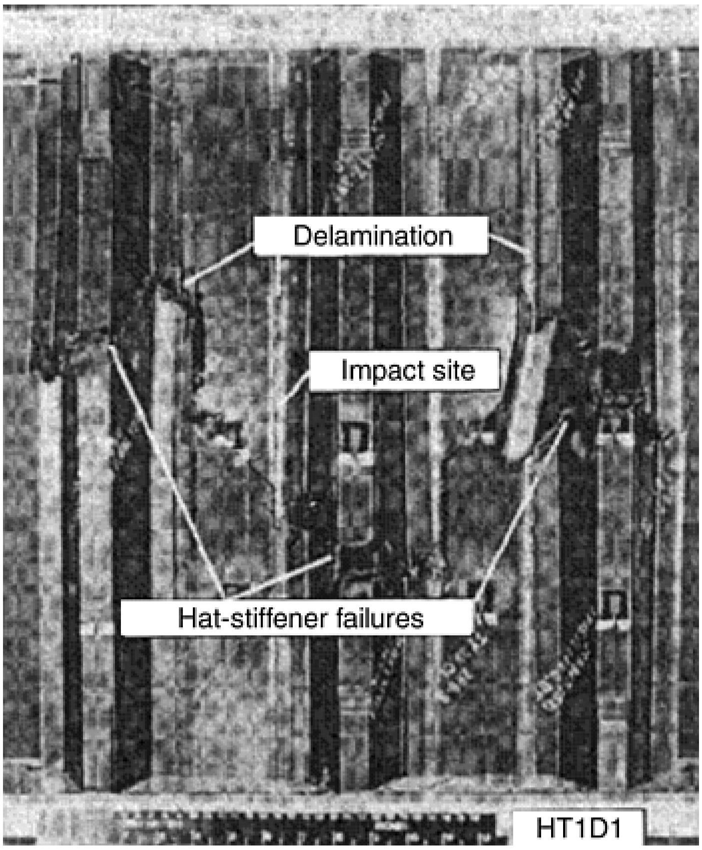

Fig. 13 Three-stringer element-level compression test specimen. Source: Ref 28

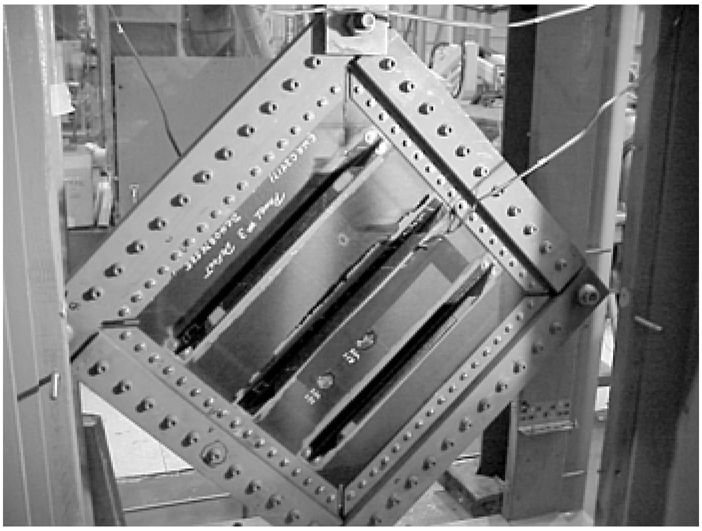

Fig. 14 Three-stiffener element-level shear test specimen. Source: Ref 27

Nonlinearities may also arise from the onset and growth of subcritical damage. Stiffened shear panels have exhibited good damage tolerance capability, operating well beyond the initiation of damage in webs and along stiffener bondlines. Strain gage data have been used effectively in monitoring the onset of damage growth; the stress levels at which growth begins are often used for damage-tolerant design purposes. Damage detection in these specimens primarily centers on nondestructive ultrasonic inspection while the test is being conducted, followed by destructive evaluation upon failure of the specimen.

Failure Mode Prediction. Failure modes observed in these tests can differ from the critical failure mode as predicted by strength analysis using design allowables. This primarily results from differences in failure criteria, environment, and statistical sensitivity (Ref 1). With regard to failure criteria, some allowables are generated using conservative values for fastener torque, hole clearance, and so forth, which may not be present in a representative element or subcomponent test. For example, design strengths for net section tension and crippling are closely tied to catastrophic failure, whereas bearing and compression strengths are restricted to cutoff values, low clamp-up torque criticality, and so forth. Similarly, allowables developed for hot/wet or cold/dry criticality may not be critical in a room temperature test; subsequently, failure modes not as severely impacted by environmental effects may be found critical in a room temperature test.

Global-Local Modeling. Finite element methods have been highly effective in modeling element and subcomponent specimens containing defects, damage progression, and so forth, as they lend themselves to global-local modeling techniques. In such models, a coarse global mesh is used to account for the overall geometry, boundary conditions, loading conditions, and deformation (including post-buckled behavior) of the test specimen. Nodal deformations are monitored at the boundaries of a "patch," or group of elements locally surrounding the stress concentration. In the location of the patch, a fine local mesh is developed and modeled separately. In the local model, boundary conditions are forced to match the deformations calculated by the global model at the edge of the patch. Using the fine mesh, local stresses, strains, interlaminar strain energy release rates, damage progression, and so forth can be calculated. Stiffness changes calculated in the local model, due to damage onset and growth, are then "fed back" into the global model for use in the next iteration or load step. The global-local feedback process is then repeated until catastrophic failure is predicted.

Examples of global-local models are shown (Fig. 15 and 16). Figure 15 displays a global model containing a local patch for a stiffened compression panel, a local model of the skin containing delaminations, and local-model sample results (Ref 28). Figure 16 shows a local model for a bonded joint containing a matrix crack at the edge of the bondline. This model is used to correlate strain energy release rates to applied in-plane loads and moments for a given design detail. Data of this type are then used to predict the progression of bondline disbonds and delaminations in skin-stiffener panels (Ref 29).

Conclusions

The types of tests and analyses performed at the various building- block levels vary due to the different requirements and issues addressed at each level. Common techniques for stress, strain, strength, and failure-mode prediction can be used in the analysis of design-allowables coupons, elements, and subcomponents. Finite element techniques have proven especially useful in the modeling of contact, three-dimensional effects, postbuckling behavior, damage growth, and so forth. Model predictions are compared to data obtained from instrumentation (strain gages, photoelastic and shadow-moiré, etc.), nondestructive evaluation (ultrasonic, radiography), and destructive evaluation. As demonstrated in this article, recent finite element and cubic spline-based models have been used successfully in correlating predicted and actual damage progression in test specimens. However, more work in this area remains in transitioning these tools for use in general stress analysis.

Testing and Analysis Correlation

Design Criteria

Greg Kress, Delta Air Lines

Introduction

DESIGN CRITERIA are the decisive quantified goals that a product must attain. A product needs to achieve a certain level of safety, cost, and functionality. To achieve these design criteria, particular detailed considerations must be evaluated. Design considerations include what materials are used, the manufacturing

processes, and the configuration that is selected. This article addresses criteria that are established in the engineering design phase of a composite structure. A broader overview of the entire design process is provided in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

Design Criteria

Greg Kress, Delta Air Lines

Overview of Design Criteria for Composites

Design criteria are established in the initial phase of a design program, but may be changed throughout the development and production process. Products are manufactured and purchased to satisfy specific real or imagined needs. An airplane may be produced for high speed, large payload capacity, or flight endurance. An automobile is produced for ground transportation, but could be functionally classified as a sports car, luxury sedan, racing car, or cargo van. Similarly, rockets, boats, trains, sporting goods, medical devices, storage tanks, walking bridges, or highway overpasses are all produced for specific purposes. Composite materials have been used in every one of these industries, and in these applications, composites, as well as other materials, have met with successes and failures. To meet the intended function for a product, a designer needs to know clearly the expectations of the user, the expected life of the product, and the expected environment that the product will encounter. The way in which the designer applies the many design considerations will determine the margin of success that the application achieves.

Perhaps more than any other engineering material, composites, by their very nature, possess the flexibility to be tailored to achieve specific design requirements. However, there may be goals specified at the start of a design program that:

- Are more significant than others
- Are more achievable than others
- May only be accomplished at the expense of others

Design engineering is often the art of compromise.

Composites achieve their design flexibility from the large possible selection in material types, arrangements, and forms; the wide variety of processing methods available; and the many different variations available when choosing a structural configuration. Because composite design offers such a large selection, one can get lost in the details, and the result may be a final product that does not meet all of the original expectations. To ensure the correct design choices are made, it is best to take a methodical approach to evaluating the design requirements. To begin, for a particular application, the following design criteria might be determined to be the most relevant and should be listed in order of priority for the particular design:

- Cost
- Strength
- Stiffness
- Weight
- Size
- Repeatability and precision of parts
- Environmental constraints in processing, use, and disposal
- Aesthetics
- Manufacturability and production rates
- Assembly restrictions
- Life cycle durability and damage tolerance
- Maintainability and reparability
- Nonmechanical properties, such as flammability and electrical properties

From the prioritized design criteria, all of the engineering, material, process, and configuration options should be evaluated for their ability to fulfill the design requirements. One selection will not meet all of the prerequisites. However, based on the priority of the design criteria, the design team can more efficiently evaluate all of the options and more easily eliminate unacceptable alternatives.
Common composites material selection options are:

- *Fiber types:* Glass, carbon, aramid, boron, polyethylene, ceramic, tungsten
- *Fiber forms:* Unidirectional, woven fabric, random mat, chopped fiber, braided fabric
- *Polymer matrices:* Polyester, vinyl ester, epoxy, bismaleimide (BMI), polyimide, phenolic, cyanate ester. Polymers are classified as being thermoplastic or thermoset.
- *Other matrices*: Metal, ceramic, carbon, glass
- *Structural configurations:* Solid laminate, sandwich panels, stiffened panels
- *Core materials:* Honeycomb, foam, wood, syntactic

Processing options include:

- *Manufacturing methods:* Wet lay-up, prepreg lay-up, fiber placement, tape lay-up, pultrusion, resin transfer molding (RTM), vacuum- assisted resin transfer molding, filament winding, compression molding, injection molding, centrifugal casting
- *Processing equipment:* Vacuum bagging, molds, ovens, autoclaves, presses, mandrels, bladders

The application of composite materials in any industry has standard design criteria that will lead a designer toward choosing a particular design. Some criteria are mandated and are based on the collective experience within the industry. However, staying within the "standard industry guidelines" may produce results that are nearly identical to the competition. This may be the safe and possibly only path to follow, but will seldom result in industry advances or a competitive edge over any other available product. The negative aspect is that implementing a unique design comes with the risk that the design program will experience unplanned setbacks or potentially, a complete design failure. It is therefore necessary during product development that the design team fully research and understand the consequence of each design decision. The designer must evaluate the outcome that choosing one design option has on meeting its intended design criteria, as well as the effects that this option has on the other design criteria needed to make the product a success.
This article describes common design criteria and identifies the design considerations that have a significant effect on the end product. From the discussion, it should become obvious how seemingly independent design criteria and design considerations interact with one another. Used in conjunction with the detailed subjects covered elsewhere in this Volume, this article should help the designer make decisions in a design program that will enable it to achieve the maximum benefits of composite materials.

Design Criteria

Greg Kress, Delta Air Lines

Cost

The cost versus benefit judgement is usually the prime factor in the choice of a design path. Factors contributing to the true cost are:

- Materials selection
- Component size
- Manufacturing methods
- Processing equipment

Cost alone may not be the primary design criteria driving new product development, but the respective costs associated with each consideration will affect the profitability of the project. A cost factor is associated with each step in the design process. Comparisons must take into account the number of parts being produced; their size; constituent materials; ancillary material costs, such as storage costs, energy costs related to curing temperature, and waste; and manufacturing techniques.

Materials Costs. Consider two composite structures, one made from glass fiber and polyester resin and another made from carbon fiber and epoxy. Fiberglass is the least expensive reinforcement, followed by aramid fiber, then carbon fiber, costing 5 to 10 times more. Similarly, polyester resins cost less than vinyl ester resins, and epoxy resins are the most expensive.

When considering the size of a fiber-resin part for a bicycle frame and a boat hull, a cost difference of converting from glass-polyester to carbon/epoxy would obviously result in a much larger dollar difference in the material cost of the boat. However, if the material costs of a bicycle selling for $200 were $5, an increase to $25.00 is a 500% increase in material costs and a 12.5% increase relative to the existing selling price. If a $200,000 yacht had a $5000 cost for the glass- polyester hull, the equivalent change would amount to a $25,000 cost. The $20 increase in the cost of the bicycle, which might be marked up considerably at the selling price, might be met with the same sales resistance as the $20,000 increase in the yacht, if there were no increase in the perceived value. For a racing bicycle, a 30% reduction in the weight of the frame may be perceived as a worthwhile design improvement. For a recreational bicycle or a yacht, the weight reduction may not be an acceptable benefit.

The value of a weight reduction will be evaluated based on the industry involved. A one pound weight reduction on a plane is evaluated in terms of the fuel savings over the life of the plane. A reduction of a pound in a rocket engine allows for one pound more payload and can be evaluated in those terms.

If mechanical performance is the design driver, characteristic property values are often normalized by density and cost to arrive at strength or stiffness per cost. This aids in the systematic evaluation of options. See the article “Cost Analysis” in this Volume.

Other design drivers, such as environment, manufacturability, or repairability, may require significant consideration over cost. The use of other fiber-matrix combinations made from boron, polyethylene, or quartz fiber with phenolic, BMI, polyimide, or cyanate ester resins, and metal-matrix, carbon-matrix, or ceramic-matrix materials should be considered.

Processing Costs. Although direct cost based on constituent materials may appear to be a large factor, other significant cost drivers are manufacturing considerations. Figures 1 and 2 show cost and cycle time comparisons for different manufacturing processes.

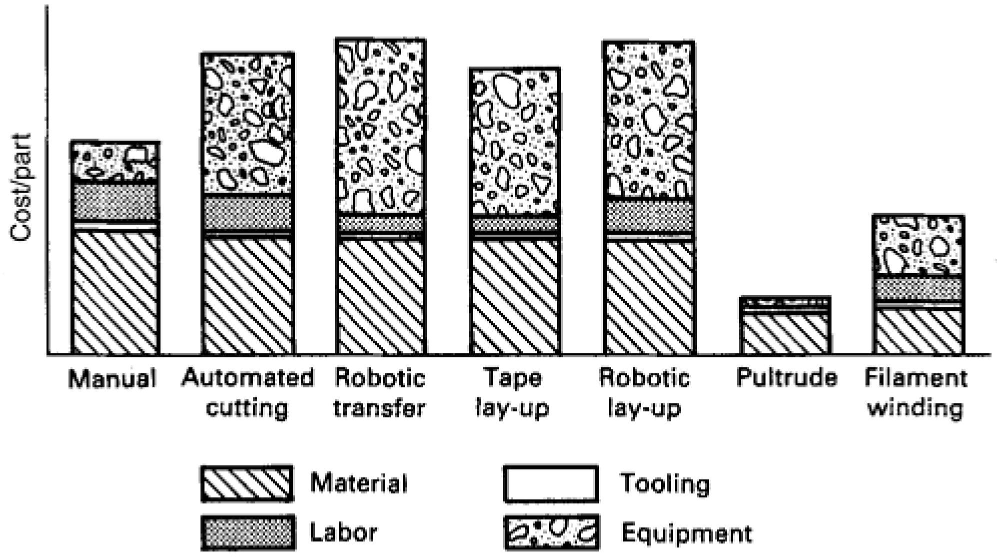

Fig. 1 Relative per unit cost for processing 0.4 m^2 (4 ft^2) 24-ply parts by different methods, based on 2000 units per year. Adapted from Ref 1

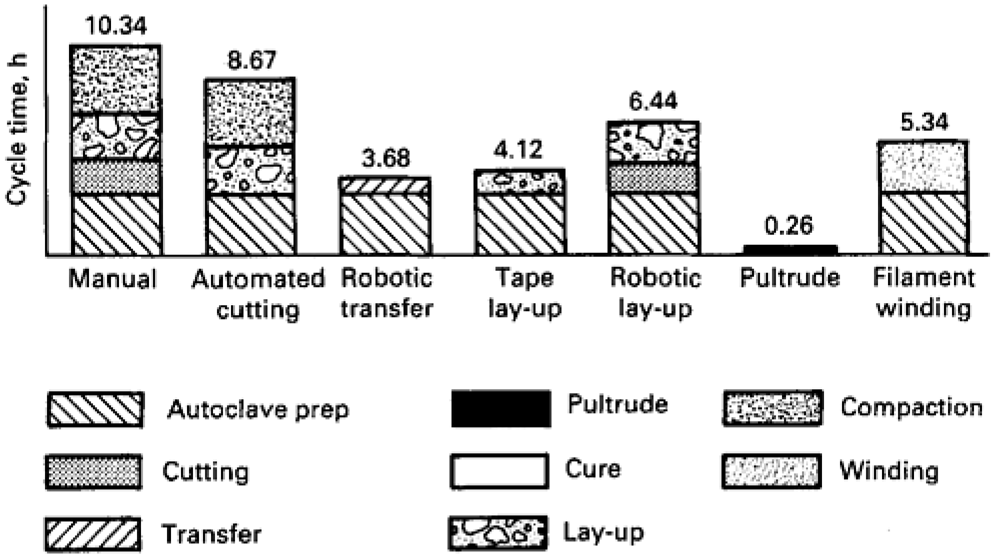

Fig. 2 Cycle time for a batch of 100, 0.4 m^2 (4 ft^2) 24-ply parts. Source: Ref 1

Wet lay-up, open molding is probably the least expensive process for a relatively small number of units. This is a common process for large- production marine manufacturing, where thick, heavy, woven fiberglass mat and random-oriented chopped fiber are hand or spray impregnated with polyester resin and cured at room temperature. Although conducive to large and inexpensive production, the optimization of fiber properties is not achieved, weight is often not minimized, and the level of precision is very operator-dependent.

Prepregs, fibers that are preimpregnated with mixed resin, optimize constituent properties by using a predetermined resin content and preferred fiber orientation. Prepregs are commonly used with both unidirectional and woven fabric forms. The resins contained in prepregs can often achieve higher service temperatures than their respective wet lay-up resins. However, they typically require frozen storage to prevent premature curing. Resin flow during cure is limited, so prepreg lay-ups will require vacuum bagging oven cures as a minimum and potentially press or autoclave pressure to achieve ply consolidation. Prepreg materials, frozen storage, short shelf lives, vacuum bagging, ovens, autoclaves, and presses all add significantly to the final cost. To relate this to the previous example, a prepreg fiberglass-polyester, vacuum-bagged, oven- cured composite can, in the end, become more expensive than a wet lay-up carbon/epoxy, open- molded, room-temperature-cured laminate.

Cost reduction measures have been developed through advances such as room-temperature- storage prepregs. A general aviation aircraft manufactured in Canada uses an impregnator. This equipment meters a specific quantity of resin onto the fibers as the fabric is pulled through it. This reduces the material cost of prepregs while still providing the desired precise resin content. Personnel are still needed to locate the material in the mold, ensure the reinforcement is completely saturated, and apply the vacuum bag.

Vacuum-assisted resin transfer molding involves liquid resin being drawn through prepositioned dry reinforcement under vacuum, using traditional single-tool surface molds. This manufacturing technology is designed to reduce the cost of hand lay-up, requiring less manpower, while providing a more predictable resin content and vacuum bag compaction. Vacuum-assisted resin transfer molding has been used from low- cost manufacturing of small bicycle frame-sized components, to making objects as large as 20 m (65 ft) long train boxcar bodies and even larger boat hulls. Traditional RTM is a more costly process used to create composite parts to nearly net shape. Resin transfer molding is a closed-molded process where a dry fiber preform is placed in a two-sided (closed) mold, and heated resin is forced in under pressure. The mold part has a tooled surface on both sides, and hollow parts can be made with the use of mandrels and bladders. Resin transfer molding is ideal for small precision parts, where the size of the molds does not become cost-prohibitive.

Complex and accurate manufacturing often requires automation. This type of automation comes in the form of computer-controlled material cutters, ply-placement equipment, filament winding, pultrusion, tape wrapping, and fiber- placement machines. Although each has its own unique purpose, they all use large, computer-operated equipment that requires a significant capital investment. Even so, these advanced techniques have reached across the full spectrum of manufacturing, from filament winders for pipes, ducting, and storage tanks in industrial applications, to fiber-placement machines for advanced military aircraft.

Design Criteria

Greg Kress, Delta Air Lines

Size

Size considerations impact both the manufacturing environment and the application of the composite in the final assembly. An advantage of composite structures is often the large size of the individual bonded assemblies. This extends from the ability of composite raw materials to be easily spliced with a simple overlap during lay-up. Complex contours that would typically require multiple metal parts can easily be molded into a single composite part. Additionally, one large mold can be less involved to construct than several smaller molds. Fabricating a single large component is less time-consuming, requires smaller inventory, and has fewer assembly joints than multiple smaller parts. No matter what the building material, joints are always a source of possible failure. Fewer joints result in material savings and weight savings, because the region around a joint requires material buildup to prevent the joint from failing first.

Excessively large size can become a detriment to a design. Large bonded panels can be cumbersome to handle and can get damaged easily while being moved during assembly. They can be cracked from bending, if not properly supported. Once in service, repairs to composite structures may require partial disassembly. The nature of composite construction makes panels stiff and resistant to bending. Whether adjacent panels are bonded together or mechanically fastened, these inherently stiff panels do not allow any deflection to provide access to within the structure. It is necessary to completely disassemble a panel at all of its joints to gain access within the structure. The larger a panel is, the more extensive the disassembly required to perform the repair. An example of this is a large commercial airline rudder. The composite assembly for the rudder is over 10 m (32 ft) in length (Fig. 3). Each side of the rudder is made from only two skin panels. The lower skin panel spans 5.87 m (19.25 ft) and requires removing mechanical fasteners 1.8 (6 ft) beyond the damage site to achieve enough bending in the panel to access the inside of the structure. It is wise to limit the size of components prone to wear or damage that will require replacement as a part of routine maintenance.

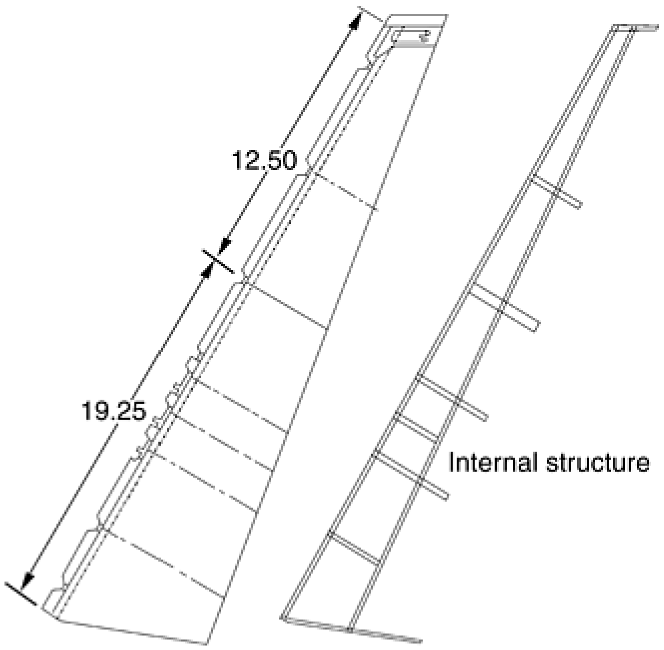

Fig. 3 Two large composite skin panels that make up the rudder of a large commercial aircraft. Dimensions are in feet.

Large panel size stipulated as a design requirement can also lead to prohibitive manufacturing costs. Although lay-up tooling costs for prepreg and wet lay-up manufacturing may not give a compounded cost increase, the equipment costs for other fabrication methods may greatly increase. The complex equipment for filament winding, automated tape lay-up, RTM, and press, oven, and autoclave curing can become exponentially more expensive as individual components increase in size. Consideration must be given to residual stresses created in materials as they cool from elevated cure temperature. Larger parts are more prone to differential cooling.

The size of a final composite structure may be determined by some physical design requirement. For example, the number of joints, with their attendant costs and design challenges, may be reduced with larger components. Edges of laminates are subject to damage and stresses that cause delamination. Joints and edges can be reduced in number and located advantageously by adjusting the size of the components. The designer often has freedom to choose the size of the individual components. Instead of designing large composite panels just for the sake of being big, it is necessary to factor all of the design considerations to minimize the adverse effects.

Design Criteria

Greg Kress, Delta Air Lines

Mechanical Properties

Stiffness, strength, and weight are functions of constituent materials, their relative quantities, and placement. The interactions between stiffness, strength, and weight design considerations can be misunderstood when applying composite materials to a new design. Noncomposite materials, such as metals, typically exhibit proportional properties. For example, the strength, stiffness, and weight of stainless steel are all greater than that of aluminum. The ratio of stiffness to density is approximately the same for steel and aluminum. However, the same is not true for composites. Of the primary reinforcement fibers, fiberglass, aramid, and carbon, each have stiffness, strength, and weight values that are not proportional. These considerations make composites material selection a more complex issue.

As weight is often the critical factor in evaluating the use of composites, the strength and stiffness are often listed as specific strength or specific modulus. The specific values are normalized by dividing the property

value by the density. The specific values can also be normalized by dividing by the cost per mass or weight so a strength per cost comparison can be made.
It is easiest to categorize fiber selection by understanding several significant comparisons. These comparisons rank the fibers in a situation where all resins are equal, and stiffness and strength are evaluated based on weight, cost, and thickness. Laminate weight will obviously affect the final weight of the part, cost will relate the material investment, and thickness will compare the material characteristics per ply. Therefore, consider that currently:

- Fiberglass provides the greatest strength per dollar.
- Aramid provides the greatest strength per pound.
- Carbon provides the greatest stiffness per pound.
- Fiberglass and carbon provide comparable strength per ply thickness, both greater than aramid; however, fiberglass is considerably less stiff per ply than either carbon or aramid.

Weight is based primarily on the density of the fiber. Because nearly all resins fall within the same range, the fiber will determine the laminate weight where:

Constituent	Density	
	g/cm^3	lb/in.^{3}
Resin	1.15–1.35	**0.0415–0.0488**
Fiberglass	2.46–2.55	**0.0900–0.0921**
Aramid	1.44	**0.0520**
Carbon (graphite)	**1.80**	**0.0650**

Stiffness is presented with values that can be very deceiving when designing with composite materials. Once again, resin will not greatly impact laminate property differences during material selection, because resin has very low stiffness. The fiber will be the primary factor in the laminate stiffness where:

Constituent	Modulus of elasticity	
	GPa	10^6 psi
Resin	3.4	**0.50**
Fiberglass fiber	73.1–85.5	**10.6–12.4**
Aramid fiber	124–179	**18–26**
Carbon fiber	207–414	**30–60**
Graphite fiber	**414–965**	**60–140**

However, the previous numbers are for the fiber and the resin individually. When the fiber and resin are combined into either a unidirectional or woven fabric composite ply, the stiffness values will change drastically. Micromechanics will provide a calculated value, but material testing is typically required to evaluate the fiber-resin interface. Representative values for different ply materials are:

Ply material	Modulus of elasticity	
	GPa	10^6 psi
Unidirectional fiberglass	34	**5**
Woven fiberglass	24	**3.5**
Unidirectional aramid	76	**11**
Woven aramid	38	**5.6**
Unidirectional carbon	124	**18**
Woven carbon	**59**	**8.5**

The previous differences represent the use of different fiber forms. This should be obvious, because unidirectional materials have fibers in only one direction (0°), and woven fabrics have fibers in two directions (0° and 90°). For symmetric weave fabrics, the stiffness may be identical in both the 0° and 90° directions. Unidirectional materials have considerable stiffness in the fiber (0°) direction and negligible stiffness transverse to the fiber (90°) direction. To determine the off- axis stiffness properties between the 0° and 90° directions, classical laminate plate theory uses equations representative of generalized Hooke's law and tensor transformation, in matrix form.
To achieve equal stiffness in all directions, as found in isotropic materials (metals), $[0°/90°/+45°/–45°]_s$ and $[0°/+60°/–60°]_s$ unidirectional laminates or $[(0° \text{ or } 90°)/±45°]_s$ woven fabric laminates are used. These

laminates, called quasi-isotropic laminates, will have equal stiffness in all directions in the plane of the laminate, but not normal to the plane. Typical quasi-isotropic laminate stiffness values are:

Quasi-isotropic laminate	Modulus of elasticity	
	GPa	10^6 psi
Fiberglass	19	**2.8**
Aramid	29	**4.2**
Carbon	**41**	**6.0**

Strength can be defined as the maximum stress value that the laminate can sustain. The strength that a structure must possess is based on the ultimate combination of loads that will be applied at the most severe environmental conditions for the structure. However, to ensure that the structure will not fail at this ultimate load condition, a *factor of safety* is applied. A typical factor of safety for metal aircraft structures is 1.5. This means that a structure designed to withstand a load of 6000 lbf will actually be designed to withstand 9000 lbf (6000 × 1.5 = 9000). For nonaerospace engineering applications where a weight penalty is not an issue, factors of safety of 6 to 10 may be applied. The factor of safety is often mandated by industry regulations.

A factor of safety is intended to account for engineering miscalculations, material and process flaws, or assembly defects. Early in aerospace applications of composite materials, a factor of safety of 2.0 was used. This meant that a composite structure was designed to be twice as strong as it really needed to be. This arose from the lack of precision in manufacturing techniques and the variability in material properties. As composite materials, processes, testing, and analytical techniques have improved, the factor of safety is often reduced to 1.5. A low factor of safety can be applied by purchasing composite materials to a stringent materials specification that ensures its properties and repeatability, and by employing well-defined and repeatable manufacturing techniques.

A *margin of safety* is another term associated with designing extra strength into a structure. For composite structures, once the factor of safety has been applied to the design load, and a laminate has been designed to withstand the loading condition, any additional load-carrying capability of the laminate is considered a margin of safety. An excessively high, positive margin of safety for composites can come from having a small selection of materials available where variations in ply and laminate thickness are limited.

A margin of safety is determined after the design of a laminate is completed and the laminate properties have been verified. The ability of a laminate to meet and exceed the required design strength or other criteria is identified by having a positive margin of safety. Verification of strength is often a controversial issue with composites. Stress is easy to calculate from basic mechanics as the load or force divided by the given area. The Système International d'Unités (SI) units of stress are N/m^2, called pascal, Pa, or in customary units, pound force per square inch, lb/ in^2, or psi. For a given laminate comprised of known materials and orientations, the stress at failure strength, can be experimentally determined using standardized mechanical testing methods. The strengths are usually determined for a single load direction applied with the testing machine. Results will vary from test coupon to coupon, with different laminate configurations. See the Section "Testing and Certification" for a full treatment of data analysis and test methodology. It should be noted that multiaxial testing is done, but this testing capability is limited, and usually it is reserved for thick composites.

Detailed analysis can provide the solution to determining the strength at all locations throughout a composite structure. This analytical procedure can use one of several composite failure criteria. There are many failure criteria that exist, but none have proven to be applicable for all materials in all loading situations. The designer must consider situations of compressive loading and out-of-plane loading carefully.

Within a structurally acceptable range of resin content, the values for strength and stiffness will increase with lower resin content and higher fiber volume, because the fiber is the primary means for providing strength and stiffness in a composite. However, the normalized strength and stiffness multiplied by the ply or laminate thickness will indicate the actual strength and actual stiffness per ply in units of force per unit of width. Figure 4 and Table 1 use this concept. To avoid resin content effects in determining strength, it is easiest to look at composite failure based on elongation, or strain. Hooke's law illustrates that, to a certain limit, stress is directly proportional to strain. Because both stress and stiffness are in proportional units of force per unit area, the strain is independent of thickness, as shown in Fig. 4. Therefore, within the structurally acceptable range of resin content, the determining consideration for resin content should not be the change in mechanical properties, but the weight considerations associated with higher resin content and the environmental considerations associated with lower resin content.

Table 1 Properties of lamina plotted in Fig. 4

Resin content, %	**0° modulus, 10^6 psi**	**Ply thickness, in.**	**Actual modulus, 10^6 lbf/in.**	**Tensile strain in./in.**	Strength per ply, lbf/in. of width
35	9.3	0.0074	0.06882	0.009	**0.00062**
37	8.8	0.0078	0.06864	0.009	**0.00062**
40	**8.3**	**0.0083**	**0.06889**	**0.009**	**0.00062**

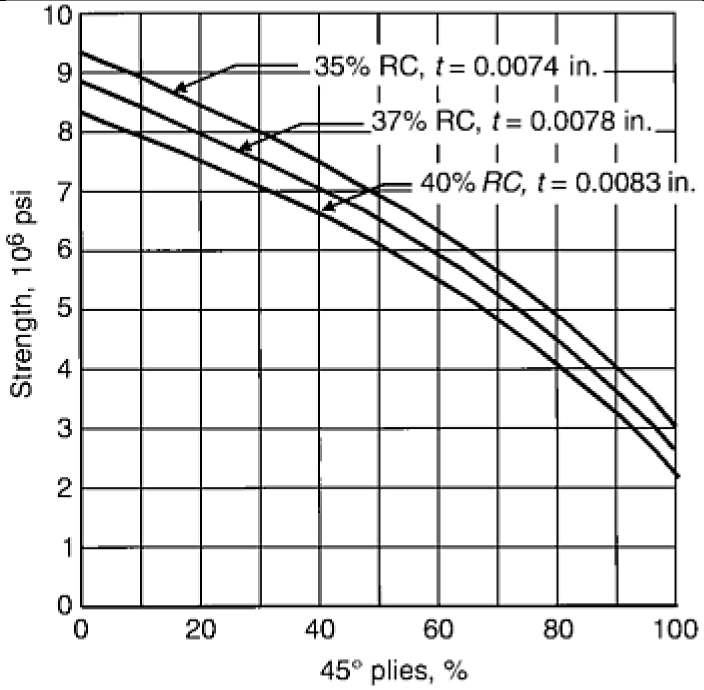

Fig. 4 Strength versus percent 45° plies for three lamina, with resin content (RC) and thickness (*t*) as indicated. Selected values are given in Table 1.

Example: Effect of Fiber Areal Weight on Material Usage and Other Design Considerations. Unidirectional carbon fiber used in aerospace structures is typically available in 95, 145, and 190 g/m^2 (0.31, 0.477, and 0.623 oz/ft^2) fiber areal weight (FAW). The FAW is the weight of dry reinforcement per unit area (width × length) of tape or fabric. Because a FAW of 95 g/m^2 (0.31 oz/ft^2) is half that of 190 g/m^2 (0.623 oz/ ft^2), it also has half the thickness. Designing in three plies of 95 g/m^2 (0.31 oz/ft^2) unidirectional material will allow a more precise strength to be achieved compared to two plies of 190 g/m^2 (0.623 oz/ft^2) unidirectional tape if only 280 g/ m^2 (0.91 oz/ft^2) of material is needed. If 145 g/ m^2 (0.477 oz/ ft^2) material is available, only two plies would be required to supply the same amount of carbon fiber as three plies of 95 g/m^2 (0.31 oz/ft^2) material. Design considerations to be evaluated are the added cost and weight if unneeded material is used, the additional time in laminating more numerous plies, and the excess inventory that must be maintained if multiple variations of the same material type are used.

Design Criteria

Greg Kress, Delta Air Lines

Repeatability and Precision

The level of repeatability and precision required in the final product must be considered in the initial design. On the production level, a tolerance for precision in size and shape will be set to assure proper fit of joined components. Manufacturing precision is achieved with proper materials selection, tooling, lamination sequence, processing control, and final trim.

Tooling considerations involve molds that retain accuracy after repeated cure cycles. Metal tooling has long been used for its ability to maintain a precise shape. Metal tooling is also the most expensive, because complex tool surfaces must be machined from the tooling metal. Metal tooling is often heavy, and the thick sections act as a heat sink, which can interfere with the proper curing of the composite materials. Metallic tooling methods involving deposited metals, such as electroformed nickel or cast aluminum, are able to produce thinner metal molds without large machining operations. Composite tooling is considerably easier to fabricate, using lay-up and fabrication techniques similar to manufacturing composite parts. Composite tooling typically cannot withstand the numerous repeated thermal cycling, nor are composite tools as resistant to damage as metal tools, but the reduced price will offset the lower life span. See the articles “Electroformed Nickel Tooling”, “Elastomeric Tooling”, “Design, Tooling, and Manufacturing Interaction”, and “Composite Tooling” in this Volume.

Automation can increase manufacturing precision and increased productivity. Computer-operated cutting tables are used to quickly and accurately cut plies. These usually have software that nests plies along the length and width of the roll to reduce material waste. Computer-operated filament winding, tape wrapping, and tape-laying machines use numeric control to accurately laminate parts. Five-axis routers are used to quickly and accurately trim parts. Computerized equipment is available for all phases of fabrication, but at a significant cost that must be justified. Hand lamination is still a viable technique, but it is susceptible to operator variability. Increased accuracy can still be achieved. Using prepregs versus wet lay-up will ensure accurate resin content. Laser ply projection can be used to both accurately cut plies as well as accurately locate plies in a mold. Trim and drill fixtures can be incorporated to help guide the final trimming and drilling operation. The objective is to develop the optimal combination of automated technology and manual operations to produce the most cost-effective production.

Mechanical Properties. From a mechanical properties standpoint, precision is viewed as the ability to achieve a repeatable strength. The value used to statistically represent an achievable strength of a material is called an allowable. As identified in the previous discussion on strength, stiffness, and weight, composite design often uses strain or elongation to evaluate the strength. When determining at what point a ply will fail in elongation, numerous mechanical coupons are tested to achieve the design value. Calculating an average of all the test values yields a result where approximately half of the values have already failed. The average, or mean value, is typically not acceptable in determining the design allowable, because a 50% probability of failure is not acceptable; however, average values are used in test correlation to evaluate the accuracy of an analysis method.

The minimum specified mechanical property value is called the S-value.

Design allowables are chosen to select a value to ensure that failure will not occur. Statistics are applied to select an acceptable likelihood of failure. Typical statistical values are termed A-basis and B-basis. For A-basis, 99% of the test results should exceed the allowable value with a 95% assurance. For B-basis, 90% of the test results should exceed the allowable value 95% of the time. A-basis allowables are more conservative and used on single-load-path structures, where a failure of the part will result in failure of the structure. B-basis values are typically higher than A-basis values and are used where multiple load path exists, and failure of one part will not result in failure of the entire structure. Being based on statistics, the lower the spread between the minimum and maximum test values and the greater the number of values pooled in the statistical data, the higher the resulting allowable. Repeatability and precision are necessary to translate the test values into the final product. Detailed discussion on test methods and statistical reduction methods can be found in the article “Design Allowables” in this Volume, and in MIL-HDBK-17 (Ref 2).

Whether stress or strain is used to model the failure, only those values will be statistically reduced. Separate statistical allowables are usually determined for tension, compression, and shear. Axial stiffness (E_1), transverse stiffness (E_2), shear stiffness (G_{12}), and Poisson's ratio (ν_{21}) values will be determined from the test results. For many materials and applications, the stiffness and Poisson's ratio value will be an average between tension and compression tests. Only in cases where tension stiffness is significantly different from the compression stiffness will different values be used during the design analysis. Stiffness and Poisson's ratio are often only determined at room temperature. For a structure that experiences primarily room-temperature conditions, these elastic constants are acceptable. When the structure is subject to loads at sustained high or low temperatures, it is necessary to evaluate these elastic properties at these conditions.

Allowables must account for the environmental spectrum that the structure will be exposed to during its service life as well. Mechanical testing is performed with coupons conditioned at room temperature, the minimum and

maximum temperature range, and with fluid contamination. Determining separate allowables for each environmental condition is recommended.

With the high costs and time-consuming nature of mechanical testing, determining a separate allowable with data pooled at each environmental condition has come under considerable scrutiny. The Advanced General Aviation Transportation Experiment (AGATE) program has implemented a methodology where normalized test data are pooled from all environmental conditions to determine allowables; this approach uses the statistical benefit of pooling large quantities of data (Ref 3). The AGATE methodology has made materials testing less of a burden for smaller companies.

Material allowables are typically generated for unidirectional material. The ultimate strength or ultimate strain has been shown to depend on the laminate stacking sequence. The 0° failure strain can be higher for laminates that have more ±45° plies. To account for this, some statistical models for determining allowables are based on percentages of 0°, 90°, and ±45° plies.

Damage Tolerance and Durability

Damage of a massive nature, as well as hidden damage and flaws, are considerations for the designer.

Massive Damage. If a structure is going to be operating in an environment where it may potentially become damaged, it is a concern that a catastrophic failure not occur before the damage is discovered and can be repaired. Significant damage that affects a large area may impact a primary load-carrying member of a structure and lead to immediate failure. To prevent this, a designer must employ multiple load paths so other structural members are present to carry the load. Multiple-load-path structures require the use of B-basis material allowables. A single-load-path structure is one such that a single member failure would lead to a catastrophic failure of the structure. Single load path requires A-basis material allowables.

Minor Damage. Of equal concern to significant damage is small damage that can go unnoticed or is barely visible. This type of damage is often referred to as barely visible impact damage and is of great concern, because small damage can grow without being detected and eventually lead to a catastrophic failure. The study of damage growth is called fracture mechanics. Predicting damage growth with composites is very involved, because variability in fiber, fiber forms, ply orientation, matrix material, and laminate configuration will affect the results. Determining if the damage growth will lead to a catastrophic failure is the study of damage tolerance. Cyclic mechanical testing and analytical methods are used in damage tolerance calculations to help determine inspection intervals that would discover damage growth before failure occurs. Related to damage tolerance is damage resistance, which involves the materials selection and structural configuration categories of the design considerations. These considerations focus on designing a structure that is not prone to damage and likewise result in a structure that is more damage tolerant.

Damage growth in a composite typically occurs when delamination forms at the tip of a crack. The delamination grows with increasing severity of load cycles. The delamination can reduce the effective laminate modulus and cause a redistribution of stress that eventually leads to fiber breakage and finally, laminate failure. Damage tolerance can be improved by using toughened resin systems that resist crack propagation. The use of honeycomb core in frequent-impact areas needs to be closely evaluated. The choice of stiffened solid laminate

substructures or sandwich panels will affect the damage resistance of a structure. Sandwich panels are significantly stiffer for the weight and amount of material used, but are more subject to impact damage normal to the plane of the panel. Increasing the compressive strength of the core provides greater impact resistance to the facesheets for low-energy impacts, but for high-energy impacts, the core properties have very little effect on penetration of the facesheet. The effects of impact damage on core panels can be seen in Fig. 5. See the article "Damage Tolerance" in this Volume.

Design Criteria

Greg Kress, Delta Air Lines

Environmental Constraints

Environmental factors, such as temperature, moisture, corrosive liquids, light, and other radiation, must be considered. If the environment of the final assembly is not known by the composite designer, the allowable service environment should be stipulated. Often, industries classify materials for use in specific environments.

The effect of environmental degradation on the mechanical integrity of a composite is significant. Moisture can also migrate through sandwich panel facesheets or enter as a result of impact damage and be absorbed in the honeycomb core, as shown in Fig. 6. Low-resin-content prepregs and sandwich panels with a low number of facesheet plies are easy candidates for moisture intrusion. Moisture can also seep through open-cell foam cores. Open-cell foams, as opposed to closed-cell foams, have an interconnected network of cells, similar to a sponge. Many foaming adhesives used to bond honeycomb core pieces together have an open-cell structure that allows water to migrate deep inside honeycomb core sandwich panels. The absorbed moisture can freeze, expand, and delaminate the skin from the core. The combination of low- resin-content aramid fiber sandwich laminates, using aramid paper core, assembled with open- cell foaming adhesives have been problematic.

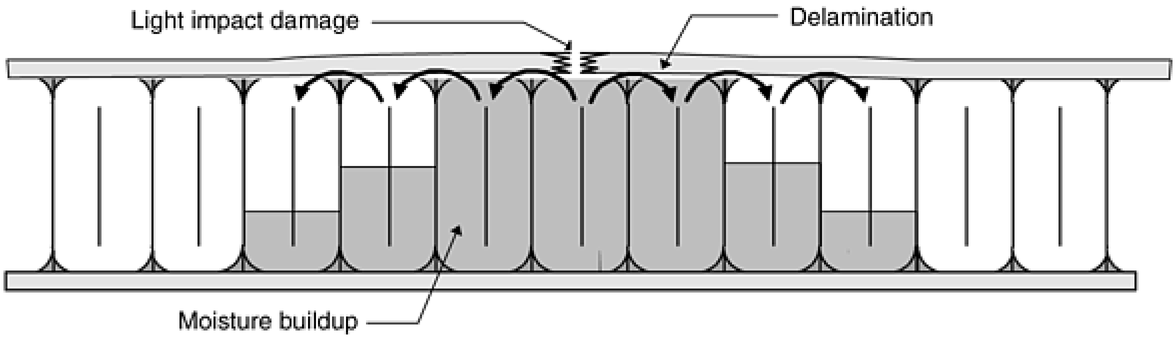

Fig. 6 Moisture propagation into a honeycomb core sandwich structure

Environmental considerations need to be addressed at all phases in the life cycle of a composite. In the production phase, uncured composites can be drastically affected by temperature, moisture, and contamination. B- staged prepregs and adhesives have limited storage times at frozen temperatures, typically 6 to 12 months at–18 to–12 °C (0 to 10 °F). At room temperature, the shelf life is reduced even more, typically 10 to 30 days. Prepregs are so sensitive to storage time at a given temperature that the time out of the freezer and at room temperature is usually tracked in hours. This is called the out time. Liquid resins and adhesives are also affected by temperature, by increasing or decreasing the working life of the material. Increasing the ambient temperature of a resin will decrease the pot life of the material. A standard rule, called the “10 degree rule,” for resins states that increasing the temperature 6 °C (10 °F) from a specified temperature will reduce the working life of the resin by half.

Moisture affects uncured composite materials by being absorbed into the resin. Prepregs, while in frozen storage, are sealed in plastic bags to prevent frost from forming on the B-staged material. Because moisture condenses on objects removed from a frozen environment, prepregs are not removed from their plastic storage bags until after the material has warmed to the surrounding temperature. Out time is logged as the time from when the roll is removed from the freezer until it is resealed and placed back in the freezer.

Moisture, even humidity in the air, affects liquid resins by chemically altering the material. Absorbing moisture results in lowering the glass transition temperature, T_g. The T_g, which can be determined several ways, is an indication of the service temperature of a composite laminate. Moisture can also absorb into fibers and core and have an effect on elastic and strength properties. Aramid fibers and aramid paper core are known for absorbing moisture. This moisture must be removed prior to a high-temperature cure, to prevent delamination from moisture expansion. All aramid-based materials should be stored in a low-humidity environment. Fiberglass is also susceptible to moisture degradation. Common fiber finishes applied to fiberglass to promote resin adhesion are water soluble and can be removed if dry fiberglass material comes in contact with moisture.

Uncured composite materials are also very susceptible to environmental contamination. Oils, grease, or silicone-based products should not come in contact with dry material, prepregs, or core material. Compressed air and careless application of release agents are common sources of contamination. The need to limit heat, moisture, and contaminants have led to the use of “clean rooms” as the location where raw composites are processed. Clean rooms have strictly controlled temperature and humidity. The use of compressed air, release agents, and room pressure are controlled to maintain the location free of contamination.

Cured composites are also susceptible to environmental degradation. In hot/wet conditions, the resin is typically attacked first; moisture absorbed into the cured resin lowers the T_g. At elevated temperatures when the T_g is reached, the resin softens to the point where load is not efficiently transferred through the laminate, and premature failure occurs.

Resins are the environmental “weak link” in a composite. Hydraulic fluid, brake fluid, paint strippers, and other corrosive chemicals soften and dissolve various resins. Small impacts, heat, and ultraviolet rays can erode away the resin on the surface of a laminate and leave the fiber reinforcement unsupported. Maintaining a proper surface finish, controlling service temperature, and keeping trimmed edges and fastener holes sealed mitigate the adverse effects of environmental degradation.

Conclusions

Composite materials offer a wide range of flexibility for the designer. Although so many possibilities give the designer many options, it needs to be remembered that some combinations will work better and cost less and will be easier to manufacture, easier to repair, stronger, stiffer, lighter, or more damage resistant. Having so many options also means that there is a greater opportunity to make the wrong decision. Because the widespread use of composites is still relatively new, there are many design considerations that have not been fully evaluated. Some applications evolved as replacements for parts made from metal or natural materials. The design was dictated by the characteristics of these materials. The possibilities of composites allow for imaginative designs. A designer can evaluate the past applications of composites and determine which combinations have produced better results. The designer should remain mindful of previous successes and failures, but also maintain a close watch on new developments and future trends. A designer must use sound engineering practices to ensure the integrity of a composite design. Applying these practices to modern composite technology will guarantee viability in the marketplace.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Introduction

DESIGN ALLOWABLES are statistically determined materials property values derived from test data. They are limits of stress, strain, or stiffness that are allowed for a specific material, configuration, application, and environmental condition. The selection of appropriate design allowables for structures composed of composite materials is essential for the safe and efficient use of these materials. To help ensure safety, the use of appropriate design allowables is required by regulatory agencies for aircraft structures, for example. An extensive discussion and guidelines for the development and use of design allowables is contained in MIL-HDBK-17 (Ref 1). While certain industries use different terms, and unfortunately, similar terms are assigned different meanings, the general concept of design allowables is applicable to other industries as well.

A design engineer or materials scientist is often faced with the difficult challenge of finding or generating these allowables. While more conventional structural materials, such as metals or plastics, have allowables, these materials are generally considered to be homogeneous, which limits the possible failure modes, and hence, the testing required to characterize the material. Composites are heterogeneous and show varying degrees of anisotropy, resulting in a larger variety of potential failure modes. Because composites are an engineered material, the designer often cannot simply look up composite design allowables in a handbook or generic database, but must rather make informed decisions as to the selection, computation, quality, and applicability of allowables. This article discusses:

- The need for design allowables
- The development of design allowables
- Important factors that affect the selection of allowables
- Lamina versus laminate allowables
- Extending laminate results
- Specific techniques used in the statistical development of allowable values

The selection of the appropriate degree of testing to achieve the proper balance of initial cost versus the degree of certainty required for design allowables is discussed briefly here and in more detail in the Section “Testing and Certification” in this Volume.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Need for Design Allowables

Design allowables are used to ensure the safe and successful operation of a part or structure. Design begins with a determination of the use of the structure. See the article "Design Criteria" in this Section. The anticipated static and dynamic loads as well as the environment are among the considerations. Conversely, failure is defined. This is not always obvious. Microscopic "failures" are a strain relief mechanism that may increase the toughness of a material. Structural analysis will determine the most likely failure modes. The mechanical failure of a structure or substructure is usually related to exceeding the strength or deformation capabilities. Whether strength or deflection controls the design, an allowable strength value is a specified stress or strain level that must not be exceeded. The design allowables are obviously a function of the constituent material, the amount, and the arrangement of that material.

Allowables are normally determined in a manner appropriate to the consequences of failure; the allowables for a component for which failure is cosmetic would be determined much differently than the allowables of a structure for which failure might lead to loss of life.

Design allowables are the statistically defined materials property allowable strengths, usually referring to stress or strain, that are determined by a well-documented test program. Design allowables must account for all materials property variability that can reasonably be expected in the manufacture and assembly of a composite component. They must also account for manufacturing process variations and acceptable anomalies and for structural analysis limitations. Often, design allowables are intimately tied to a particular analysis method and, in these cases, cannot be used with other analysis approaches.

The factor of safety (FOS) is the ratio of the allowable load that the structure can carry to the applied load on the structure. Regulatory agencies prescribe minimum FOS for specific structural applications. These regulatory minimum FOS are established to account for all the uncertainties in loading, geometry, workmanship, variations in use and environment, accuracy of the design mathematical models, and uncertainty in the knowledge of the materials property values.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Development of Design Allowables

Historically, calculation of composite material design allowables has been modeled after the techniques used for metals. In the aerospace industry and in other design venues, the use of *A*- and *B*-basis allowables, originally developed for use with metallics, is commonly accepted by most certifying authorities. Simply stated, the *A*-basis allowable of a given materials property is the value that 99% of the property value population is expected to exceed with 95% confidence. Similarly, the *B*-basis allowable is the value expected to be exceeded by 90% of the property value population, also with 95% confidence. For a given set of experimental data, the determination of *A*- or *B*-basis allowables is primarily affected by three parameters: the mean, the variability of the test data, and the number of tests. The specific distribution model for the variability of the data also has a large effect. For homogeneous materials, this approach works well. These allowables can be developed under a moderate degree of testing of relatively small samples, and allowables can be concisely summarized in a specification, database, or handbook. For composite materials, the situation is a great deal more complex.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Factors Affecting Design Allowables

Heterogeneity. Composite materials are, by definition, heterogeneous. This heterogeneity confers unique advantages to composites over homogenous materials, but complicates the development of design allowables. The number of potential failure modes of the material is increased due to the presence of multiple constituent materials. For example, in polymer-matrix composites (PMC), some failure modes are sensitive to matrix properties, some failure modes are dominated by reinforcing-fiber properties, and some failure modes are most strongly influenced by the properties of the fiber-matrix interface. The dependence of specific failure modes on polymer-matrix composites is shown in Table 1. It is vital to understand how failure modes are influenced by constituent properties so that tests can be properly configured to yield rational design allowables. It is also critical that multiple failure modes are not contained in a set of data used to calculate an allowable. Test results with different failure modes should be separated before allowables calculations are performed.

Table 1 Failure modes of composite materials

Property/failure mode	**Dominant constituent**	**Stress-strain behavior**	Factors affecting properties
Stiffness			
Elastic constants	Fiber	Linear (except shear)	**Temperature**
Buckling	Fiber	Linear	**Fiber alignment**
Crippling	Fiber	Linear	**Element geometry**
In-plane strength			
Tension	Fiber	Linear	**Low temperatures**
Compression	Matrix/interface	Some nonlinearity	**Moisture/elevated temperature**
Shear	Interface	Nonlinear	**Moisture/elevated temperature**
Pin bearing	Matrix/interface	Some nonlinearity	**Element geometry**
Bearing/bypass	Matrix/interface	Some nonlinearity	**…**
Out-of-plane strength			
Interlaminar shear	Matrix	Nonlinear	**Elevated temperatures**
Interlaminar tension	Matrix	Nonlinear	**Moisture content**
Free-edge failure	Matrix	Nonlinear	**Chemical exposure**
Durability/damage tolerance			
Notched tension and compression	Interface	Some nonlinearity	**Elevated temperatures**
Compression after impact	Matrix/interface	Nonlinear	**Moisture content**
Fatigue	**Matrix (only for properties sensitive to fatigue)**	**…**	**Load history**

Anisotropy. As an engineered material, a composite can be designed to satisfy specific directionally based needs. The designer of a composite structure can modify the percentage of fibers aligned in a given direction to meet specific design requirements. This feature is one of the principal advantages of composite materials. This ability to customize the composite adds to the complexity of determining allowables. Composite structures can range in degree of anisotropy, from isotropic to fully anisotropic. Many laminated composites exhibit orthotropic behavior. Fibers are usually aligned within a two-dimensional plane, either uniaxially or cross-plied, thus imparting relatively high (but variable) stiffnesses and strength within this plane. Properties normal to this plane are dependent almost solely on the properties of the matrix and thus, are usually much lower.

Equipment and good design practice often limit the options of fiber lay-ups and stacking sequences. Fortunately, unsymmetric or unbalanced laminates are rarely found in actual components. The presence of extension-bending coupling or shear-extension coupling found in unsymmetric or unbalanced lay-ups can make

the development of allowables significantly more difficult. Other design guidelines can further restrict the permissible design space, as is discussed later.

Stacking sequence effects are important, however, even in a symmetric, balanced laminate. For failure modes influenced by bending loads or for failure modes sensitive to free-edge stresses, the specific order of the plies has a significant effect and warrants consideration in the development of allowables.

Environmental Effects. The environment in which a composite material is used can have a significant effect on materials properties. Changes in temperature affect all materials, and constituent materials of composites can be influenced to differing degrees. This difference in thermal expansion will create residual stresses within the material. Other important environmental effects include moisture (especially for PMC), exposure to specific gases, liquids, or solids, or even exposure to ultraviolet light or high- energy particles. The article "Hygrothermal Behavior" in this Volume addresses thermal and moisture effects.

In determining allowables, one must obviously have knowledge of the projected environment. One will also need to know the degree of impact that a particular environment has on constituent materials. For example, moisture has very little influence on carbon fibers, but can significantly affect the properties of polymer-matrix materials. Such knowledge is vital to efficiently determine allowables over the entire range of expected design conditions. However, it is very important not to make unfounded assumptions about which environmental conditions are critical, especially with new materials systems. Sometimes, complex interactions between the fiber and matrix lead to unexpected environmental conditions becoming critical.

Consider the case of a carbon-fiber-reinforced PMC. For subsonic aircraft, a typical range-of- use temperature is–54 to 82 °C (–65 to 180 ºF). A wide range of humidity conditions is to be expected, so the moisture content of a composite structure could range from fully saturated to completely dry. At lower temperatures, the matrix tends to become more brittle, and tensile properties can be reduced. The presence of moisture would serve to reduce brittleness, so one should expect that tensile properties would be more critical at lower temperatures under dry conditions. At the other extreme of temperature, the stiffness and strength properties of the fibers should remain largely unaffected, while matrix properties can degrade significantly, especially in the presence of high moisture content. One should therefore concentrate testing efforts on those failure modes that are influenced by the constituent most sensitive to environmental effects. For in-plane tensile properties, low-temperature, dry conditions are typically critical. For shear and compression failures, the critical environmental conditions are usually at elevated temperature and fully moisture-saturated conditions.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Lamina Versus Laminate Allowables

When developing a plan to determine composite material allowables, a decision must be made to develop allowables for lamina or laminate properties, or both. If allowables are developed for lamina properties only, the list of required properties is relatively brief, with only a few stiffness and strength terms required. Unfortunately, lamina properties by themselves are rarely sufficient for design of composite structure. Lamina data can be used to predict laminate behavior with certain analytical assumptions. The results can be used as a first step in the materials selection process, but this building-block testing approach may or may not result in what are considered "laminate allowables." The articles "Overview of Testing and Certification" and "Testing and Analysis Correlation" in this Volume address this testing approach.

Analytical limitations currently exist in predicting failure for important failure modes when moving from lamina properties to practical laminates. Important failure modes that dominate design, such as bolted joint design, compression after impact, and notched strength, embody complex geometries and stress states that are extremely difficult to predict on a general analytical basis. The practical approach in dealing with these failure modes is therefore to employ empirical or semiempirical prediction methodologies that use laminate design allowables that are "tuned" to a specific analytical approach. Accurate predictions can then be achieved over a prescribed design space for which properties and allowables have been determined.

Stiffness-based failure is one subset of failure predictions in which values derived analytically from lamina properties can be reliable. Failure modes, such as panel and local buckling or design requirements based on deflection or stiffness, can be adequately predicted based on lamina stiffness properties. Common practice is to establish stiffness properties on a lamina. Note that because excessive stiffness can alter load paths and result in unexpectedly high stresses, upper and lower bounds are often placed on lamina stiffness properties. Also, because of the potential for matrix nonlinearity, techniques to “linearize” certain nonlinear stiffnesses are often employed. For example, for PMC, the secant shear modulus of a lamina is often substituted for the initial shear modulus when assessing composite strength.

Efforts are currently underway to develop general failure prediction methodologies based upon fundamental constituent materials properties and laminate geometry. Should these efforts result in accurate, robust failure predictions over a wide range of materials and failure modes, allowables development could be shifted to a lamina, unit cell, or constituent level, thereby reducing the effort in laminate allowables development (Ref 2).

Manufacturing Techniques and Constituent Forms. The use of certain manufacturing methods or constituent forms invalidates the concept of lamina or laminate. For example, the use of three-dimensional textile fiber forms in conjunction with injection molding processes produces a composite with no lamina or laminate in the conventional sense. Bulk molding compounds are another example of composites that are not laminates. The use of a unit cell concept in this context is more logical, and allowables generated for the unit cell might be an efficient approach.

Requirements for Laminate Allowables. As previously discussed, laminate allowables are employed due to the difficulty in predicting most strength-dependent failure modes using lamina properties. It is important to recognize that laminate allowables are usually developed for a specific analytical technique that has been proven to correlate to a particular failure mode. The test specimen geometry, the test procedure, experimental results, and the analytical methods used to predict failure are all interconnected, and the resulting allowables are appropriate only for use in that specified analytical method. An example of this analytical dependence is the prediction of bolted joint strength. Test data are collected on specific geometrical and loading conditions, then semiempirical analytical techniques are used to extend the test data to other geometries and loads. Several analytical techniques are in use today in the composite industry to predict bolted joint strength, with each technique requiring the collection of specific test data under specific experimental configurations (Ref 3). See the article “Bolted and Bonded Joints” in this Section for more information.

Design Allowables

Chris Boshers, Composite Materials Characterization, Inc.

Extending Laminate Results

Extrapolation of design allowables, that is, the use of design allowables beyond the point for which supporting test data exist, can lead to very unconservative results. Because of unexpected changes in materials behavior and failure modes, extrapolation should *never* be used. Laminate allowables should be developed to the actual working loads. Certain failure modes exhibit dramatic changes beyond given points. Consider, for example, the

case of the transverse tensile strength for a laminate as the percentage of 0° fibers increases. When the percentage of 0° plies increases to 100%, the transverse tension strength drops dramatically. Good design practice limits this sort of extreme example, but the dangers of extrapolation exist for most failure modes.

Interpolation between two or more values is acceptable as long as no significant nonlinearities or discontinuities are expected and the failure modes are the same. Certain failure modes can exhibit local minima or maxima, which could cause problems on interpolation. Obviously, caution must be employed, but one can usually deal with such behavior through increased testing, analytical treatment, and experience.

Design space includes a variety of variables, including lay-up, thickness, temperature, and other design or environmental effects. Laminate allowables must be developed across the *design space* for which one intends to use the selected material. Figure 1 illustrates the lay-up design space for a two-dimensional laminate composed solely of 0º, ±45°, and 90° oriented unidirectional tape plies. The design space meeting the guidelines is shaded. Possible laminates at which to evaluate design allowables are indicated. These identified laminates bound the laminate design space. Combined with other test data taken at the extremes of temperature, moisture content, and other environmental effects, one should be able to confidently use the resultant design allowables for all permissible structural configurations.

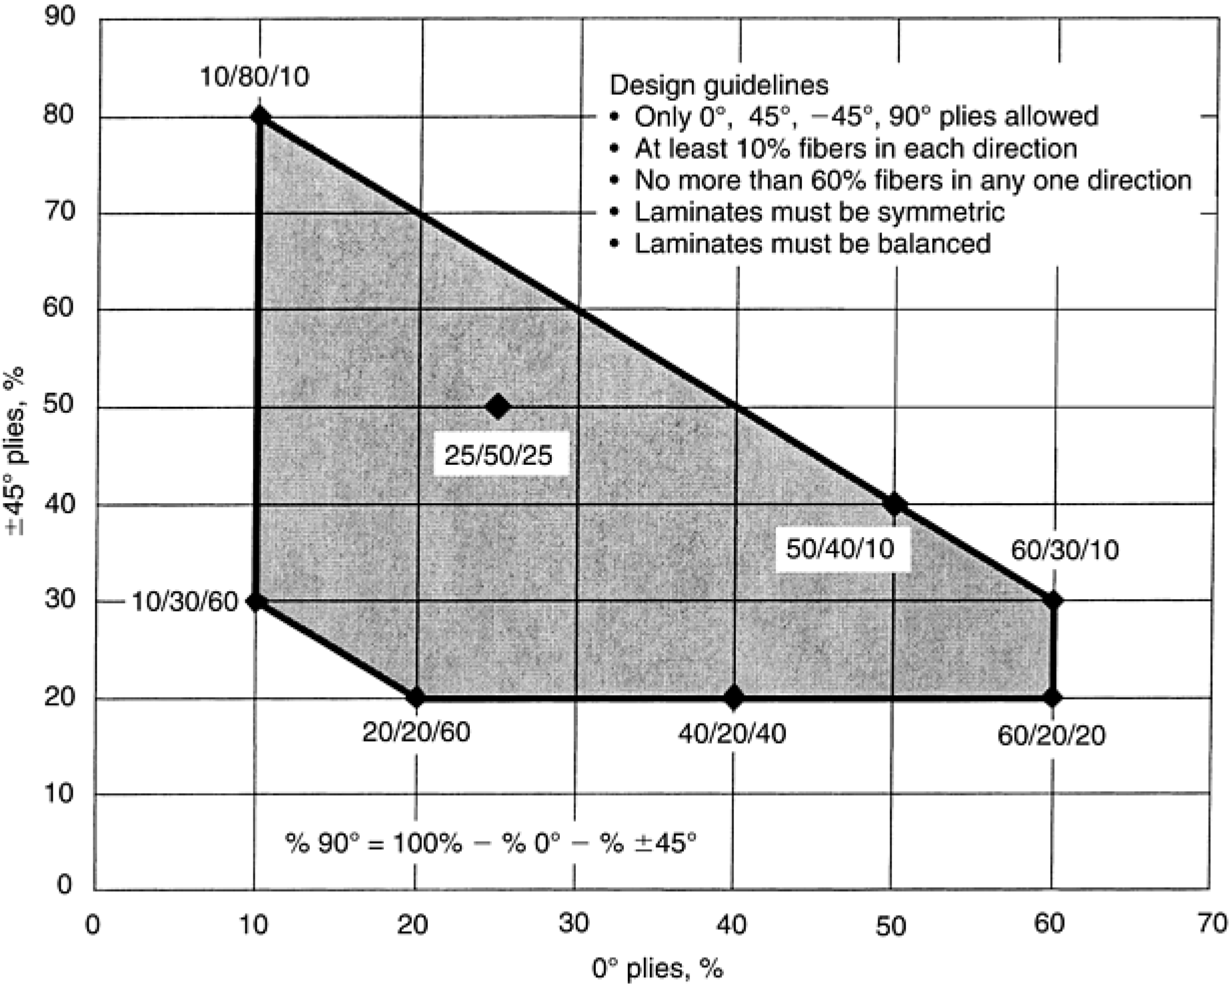

Fig. 1 Sample laminate design space

One can also quickly grasp the main problem associated with the use of laminate-based design allowables. A significantly greater degree of testing is needed to generate design allowables for laminates than for lamina allowables. The costs associated with a test program can be enormous, and if the budget will not support such a test program, there are two options: limiting the design space so that allowables are needed for fewer combinations of laminates and environmental condition, or using statistical techniques that reduce required testing. As an example of limiting the design space, the designer may specify that only quasi-isotropic laminates (25/50/25) will be used in a particular design, thus dramatically reducing the required scope of testing. Such a limitation can reduce the advantages composites have over other structural materials, however.

Hybrid methods can be a very cost-effective means of obtaining high-quality lamina or laminate allowables. As an example of a hybrid method, laminate mean values could be developed across the design space for all

important failure modes, and using statistical data gathered through lamina testing, allowables could be determined. A lamina/laminate approach is under development and evaluation by a MIL-HDBK- 17 committee at the time of this printing.

Carpet Plots. The ability to predict an infinite number of variations in laminates without sophisticated software could potentially constrain and confuse the design process. In the past, some companies had restricted themselves to the use of 0°, ±45°, and 90° lamina orientations. This is becoming less true, as a generalization, with the advance in composite technologies. Given specific angle orientations as a constraint and the assumption of a uniaxial load case, laminate data can be represented by *carpet plots*, which are maps of a laminate property versus the percentage of one of the lamina orientations. Figures 2, 3, and 4 show the axial stiffness, axial strength, and Poisson's ratio for a 0°, 45°, and 90° laminate family. The carpet plot is for a given design temperature and for a certain design strength criterion, such as *B*-basis for the ultimate properties. The carpet plots assume that the laminate is linear to failure (that is, no material nonlinearities, no ply cracks, and no extraneous failures such as free-edge stresses). For some materials, carpet plots of strength are inaccurate at the 0% 0° ply laminates.

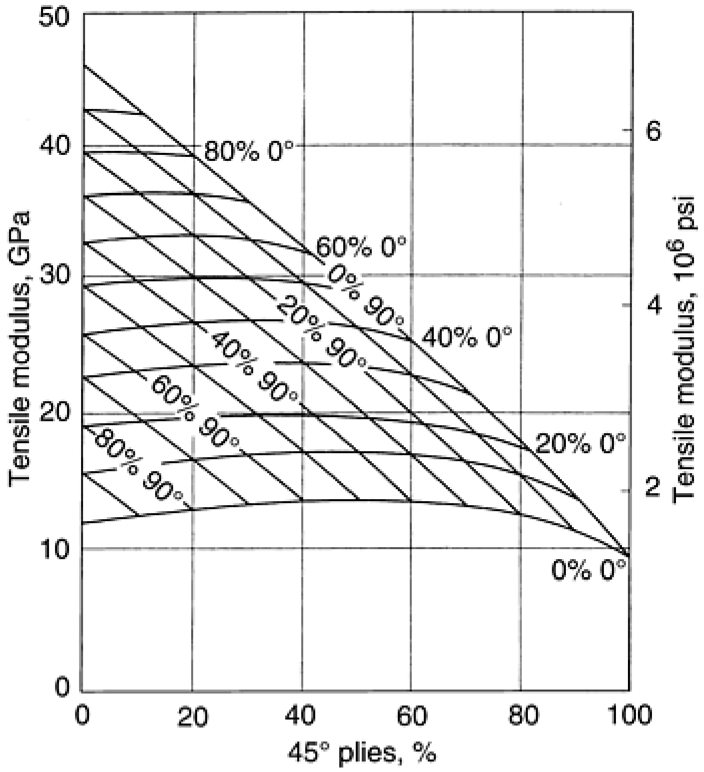

Fig. 2 Carpet plots illustrating tensile modulus of laminates

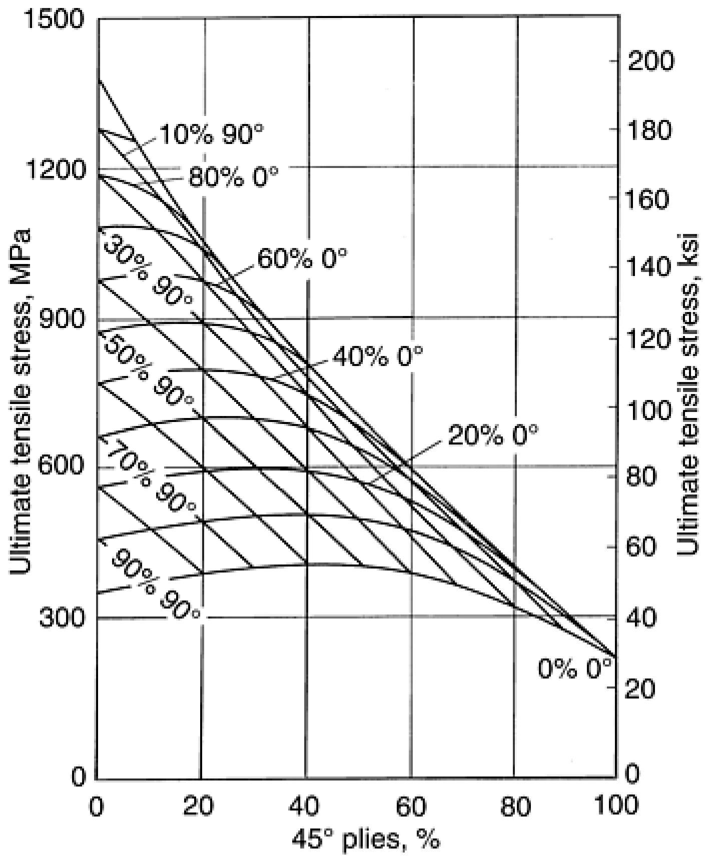

Fig. 3 Carpet plots illustrating tensile strength of laminates

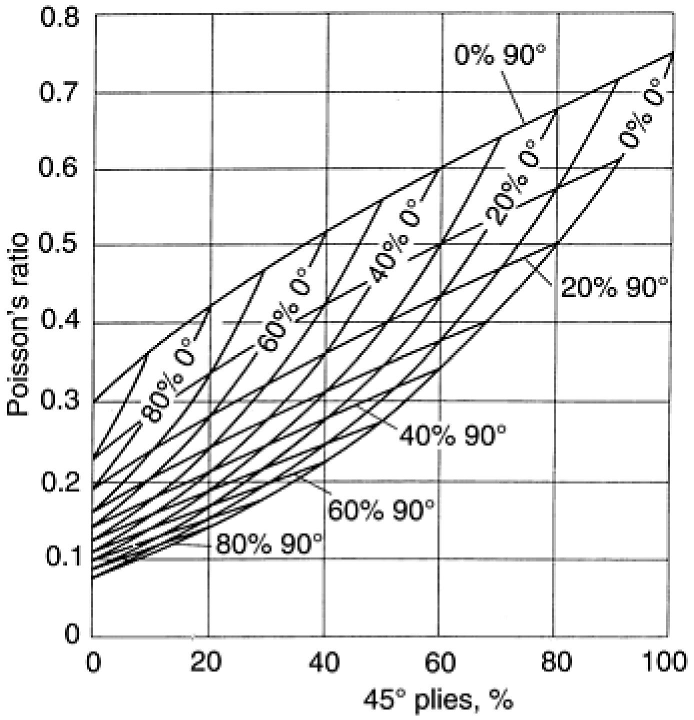

Fig. 4 Carpet plots illustrating Poisson ratio variation

Carpet plots are simple to use. One interested in a particular laminate property would first select the appropriate plot for the design application. Stiffness properties are given in Fig. 2. For a laminate composed of 40% 0° fibers, 50% ±45° fibers, and 10% 90° fibers, the stiffness is read at 26 GPa (3.8×10^6 psi). The procedure is to first find the percentage of ±45° plies, and then follow that value vertically until it intercepts the correct percentage of 0° or 90° plies, both at the same point. Then, the ordinate value for the laminate stiffness can be read.

Equivalence. Certification efforts that build on existing materials property information are also worthy of investigation. If one can demonstrate materials and process equivalence to a material in an existing materials property database, then potentially one can use the higher allowables determined for the combined data set. It has been recognized by agencies such as the Federal Aviation Administration (FAA) in the United States that a significant cost savings can be realized by industry and the FAA by sharing an approved central database and standardizing the engineering protocol to demonstrate materials equivalency (Ref 4).
The effect of the population size is illustrated in the example that follows in the next section. This approach offers dramatic cost and time savings. Details are found in the article “Test Program Planning” in this Volume.

Design Allowables

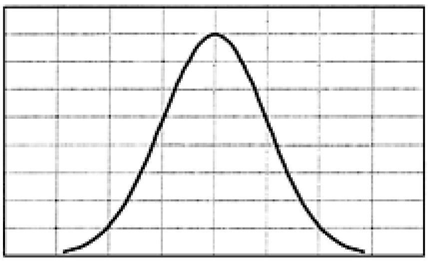
Chris Boshers, Composite Materials Characterization, Inc.

Statistical Determination of Allowables

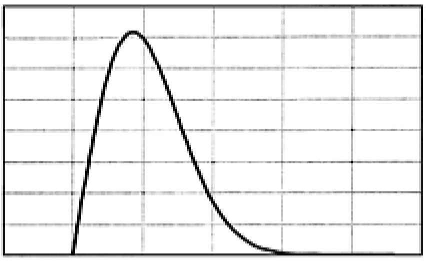
In this section, a brief overview of the procedure for computing *A*- or *B*-basis allowables is presented. A comprehensive treatment of the subject can be found in the MIL-HDBK-17-1E (Ref 1). Computer software and spreadsheets are also available from the MIL-HDBK-17 web site (www.mil17.org) to assist in establishing allowables. The flowchart from the Military Handbook that illustrates the *B*-basis procedure is reproduced in the article “Overview of Testing and Certification” in this Volume.
The actual computation of an allowable is conceptually quite simple. However, in practice, a high degree of experience and judgment related to testing, data analysis, and statistical calculations are required. The *A*- or *B*-basis values described earlier are functions of the following:

- Probability distribution
- Number of specimens tested
- Statistics describing the probability distribution

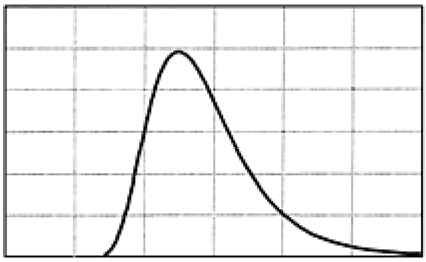
MIL-HDBK-17 contains a detailed description of the statistical procedures for determining allowables for composites. The simplest method for allowables calculation, using the normal distribution method, is described subsequently. Besides the normal distribution, the population may be better described by a Weibull or lognormal distribution, or if it fits none of these, a nonparametric calculation is used (Fig. 5). The *B*- basis value can be determined from the formulas given in MIL-HDBK-17 section 8.3 for each type of distribution.



Normal distribution



Weibull distribution



Lognormal distribution

Fig. 5 Common types of population distributions

Normal Method for Obtaining *B*-Basis Values. These examples consider the case of a set of data that are normally distributed, have no batch-to-batch variations, and have no outlier data points. If these assumptions are validated, the *B*-basis value is then calculated using the formula:

$$B = \bar{X} - k_B s$$

where $\bar{X}$ is the mean, s is the standard deviation, and k_B is the one-sided *B*-basis tolerance factor for a normal distribution, obtained from Table 8.5.10 of MIL-HDBK-17-1E.

Example: Effect of Number of Specimens Tested on *B*-Basis Values. Suppose that 12 specimens were tested. The data are a normal distribution with the mean and standard deviation computed as:

$$\bar{X} = 45.2 \quad s = 4.6$$

For the number of specimens tested (n = 12):

$$k_B = 2.211$$

and the *B*-basis value (*B*) can be computed as:

$$B = \bar{X} - k_B s$$

$$B = 45.2 - 2.211 \times 4.6$$

$$B = 35.0$$

As an illustration of the effect of a change in sample size, if the samples were doubled through more testing or finding valid database information, and the mean and standard deviation were still unchanged:

$$k_B = 1.854$$

and the *B*-basis value (*B*) can be computed as:

$$B = 45.2 – 1.854 \times 4.6$$

$$B = 36.7$$

This may not appear to be a great difference, but it does represent an almost 5% increase in the design allowable, with the same degree of confidence in the result.

If the population size were infinite, the largest *B* value would be attained by definition of the 90th percentile for a normal distribution:

$$k_B = 1.282$$

and the *B*-basis value is:

$$B = 45.2 – 1.282 \times 4.6$$

$$B = 39.3$$

Each population distribution-type has a unique means of determining allowable values, but the basic procedures are similar.

Sample Size. The most common question when planning a test program to determine allowables is probably, “How many tests are enough?” As seen previously, the answer is significant. Unfortunately, the answer is not simple. The size of the test sample depends upon:

- Statistics used
- Expected variability exhibited by the material
- Anticipated use of the material
- Whether *A*- or *B*-basis allowables are required

>An often-quoted number of individual tests at a given set of test and laminate conditions is 30 tests (six tests from each of five material batches) for the development of *B*-basis allowables for a particular property for a new material. For particular industries, standards or certifying organizations may have guidelines or mandates. Under the Advanced General Aviation Transport Experiments (AGATE) program, sponsored by the National Aeronautics and Space Administration (NASA) and the FAA, three batches of materials with 18 total

specimens are recommended for *B*-basis allowables, and five batches with a total of 55 specimens are suggested for *A*-basis allowables (Ref 5).

If not bound by specific requirements, the answer to the question of sample size lies in the economics of the cost of the testing as compared to the cost of the reduced allowable values. As seen previously, reducing the sample size has a direct effect on allowables; for two samples with the identical mean and variability, the sample with fewer tests will have a lower allowable. If one has a rough expectation of the average and standard deviation, the impact of sample size can easily be evaluated, and sample size can be selected based on trade studies of testing costs versus the cost of lower allowables. The distribution of *B*-basis values as a function of sample size is shown in Fig. 6.

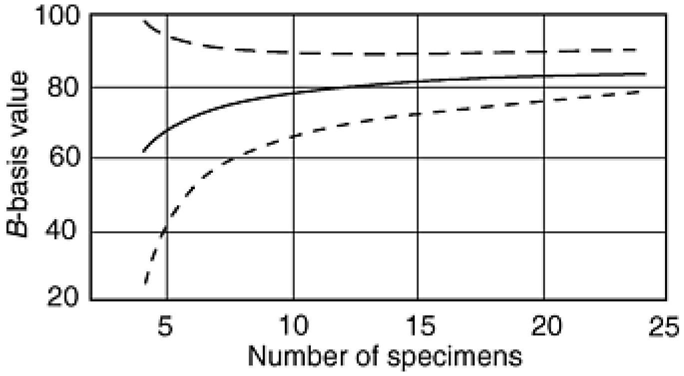


Fig. 6 Range of *B*-basis values as a function of the number of specimens. One sigma limits; mean = 100; standard deviation = 10. Source: Ref 1

The use of regression, data pooling, or other statistical techniques can reduce sample size while not incurring the same negative impact on allowables normally incurred by performing fewer tests. These techniques can be more difficult to use, however, and may incur greater scrutiny from a certification authority such as the FAA.

Computational Procedures. While the example calculations for design allowables were simple, the steps leading up to that point are much more involved. These steps include:

- Determining whether the data is from a single batch or multiple batch, and whether there are statistically significant variations between batches
- Selection of the calculation based on whether data is structured or unstructured
- Detecting and evaluating outliers
- Selection of distribution type by analysis

Structured versus Unstructured Data Sets. The sources of variability in a composite material include the materials property variability of the constituent materials, batch-to-batch variability, panel-to-panel (or component-to-component) variability, or variability within a given panel or component. Since multiple test coupons could be composed from a single batch or machined from a given panel, if batch or panel variability is significant, the resulting data set is said to have structure. The presence of structure in a data set is undesirable—in effect, the size of the data set is reduced, thereby negatively affecting allowables.

The effect of structure within a data set can be dramatic. The best means of dealing with expected variability due to differences in material batches or panels is to include sufficient numbers of batches or panels, such that the variability of these effects can be assessed separately from the basic material variability. Five independent batches of material are commonly recommended for use in the development of allowables for a new material. Proper planning of the test program is also important. One can minimize the effects of panel variability by using test coupons taken from different panels for identical test conditions. Using larger numbers of smaller panels is also preferred over using fewer numbers of large panels.

Outliers in the Data Set. The data should be screened for possible *outliers*. These are data values that vary greatly from the rest of the population. Possible reasons for outliers are clerical or test procedural mistakes, mishandling of test samples, or simply poor-quality material. The outliers should be investigated to determine source of the discrepancy. If it is truly determined to be erroneous, it may be dropped for the data set. If no cause can be found for the discrepancy, the data must be kept as being a valid result. Statistical methods are available to define the deviation from the mean when compared to the standard deviation, which would categorize a data point as being an outlier.

Selection of Proper Population-Distribution Type. Use of the population-distribution type, which best describes the specific failure mode results, is obviously very important in obtaining accurate design allowables. Proper selection is aided by statistical procedures that test whether the data fits a Weibull, normal, or lognormal distribution (Ref 4). The Weibull distribution is often considered to be the most appropriate for strength distributions of classical brittle materials and is appropriate for many composite failure modes. However, the normal distribution has been found to fit composite material data just as well as the Weibull distribution and is much easier to work with. Once the appropriate distribution is selected, one may compute an allowable value, using data set statistics and methods appropriate to the selected distribution.

Ensuring the Validity of Allowables

As the intent of determining design allowables is to promote reliability and safety of the structure, it is important to remember that a linkage must exist between the test population used to determine the results and the population of materials in the actual fabricated structures in service. The characteristics of composites that lead to the variability that challenges the determination of design allowables are still present, and these variables must be monitored in production and application. Obvious factors include:

- Changes in the constituent materials used in lamina
- Changes in suppliers
- Variations in manufacturing processes of making laminates and components
- Materials handling and storage that could degrade material

The responsible organization must have established and implemented procedures to ensure that the materials properties of the fabricated composite structures are the same as those of the materials used to develop allowables. This organizational effort is usually the responsibility of materials and process organizations as well as quality assurance experts. Details of this effort are beyond the scope of this article.

Design Allowables

Computer-Aided Design and Manufacturing

Olivier Guillermin, VISTAGY, Inc.

Introduction

CONTINUOUS FIBER COMPOSITE MATERIALS offer dramatic opportunities for producing lightweight laminates with tremendous performance capabilities. However, the high cost and complexity of designing and manufacturing composites have largely offset the benefits of using these materials. To unlock the full potential of lightweight laminates, new software applications have been developed that transform general computer-aided design (CAD) systems into a high-performance composite engineering environment for designing and manufacturing composite parts. These applications have evolved from software programs that originally attempted to model the draping of fabric onto complex curved surfaces.

Computer-Aided Design and Manufacturing

Olivier Guillermin, VISTAGY, Inc.

Overview

History. As early as 1878, the mathematician Chebyshev made an attempt at modeling the fitting of a woven fabric onto a curved surface, assuming inextensible fibers and pivoting yarn crossover joints (Ref 1). Since then, the mapping of clothes to three-dimensional (3-D) surfaces has been the subject of constant research, especially in the textile industry, as exemplified in Mack and Taylor (Ref 2). More recently, the draping of fiber-reinforced composite sheets on curved tool surfaces has generated numerous research efforts. For example, important advances in analytical and numerical draping algorithms for compound curvature surfaces

have been made by Robertson et al. (Ref 3, 4), Van der Weeen (Ref 5), Smiley and Pipes (Ref 6), Van West et al. (Ref 7), Heisey and Haller (Ref 8), Gutowski et al. (Ref 9), Tam (Ref 10), and Gelin et al. (Ref 11). In the last five years, the results of this research have been integrated in major CAD systems, which has led to the advent of commercial composite engineering software now used in production at large aerospace and automotive companies worldwide (12, 13 14, 15).

Challenges. Identifying shapes that can be easily draped, selecting lay-up processes that will minimize the amount of rework, and knowing how to design tooling ahead of time are all very valuable to the composite engineer. Being able to make decisions early on at the predesign stage, before the part is built, is even more valuable. Using composite engineering software in the design and manufacturing process of composite parts allows the engineer to design with composite features directly in the CAD system. Composite engineering software also provides a seamless link from the CAD model to structural and flow analysis and to the manufacturing applications, resulting in shorter overall design cycles.

Composite Features. State-of-the-art composite engineering software provides high-level composite features in the CAD system, allowing the engineer to efficiently manage the large amount of data generated during laminate design. The engineer works with familiar composite features, including zones, laminates, plies, cores, and ply orientation rosettes. The engineer can also manage the nongeometric attributes for these composite features, such as part number, materials specification, and ply or fiber orientation. Composite engineering software also maintains associativity between features. The part boundary, material, ply boundary, or the lay-up skin-related items, such as flat patterns, are easily updated when changes are made to the part. As the design progresses, the actual laminate can be analyzed and the number of plies, thickness, materials, and true fiber orientations can be verified.

Complete Part Definition. Accuracy of information throughout every stage of the design cycle is essential to the proper completion of a composite design. Composite engineering software maintains the complete definition of a composite part in the CAD model. For example, plies may have both a 3-D net and 3-D extended ply boundary with a corresponding flat pattern for each. In the event of a design alteration, accuracy is assured by verifying model consistency and alerting the user to elements that may require attention. The validity of the definition of each feature is also verified. For instance, it is ensured that ply boundaries are closed and on the tool surface.

Cost-Effective Changes. Composite engineering software makes it easy to discover potential design and manufacturing problems early in the development cycle. This allows changes to be made in the initial stages of design, instead of going undetected to the manufacturing floor where the costs incurred will be 10 to 1000 times greater.

Material Databases. Composite engineering software provides user-configurable material databases that include information such as material thickness, properties, producibility, and company specifications.

Computer-Aided Design, Manufacturing, and Engineering Functionality. Composite engineering software includes computer-aided design, computer-aided engineering, and computer-aided manufacturing modules. Design functionality may include core sample and ply stacking analysis, producibility and flat-pattern evaluations, laminate surface offset, and engineering documentation. Analysis functionality may include a structural analysis (finite-element analysis, or FEA) interface and a resin transfer molding (RTM) interface. In manufacturing, a flat-pattern export file generator for nesting systems and automated cutters, a fiber-placement interface, and a laser projection interface are examples of modules used to ensure a seamless link from design to the manufacturing floor. These functionality areas are discussed in more detail in the following sections.

Composite Draping Simulation

A draping simulation is used to generate fiber paths, identify areas of wrinkling and bridging, develop flat patterns, and allow the calculation of local ply orientations and the resulting laminate mechanical properties, such as stiffness, permeability, volume fraction, and thickness. The simulation is used as a design tool and manufacturing aid to guide the lay-up process, ensure repeatability, and minimize material waste. This section describes the kinematics of fabric deformation and explains the algorithms used in draping simulation.

Kinematics of Fabric Deformation. The ease of handling and drapability of continuous fiber fabrics lend themselves to the forming of deep-drawn and compound-curved shapes (Fig. 1 and 2). In woven fabrics, drapability is facilitated by the ability of the fabric to undergo large in-plane shear deformations, due to a

trellising action of warp and weft yarns. In unidirectional fabrics, fibers slide relative to one another for in-plane shear to occur, and it is generally assumed that the distance between the fibers remains constant, whereas the fibers of the woven fabrics come closer to each other under shear deformation. The draping process consists of forcing initially flat fabric to conform to a surface of any shape. Flat or developable surfaces can be draped with no fabric in-plane shear deformation, hence fiber paths are predictable without the aid of a material deformation model. On compound-curved surfaces, however, fiber paths depend on the fabric deformations and on the lay-up process. The ability to predict fiber paths using the appropriate material and process models has important practical applications:

- The true fiber orientations in the plies allow accurate calculation of laminate physical properties, such as stiffness, strength, and thermal expansion coefficients.
- Knowledge of fiber paths and shear deformations allows prediction of wrinkling and bridging in the fabric and indicates optimal locations for the cutting of relief darts.
- Exact fabric flat patterns can be developed from the draping simulation.
- The simulation can help define the best lay- up start point and keep track of this information to assure repeatability of ply lay-up and draping.
- A number of secondary physical properties can be determined from the draping simulation, including ply thickness, fiber volume fraction, outside mold definition, and mass properties.
- The simulation can be used as a design tool for optimizing a draping in terms of minimized total fabric shear deformation or specified fiber orientations at points on the surface, or for positioning unavoidable darts and splices at noncritical areas of the part.

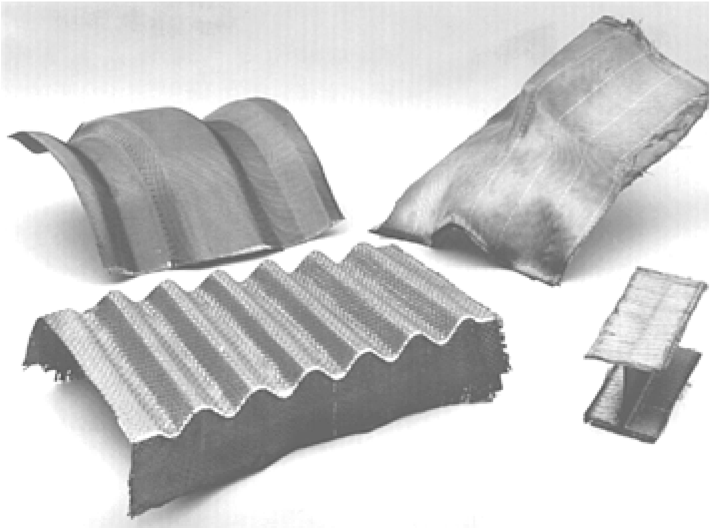

Fig. 1 Examples of woven fabric composite parts

Fig. 2 Composite part showing compound curvature

Modeling Approaches. The existing models for draping simulation fall into one of the following two categories: mapping models and mechanical models. Mapping models assume a geometric mechanism to transform an initial unit square of fabric into the corresponding draped shape. Mechanical models use the equilibrium equations that balance the internal forces in the fabric with external applied loads. The mapping model algorithms rely on the CAD system for the necessary geometry data. They are not computationally intensive and can provide a quick answer. Design engineers mostly use this approach when choosing between several ply configurations. In contrast, mechanical models require the use of FEA. This approach is used by analysts and applied to the detailed study of composites forming and stamping. More information about FEA of composites can be found in the article "Finite-Element Analysis" in this Volume. Assumptions commonly made in the mapping approach include:

- The yarns are inextensible in the fiber direction.
- Tool-ply and ply-ply friction is neglected.
- Crossover points of warp and weft yarns act as pivoting joints for woven fabric, or the transverse spacing between fibers is constant for unidirectional materials.
- The composite ply maps perfectly onto the tool surface without out-of-plane wrinkles or discontinuities.
- The manufacturing process (hand lay-up, fiber placement, tape laying) defines how the composite sheet is "pinned" onto the tool surface.

For complete background information on the mathematical aspects of the mapping approach, including finite strain measures, 3-D geometric constraints, surface coordinates, and relevant concepts in differential geometry, the reader is referred to Ref 16.

Mapping Algorithms. Current mapping algorithms are usually a variation of the fishnet, mosaic, or least-squares algorithms (5, 6 7).

In the fishnet algorithm, a net represents the fabric, with the knots simulating the warp and weft yarn crossovers. The net is draped onto the tool surface so that all the knots lie on the surface and the lines between the knots keep a constant length. The manufacturing process determines the order in which the net cells are applied onto the tool surface. Usually, the lay-up process will start from two perpendicular geodesic lines of predetermined knot locations or from one geodesic and a transverse progression rule. For a cell to be transformed from the initial flat shape to the applied final shape, three knots must already be pinned onto the tool surface, and the draping simulation engine then calculates the projection of the fourth knot (Fig. 3).

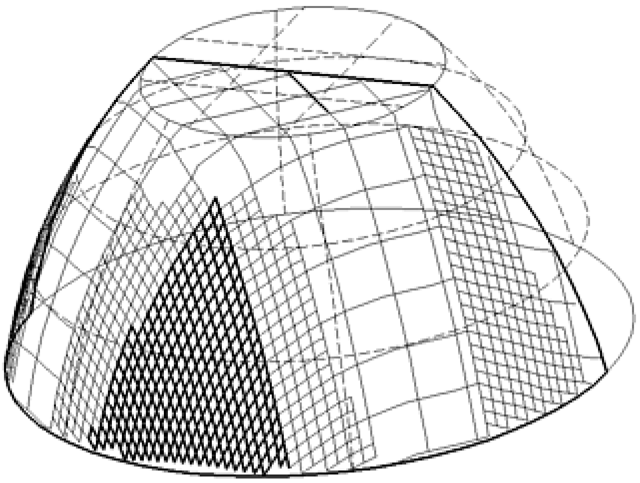

Fig. 3 Material scissoring shown by a draping simulation using the fishnet algorithm

In the mosaic algorithm, the tool surface is modeled with facets, and geodesic lines cross the element edges at constant angle. This algorithm is a simpler version of the fishnet algorithm. Very fine meshes are necessary for a good result.

The least-squares algorithm is also a variant of the fishnet algorithm, in which the position of the fourth knot of a cell is obtained by minimization of the cell elastic strain energy. This approach presents some challenges related to the choice of an appropriate finite-element formulation and mesh size. The quality of a ply can be measured by the elastic shear deformation energy stored in the ply after draping. This is a function of the elastic shear modulus of the material and the shear deformation angles over the ply. The highest-quality draping of a surface may be considered that which has the least total shear strain energy, because it would be the easiest to drape, in terms of deformation effort, and would be the least likely to have wrinkling and bridging problems.

Computer-Aided Design and Manufacturing

Olivier Guillermin, VISTAGY, Inc.

Composite Hierarchy

Laminate Definition. In the composite engineering environment, a laminate is a composite object that groups other composite objects together. The laminate can be viewed as an intuitive organization of components within the design that have unique attributes relative to the other laminates. A laminate is usually composed of a skin and a boundary associated to it. A laminate can be defined as any organization of lower-level laminate

components that aids in defining logical part assemblies. These lower-level components can be plies, cores, or additional groupings of other lower-level laminates.

One example of a laminate organization that is required for part-definition accuracy is the insertion of a core or insert object. Because inserts are usually very thick in nature, the inclusion of insert objects greatly affects the topology of the part for all plies/cores after its inclusion. Hence, a new laminate must be defined above the insert. All plies and inserts on this new laminate will be working off an accurate representation of the surface they are laid upon.

Ply Definition. A ply is the basic component of the composite hierarchy. A ply must be fabricated from a sheet of two-dimensional (2D) material. This cutout is known as a flat pattern (Fig. 4). The flat pattern is then laid up on a 3-D tool. There are several features in a 3-D ply that must be transferred accurately to the 2-D flat pattern. The composite engineering environment stores all the 2-D and 3-D information necessary to accurately define the ply. Typical ply information includes parent laminate name, lay-up sequence and step, material, fiber orientation rosette, stagger and drop-off indices, net or trimmed boundary, and holes or cutouts.

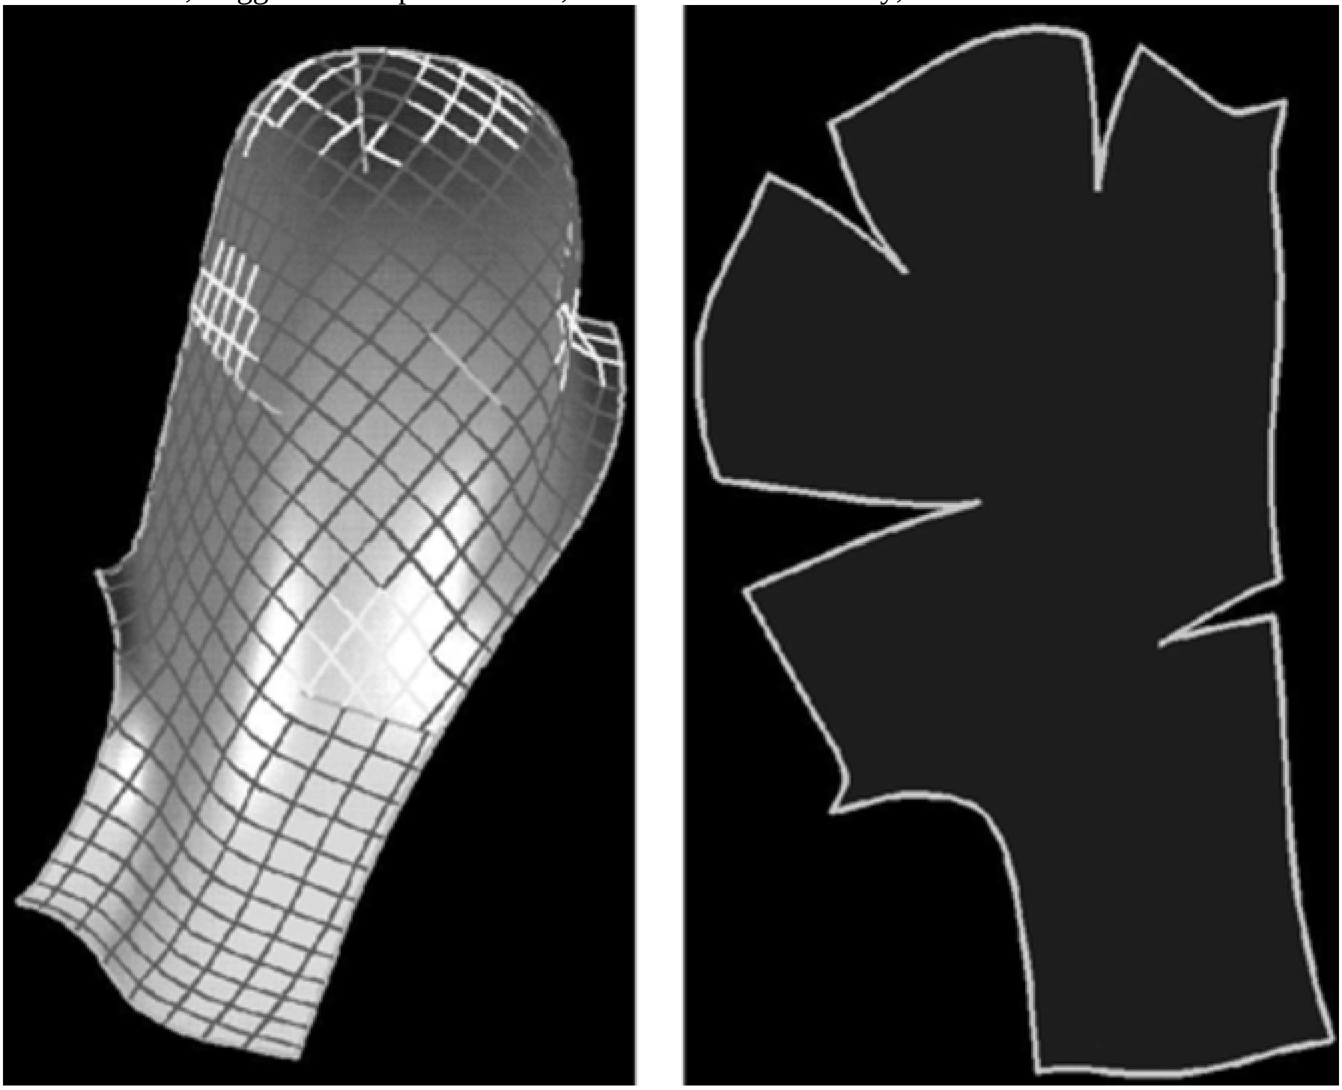

Fig. 4 Draping simulation and flat pattern for an aircraft wheel cover

Olivier Guillermin, VISTAGY, Inc.

Core Sample and Ply Analysis

Core Sample. Composite design involves the bringing together of a large number of individual components (plies, cores) to satisfy various requirements (fiber orientations, thickness, stack- up, etc.) that change over the surface of the part. It is therefore necessary to be able to check the arrangement of critical areas of the part, to ensure that all design requirements are being met. A core sample is the term used to denote the design evaluation at given points of the laminate structure. A core sample "pierces" the structure at the given points and provides information about the laminate design at those points. Core sample results include information such as target and actual thickness and fiber orientations, orientation percentages, and ply counts (Fig. 5).

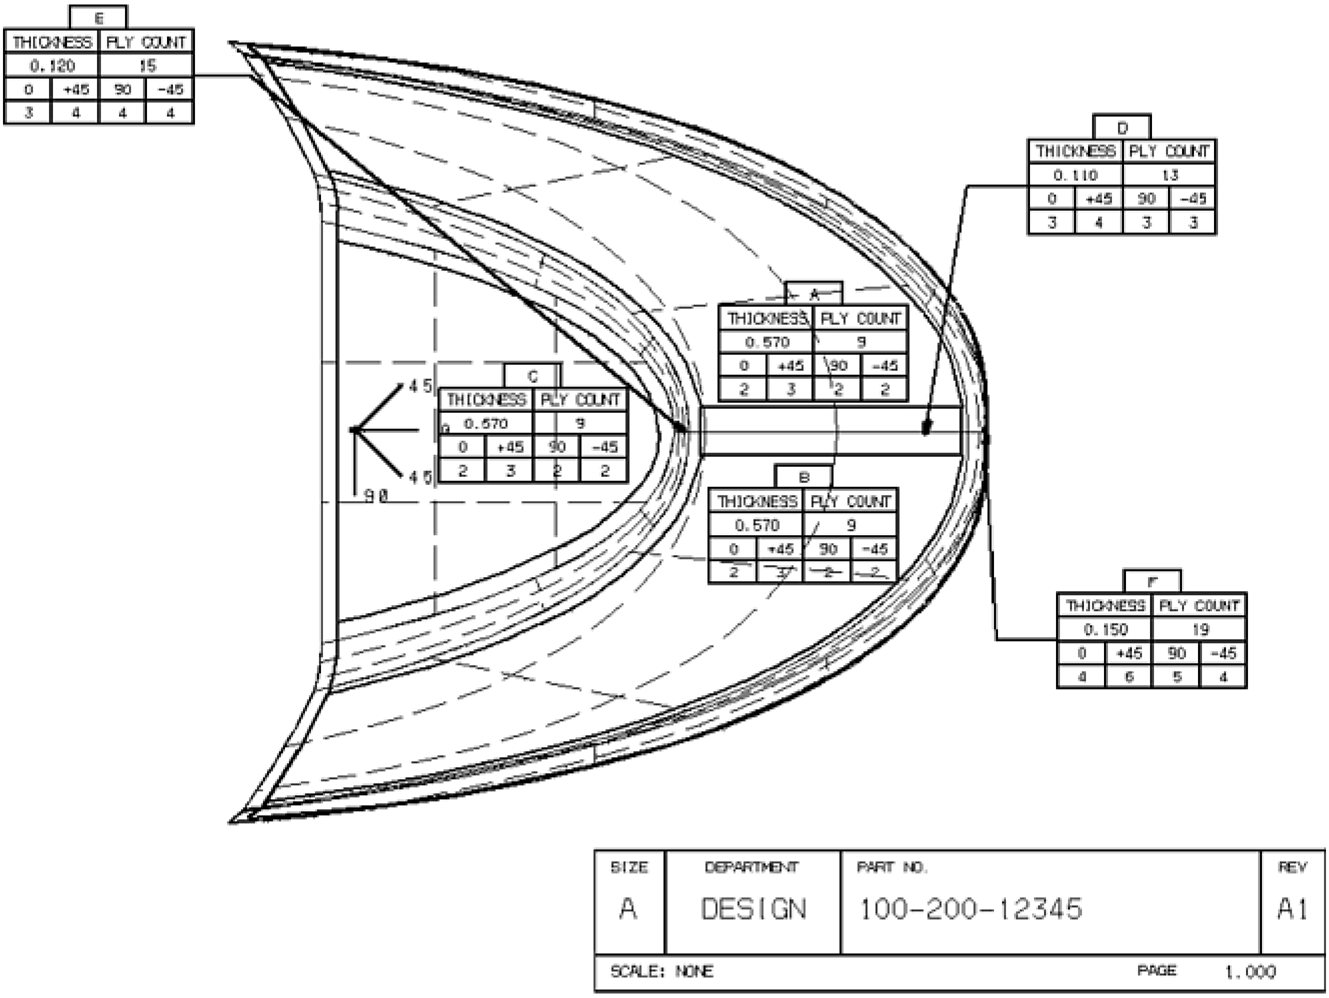

Fig. 5 Core sample results

Ply Analysis. It is easy to calculate mass, area, and cost properties after the flat pattern of the ply has been generated. Parameters obtained from a ply analysis may include ply generation date, largest and average ply deformations, length of the flat-pattern outer periphery, flat-pattern total area, total material weight of the ply, total cost of the ply material, and ply center of gravity.

Computer-Aided Design and Manufacturing

Olivier Guillermin, VISTAGY, Inc.

Producibility and Flat-Pattern Evaluations

Manufacturability Warnings. Producibility evaluations enable design engineers to balance part geometry, material, and process constraints by using draping simulation technology to predict how composite materials conform to complex surfaces (Fig. 6). By running producibility evaluations, engineers can visualize fiber orientations, predict manufacturing problems, and take corrective action during design. Producibility

evaluations highlight areas where a ply will wrinkle during lay-up or exceed available material width. Material and process models are now available for many composites, including woven and unidirectional composites, dry and prepreg materials, and various processes such as hand lay-up, tape laying, fiber placement, or RTM. Input data typically consist of one or more surfaces representing the lay-up tool, 3-D ply boundary curves, materials specifications, and ply origin and orientations.

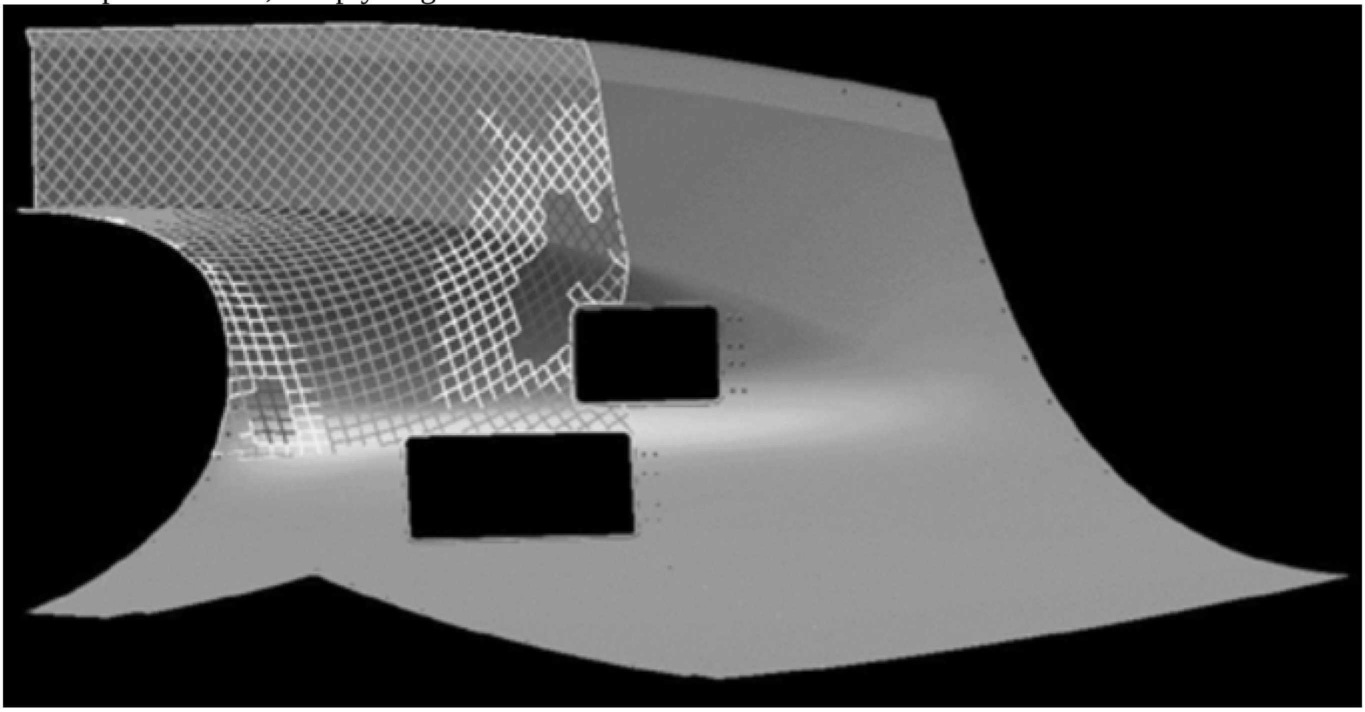

Fig. 6 Draping simulation to evaluate ply producibility for an aircraft cowling

Darting and Splicing. There are two basic types of wrinkling that can occur during the lay- up process. The first type is called out-of-plane wrinkling, or puckering. This type of wrinkling is common in apparel. Out-of-plane wrinkling is caused by an excess of material in a given region of the surface. The second type of wrinkling is called in-plane bridging. In-plane bridging is caused by a lack of material in a given region. The material, not physically able to drape over the entire surface, spans or bridges regions of the surface. Splicing the ply into two or more pieces helps alleviate wrinkling. Splicing eliminates wrinkling by reducing the overall surface a single ply has to drape. Splicing must take into consideration the width of the material to minimize the number of splices (Fig. 7). Darting techniques attempt to eliminate wrinkling without dividing the ply into smaller pieces. Darting usually cuts the fibers that initiate the wrinkling and prevents them from propagating the wrinkling outward in the ply (Fig. 4). Darting techniques cannot be used in case of bridging, because they would generate an invalid flat pattern that overlaps onto itself.

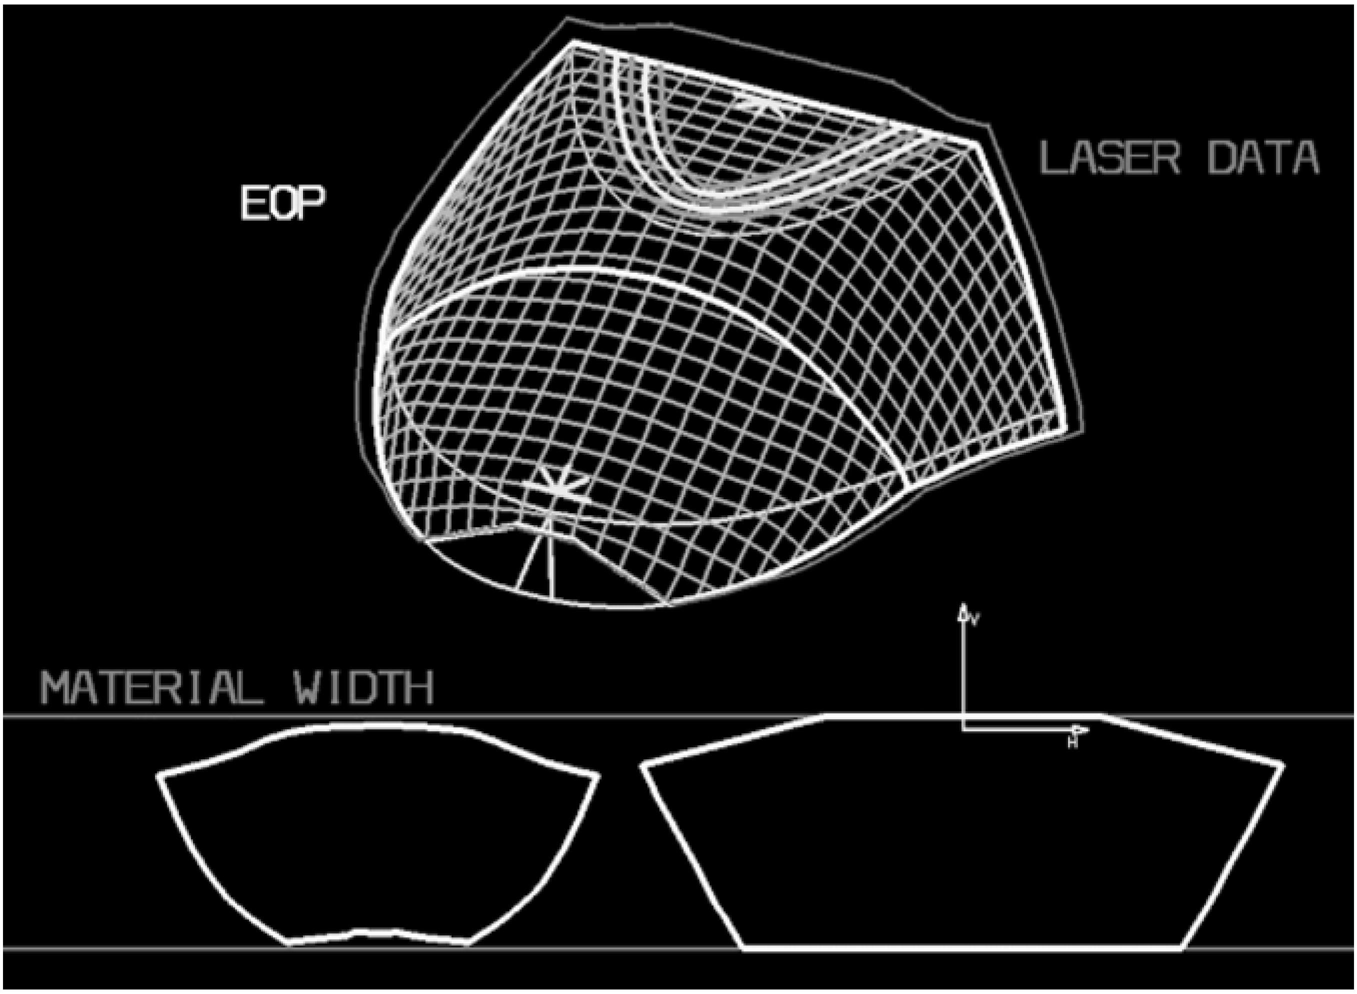

Fig. 7 Splicing of a full-body ply based on material width. EOP, edge of part

Flat-Pattern Generation. A flat pattern is generated as follows: determine where each yarn intersects the ply boundary or internal cutout and map this information to a 2-D, orthogonal representation of the undraped fabric. As a result of the draping deformation, flat patterns for 0°/90° and ±45° on nonaxisymmetric compound-curvature parts will differ (Fig. 8). Flat-pattern generation also properly accounts for changes in surface area and density that occur when woven materials conform to compound-curvature shapes. The flat patterns are usually stored within the CAD model for output to ply nesting or cutting machines.

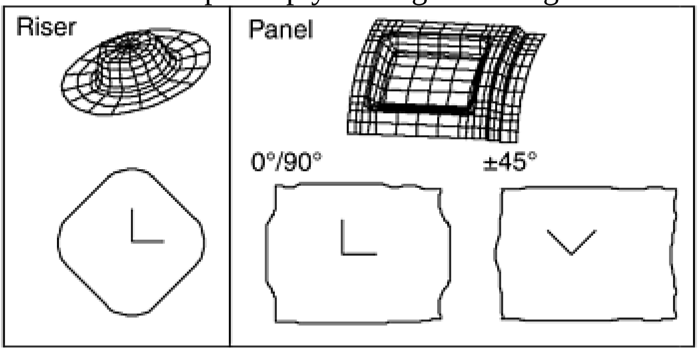

Fig. 8 Flat patterns as a function of fiber orientations

Olivier Guillermin, VISTAGY, Inc.

Laminate Surface Offset

As a result of the complex laminated structure of a composite part, the thickness of the final solid resulting from the lay-up varies throughout the part. Thus, even a part created on a very simple and smooth tool surface can produce a final volume with complex geometry, when all the details of laminate thickness changes, cores and inserts, ply boundaries, holes, drop-offs, and staggers are taken into account. It is very difficult to adequately model this solid in a CAD system, because it requires accurate knowledge of the distribution of thickness, as well as sophisticated surfacing capabilities. However, a model of the as-manufactured solid is very desirable, because it enables design of matched-mold tooling, machining of mating surfaces, and allows virtual assembly of parts to check for fit and serviceability.

Efforts to manually create the laminate offset surface in a CAD model are error-prone, and because of the difficulty of modeling the complex transitions between regions of different thickness, only an idealized representation of the laminate offset surface is generated with manual tools. At the same time, automatic modeling of all the ply drop-offs and core transitions results in extremely complex geometric models that strain the capabilities of modern CAD systems. Laminate offset surface capabilities address these issues through automatic optimization of the computed offset surface. Such a capability is built upon proven thickness calculation capabilities and advanced surfacing techniques to capture the thickness variations in the laminate without resorting to explicit surfaces for all ply transitions in the laminate. The laminate offset surface is developed from the original CAD surfaces that define the tool, and the drop-off regions are modeled through surface curvature rather than individual faces. This results in computationally efficient CAD models that have offset surface features that closely resemble the as- manufactured part, where transition regions are smoothly curved. The detail of the offset surface is thus ideally suited for all applications, including mating surfaces and mock-up.

Computer-Aided Design and Manufacturing

Olivier Guillermin, VISTAGY, Inc.

Engineering Documentation

For composite parts, a difficult task facing the engineer is creating accurate design documentation. With composite design engineering software, once the information has been entered into a model, the engineer can use electronic documentation products to automatically generate engineering drawings, material tables, sequence charts, ply lay-up diagrams (Fig. 9), sequence charts (Fig.10), arrow text, laminate thickness and ply counts, and draped and schematic cross sections (Fig.11). Documentation is generated as CAD geometry that can then be plotted to hardcopy output. The format of the reports and drawings can be customized to follow drafting standards. The accuracy of the documentation is ensured, because it is generated directly from the data stored in the composite engineering environment. As the part definition is modified during the design process, the documentation elements can be quickly and easily updated to reflect these changes.

Flat-Pattern Export

Automatic Export. Flat-pattern export modules automatically generate a flat-pattern data file for export from the CAD workstation to the nesting software and cutting system. Working directly from the CAD system, flat-pattern export maintains file integrity and eliminates the need for manual manipulation of drawings and attributes in the transfer. Engineering changes are communicated quickly and correctly to the manufacturing floor through this automated process. Flat-pattern export automatically extracts flat patterns from the CAD model, eliminating the need for engineers to manually pick through data.
Flat-Pattern Optimization. Flat-pattern export may also enable users to fillet corners with a specified radius, in order to optimize manufacturing productivity. Corners that have been filleted decrease cutting time by eliminating stop- start sequences due to direction changes of the boundaries. Flat-pattern modules detect the sharpest corner of the flat pattern and start at that location. Subsequent corners with changes in direction that are larger than a user-specified angle are replaced by fillets, allowing the cutter to proceed at a smooth, consistent rate.

Structural Analysis Interface

A typical composite part is made of tens or hundreds of individual plies of various materials, each having a unique shape, orientation, and location. This complexity is compounded by the fact that in most cases, the final design of a part cannot be analyzed in its to-be-manufactured state. Analysis interfaces solve this dilemma by

providing to the structural analyst a complete and detailed description of the final part design, enabling accurate verification of the performance of the part (Ref 17).

True Part Definition. The typical composite part design process starts with an analyst using FEA software to determine the requirements for the design, including laminate thickness, material, and so on, based on expected loads. Engineers can then use composite design engineering software to design the actual part in the CAD system. However, even with the best tools and most diligent efforts, the final design may differ significantly from the idealized part that was analyzed. Fibers in the resulting laminates may deviate significantly from the specified ply orientations, causing unknown variations in properties. The final design will also contain many details and modifications, including additional plies that were not considered in the original analysis. All of these issues can have a considerable effect on the performance of the final part. The analysis interface addresses this problem by enabling engineers to design a composite part in the CAD system, determine the state of the manufactured part using simulation technology, and then use the complete definition of a part in its to-be-manufactured form as input into the analysis software. The analyst can now rerun the analysis using the ply definitions and fiber orientations from the final part design, resulting in a more accurate assessment of the part. By linking the capabilities of the CAD system to the analysis software, the analysis interface allows designers to deliver the master model part definition that resides in the CAD system, complete with fiber orientations and all other details, back to the analyst for verification that it meets all requirements.

Resin Transfer Molding Interface

RTM Process. Thermoset polymer composites can be produced by injection of reactive liquids into molds that contain dry reinforcement of continuous fibers. One process increasingly used for that purpose is RTM, in which the resin is injected at low pressure and sometimes under vacuum (Ref 18). Resin injection through a fibrous reinforcement is modeled as a flow through a porous medium and obeys Darcy's law, which states that the resin flow rate through a unit area of material is proportional to the pressure gradient in the mold (Ref 19). The coefficient of proportionality is the permeability of the porous medium (measured by appropriate experiments) divided by the viscosity of the resin (which varies in time with temperature and degree of cure). Permeability becomes lower when the fiber volume content of the composite increases, whereas viscosity decreases with temperature.

Figure 12 shows various aspects of the RTM simulation for a complex helicopter part, including the finite-element mesh and the successive resin front positions in time. The pressure field in the mold may also be displayed. A correct knowledge of mold filling allows adequate positioning of the injection ports and vents. There are three ways to facilitate the resin flow in the mold: decrease the fiber volume content (for example, by lifting slightly the mold cover during injection), increase the injection pressure, or heat the mold and/or the resin to reduce viscosity. Using the appropriate simulation software, these three parameters can be studied and tuned adequately. This is especially important in the case of large parts (of more than one square meter), complex parts with ribs, or parts with a high fiber volume content (between 50 and 60%). A RTM simulation software should contain the following four critical features (Ref 20):

- It must satisfy the exact conservation of resin mass during injection.

- It must be able to simulate race tracking, that is, the much faster resin flows that occur in specific areas of the mold, such as the edges.
- It must solve the heat transfer problem during resin injection (i.e., calculate the temperature field in the mold and in the part).
- Finally, it must simulate curing of the part.

Linking the RTM finite-element software to the composite engineering software through a RTM interface provides a more accurate description of the resin injection process by incorporating in the RTM model local variations due to the composite material draping process. Draping may generate local changes in ply thickness and directional variations in porosity and permeability due to material scissoring.

Fiber Placement and Tape-Laying Interfaces

Fiber-placement machines combine the advantages of filament winding, contour tape laying, and computer control to automate the production of complex composite parts that conventionally require extensive hand lay-up. Using fiber-placement machines can reduce costs, cycle times, structural weight, and handwork/rework when manufacturing composite parts, but creating data files to drive the machines is time-consuming and error-prone. With a fiber-placement interface, engineers can generate fiber-placement data files directly from the CAD model. The fiber-placement interface is a powerful functionality for designing parts manufactured by the fiber-placement process. The interface manages fiber-placement design and engineering entities, including slice axis, fiber axis, mandrel alignment points, and process regions.

Olivier Guillermin, VISTAGY, Inc.

Laser Projection Interface

Laser projection systems can reduce errors and shorten the lay-up time for composite parts by displaying ply outlines directly on the lay-up tool. These outlines aid in the location and orientation of plies during the lay-up process. With a laser projection interface, users can generate laser data files from within their CAD system directly from the 3-D model of the composite part. Laser projection interfaces use the CAD model of the composite part to generate the laser projection data and calibration files. Ply and sequence labels are also automatically included. However, as the lay-up of a composite part progresses, the accumulation of plies offsets the surface on which the laser is projected. This results in considerable parallax error in the projected profile, especially in thick or highly contoured parts. Laser projection interfaces may automatically account for material thickness and offset due to ply buildup when generating the laser projection data. In addition, using the CAD model of the tool surface, the laser projection interface may provide additional data that will aid the programming of multihead systems for very large or highly contoured parts, where a single projection head may not meet the requirements.

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Introduction

THE USE OF COMPOSITE MATERIALS provides the designer with great flexibility with which to meet part performance requirements. Even after a composite material has been selected, the design must still address the microstructure of the component. The type of reinforcement—continuous fiber, short fiber, whiskers, chopped roving, woven or braided fabrics, and preforms—and its orientation greatly affect the performance of the component. Indeed, the ability to tailor a component increases its range of functionality as well as the complexity of the design. For example, the skin of an aircraft wing near its root may involve a hundred plies. Although the plies may all be the same material in the same format, it is the collective orientation of the plies that yields the desired extensional, flexural, and torsional stiffnesses. The design at the microscale is more important than simply the orientation of the reinforcement. Failure mechanisms such as delamination, fiber microbuckling, fiber kinking, and transverse cracking all occur on the microscale and are sensitive to manufacturing variations.

Just as the design must address the microstructure, the design must also address the macroscale. Composite materials can be formed into near-net shapes. Construction of components that often require many individual parts can be made in one step. Stiffeners can be staged, cocured, precured and integrated, or bonded. Sandwich construction with honeycomb or foam results in lightweight alternatives to discretely stiffened panels. As the part count is reduced, the complexity of the components is increased. The structural design may be as extensive as the aft fuselage of the V-22 Osprey (built by Boeing) or as simple as composite dimensional lumber made from recycled plastics.

Designing composites for structural performance initially involves meeting a set of desired performance specifications (typically weight in aerospace applications) at a minimum cost. When one introduces manufacturing costs as a constraint in addition to structural performance, the cost optimization process becomes more complicated. Designing composites for manufacturing is more involved than designing the part to be fabricated within specified dimensional tolerances. Indeed, the desired orientations of the reinforcement must be met with special attention paid to the presence and effects of anomalies or defects. Moreover, the prospect of large, integrated structures necessitates designing the manufacturing process concurrently with the component.

An indication of the difficulty in addressing this rather important issue is demonstrated by the material devoted in textbooks that specialize in composite structures. Since the 1975 release of *Mechanics of Composite Materials* by R.M. Jones, there have been many texts dealing with the mechanics of composite materials. A small number of these address manufacturing aspects along with the mechanics. Other texts are available with manufacturing or integrated design as their focal point. Those texts were surveyed to determine the amount of content devoted to manufacturing and are placed in chronological order in Fig. 1. Traditionally, those texts dealing with mechanics typically devote no more than 10% to manufacturing. Strong's text is the exception in that it updates much of his earlier text in manufacturing for a mechanics-based audience. In recent years, integrated manufacturing texts have been published, providing new sources. Thus, integrated manufacturing and structural design within academia is probably lagging behind structural design of composites by nearly twenty years.

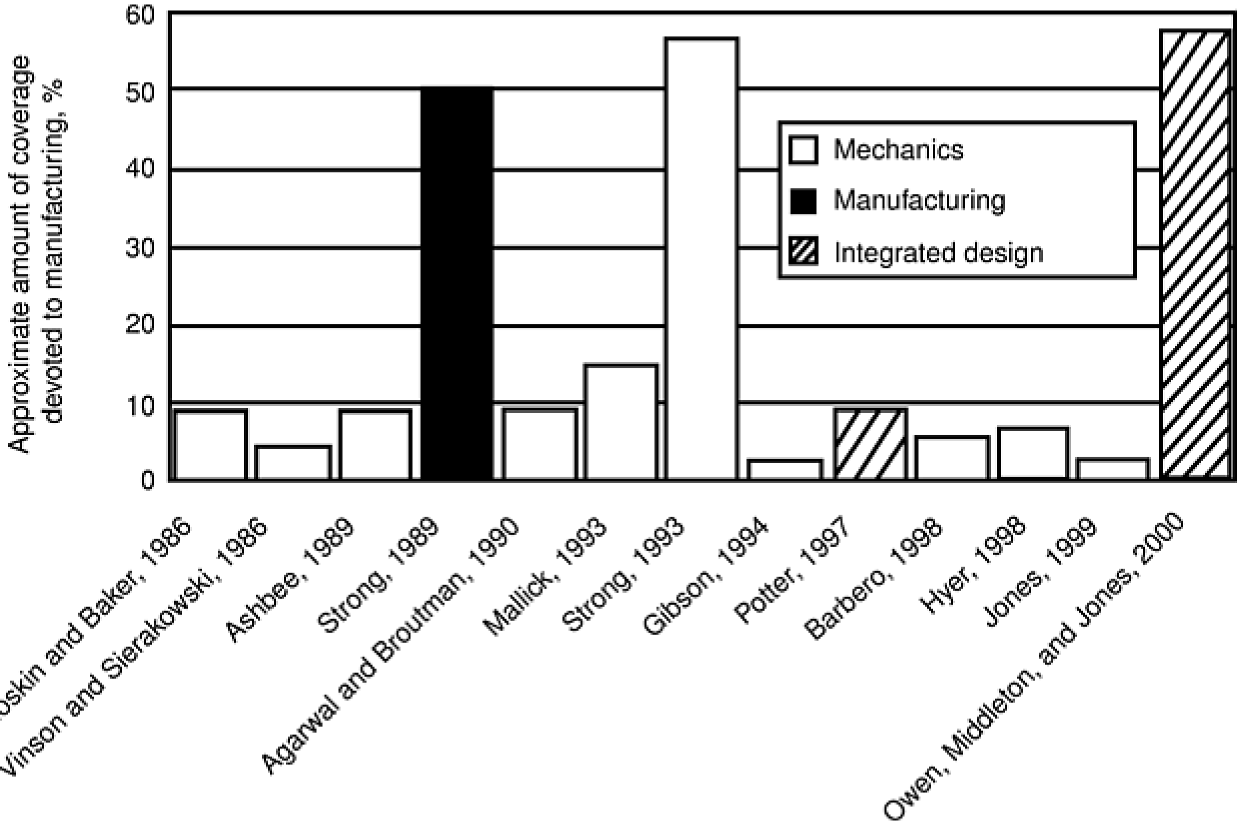

Fig. 1 Manufacturing coverage in composite texts

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Selection of Composites Manufacturing Processes

Often the design of a composite component is done in tandem with design of an equivalent metallic component to assess the cost/benefit of alternate materials. This can result in an unfair comparison as the designer employs such constraints as *black aluminum*, the use of quasi-isotropic layups to degrade the behavior of an orthotropic material to that of an isotropic material. Or the designer develops the manufacturing process concurrently with that for the metallic component. This design process does not take into account the tailorability of the composite material nor the potential advantages of the manufacturing process to increase performance, lower part count and weight, and decrease overall cost. The differences between composites and the materials they would potentially be replacing are significant enough to warrant independent development of the component and the manufacturing process.

Prior to the design of the composite component, many constraints may be imposed. Selection of the manufacturing process may be automatic based on available equipment and prior experience. The number of parts to be made may be known, thus limiting the time to manufacture and the expected costs per part. Overall dimensions (such as those for a boat hull) or dimensional constraints are specified. Surface finish and dimensional stability may be specified. The operating environment and general loadings should be known. Thus, many selections are made prior to the actual design of the component. The material system is most likely chosen based on the operating temperature, desired mechanical properties, material availability, and cost considerations. The manufacturing process will be selected based on surface finish, cycle time, and part cost. The selection of the material system often influences or limits the selection of the manufacturing process and vice versa.

The choice of material greatly influences the ability to design for manufacturing. The greatest latitude is afforded by polymeric resins. Structures that require ceramic, metallic, or carbon matrices will involve forming processes that introduce matrix into the reinforcement. In metal- matrix composites, for example, reinforcements increase strength, decrease the coefficient of thermal expansion, and improve the wear resistance at a cost of a reduction in ductility and in fracture toughness. Thus, the design of a component often will begin with the manufacturing process itself and will extend the available technology to incorporate the reinforcement. The goal is to improve the overall performance of the metal or ceramic rather than to create a material with different response than the base matrix. Thus, this article concentrates on design for manufacturing of polymeric composites.

Anthony J. Vizzini, University of Maryland

Process Considerations

Independent of selections made prior to the design, many aspects of the manufacturing process are still unknown and are a function of the microscale and macroscale design of the component. The general composite manufacturing process can be subdivided into three separate stages. The first is preparation and involves handling the raw materials as well as mold fabrication and preparation. The second stage is the actual forming process. It is in this process that chemical reactions or phase changes occur or the constituents are consolidated into the desired component as outlined in the Section "Manufacturing Processes" in this Volume. Finally, additional fabrication may be required such as trimming, machining, bonding, finishing, or coating, as outlined in the Section "Post-Processing and Assembly" in this Volume.

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Preparation

Two aspects of manufacturing that interact with the design are the handling qualities of the raw materials and characteristics of the mold. Prior to the manufacturing step, raw materials are acquired as individual constituents or in mixed form. As individual constituents they are either combined prior to the manufacturing process or combined as a result of the process. Materials premixed such as preimpregnated fabrics and tapes, sheet-molding compounds, and bulk- molding compounds may be assembled prior to the manufacturing process.

Handling Qualities. The ability of the preimpregnated ("prepreg") material to stick to itself and other materials is called *tack*. A tacky material will stay in place once it is situated on a mold or on top of another layer. Materials with little tack may require the use of a local heat source such as a heat gun to increase tack so that the materials can be held in place in the mold. Materials with too much tack increase the effort required by the operator to place the material in the correct position because errors in placement cannot be easily remedied. The degree of tack is influenced by ambient temperature, relative humidity, and the age and resin content of the material. Tack affects the design by limiting the size of the individual ply that can be handled and the ability to place it on the part. Although templates can be used for positioning individual plies, tacky materials must be placed accurately the first time, whereas low-tack materials may shift prior to consolidation, resulting in a disturbance in the location of a ply. The lay-up of dry fiber preforms for resin transfer molding often utilizes a "tackifier" compound in the form of a liquid or powder to add tack to otherwise tack-free materials.

The ability of the material (fabric, with or without resin) to conform to the shape of the mold is called *drape*. The greater the drape is, the more contour can be designed into the part. Therefore, drape limits the amount of compound curvature. This is separate from the concern of laying a planar material on a doubly curved mold or the reverse problem of representing in two dimensions a three-dimensional surface without distortions. Typically, thermoplastic materials have little drape, and, thus, are made to conform to the shape of the mold during the manufacturing process as is done in thermoforming. However, thermoplastic materials that have been cut into long, narrow strips and then loosely laid as a stretchable fabric do exhibit some degree of drape.

Because thermosets cure at any temperature, preimpregnated staged materials have a finite workable time out of storage, and wet lay-up resin systems, once mixed, have a finite pot life. Beyond these time limits, handling of the constituents becomes difficult and the mechanical properties of the resulting composite structure decrease. Thus, the time to complete the assembly must be addressed in the design of the component. If intricate ply lay-ups are required, then pre-kitting must be employed in forming the preform for wet systems or automation for cutting and material application for prepreg systems. The size of the structure may limit how much material can be applied without significant degradation of mechanical properties caused by exceeding out-time and shelf-life limits. However, there are manufacturing processes and materials well suited for long assembly times. Many of the closed-mold processes, vacuum-assisted resin- transfer molding (VARTM), or structural reaction injection molding (SRIM), when used with preforms, can result in reduced handling time of the resin. The dry reinforcement is placed in the desired orientation, and then the resin is introduced.

The ability of the resin to properly wet out the fibers, to consolidate individual layers, and to decrease void content is related to its viscosity. There is a trade-off between increased wet-out and handling characteristics. Low viscosity resins tend to pool in resin-rich areas for large parts or escape the part entirely, resulting in a lack of uniformity in, or very high, fiber volume. Resin systems must be tailored to provide low viscosity during winding processes or in flow periods of autoclave processes but must have sufficient viscosity to remain where placed within the structure during the process.

Tooling Considerations. The role of the tool or mold is to impart the shape to the composite part during the manufacturing process. Tool design is based on the requirements for the tool to maintain its shape during the manufacturing process and is a function of the processing temperature, applied loads, and curing time. In addition the number of replicates per tool affects its material of construction.

Here, consideration of the manufacturing process is very important. The geometry of the part is constrained by the ability to form the necessary tooling. Highly contoured surfaces will require a highly contoured tool. Making use of available geometries such as flats and tubes results in low-cost tooling. Complex tooling often requires manufacturing the desired master model shape using a rigid medium such as wood. The mold is then made using this machined master model shape or plug, often from composite materials.

One key aspect that must be incorporated into the mold design is compensation for the phenomenon referred to as *springback*. Springback is caused by segregation and shrinkage of the resin to one side in an area with a large change in radius. Because of differences in thermal expansion, residual stresses arise during the manufacturing process. When the part is removed from the tool, the part deforms to the state governed by the residual stress state. For example, springback results in a one or two degree change in an L-section and can be addressed by considering the residual stress state in the design of the tool.

Differences in the coefficients of thermal expansion (CTE) between the tool and the part are significant as indicated in Table 1. Most forming processes involved compliant material being placed on the tool at room temperature with a subsequent rise in temperature to cure or consolidate the material. From this *stress-free* point, the part and mold are cooled to room temperature and differential shrinkage occurs. This difference can be used as a means to release a part, such as with graphite/epoxy tubes on an aluminum or steel mandrel; however, the CTE of the tube in the hoop direction must be sufficiently smaller than that of the mandrel. In this way tubes with reinforcement in the hoop direction easily release from the mandrel, whereas highly longitudinally aligned tubes do not. To provide better dimensional stability, the CTE of the tool is matched to that of the structural component in many high-performance aerospace applications.

Table 1 Coefficients of thermal expansion for mold materials

Material	Coefficient of thermal expansion	
	10^{-6}/K	10^{-6}/°F
Aluminum	22.5	**12.5**
Steel	12.1	**6.7**

Sand/polyvinyl alcohol	12.2	**6.8**
Sand/sodium silicate	11.5	**6.4**
Ceramic	12.1–12.6	**6.7–7.0**
Glass prepreg	11.7–13.1	**6.5–7.3**
Graphite prepreg	3.6	**2.0**
Invar	1.4–5.2	**0.8–2.9**
Monolithic graphite	**0.2–1.8**	**0.1–1.0**

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Forming Processes

Because the manufacturing process is to be designed concurrently with the component, design guidelines are flexible. Manufacturing of a designed component is often limited only by the creativity of the engineer and the budget of the project. Although currently not all conceivable parts can be made with composites, the constant stream of new products using composite materials attests to the ingenuity of manufacturing engineers.

In general, the manufacturing process can impose limitations on the microscale, such as the orientation of the reinforcement, and on the macroscale, such as the ability to form an integrated structure. Although an individual forming process has specific requirements on types of resins and reinforcements that can be used, the design considerations can be discussed among three areas. Laminated hand laid-up structures require extensive labor and tooling and thus are used only in those applications where the added performance can justify the relatively high costs. A second group of forming processes is that which makes use of dry reinforcements in a semicontinuous or continuous fashion such as filament winding, braiding, or pultrusion. The third group includes the closed-mold processes as discussed in the articles “Resin Transfer Molding and Structural Reaction Injection Molding,”, “Vacuum Infusion, and “Compression Molding” in this Volume.

Preimpregnated Tapes and Fabrics. Laminated preimpregnated materials often offer the greatest mechanical properties. High specific strength and stiffness are important in weight- constrained structures within the aerospace industry. Preimpregnation provides a consistent product with a uniform distribution of reinforcement and resin, with high fiber-volume fractions possible. Such laminated structures typically require a great amount of hand labor and autoclave processing. This results in a relatively high cost of manufacturing. Nevertheless, proper design of a composite component can decrease the overall manufacturing costs.

In laminated structures, the orientation of each ply is a design variable. This increases the complexity of the design process, and thus ply angles are often limited. Several common approaches include allowing only orientations that are multiples of 15° or, more stringently, laminates made up entirely of 0, +45,–45, and 90° plies. These design strategies limit the orientations that are involved if hand lay-up is to be used. However, limitation of angles may not be necessary. Templates can be used to cut material with the desired orientations and to place the plies on the tool. A trained worker can just as easily lay a 15° ply as a 17° ply. However, if the design requires many plies (shape and orientation), then additional care must be taken to sort the individual plies and to ensure that each ply is laid down in the correct sequence. It is also important that the sensitivity to a given angle is not greater than ±3°. Mylar templates or lasers often are used to indicate on the tool the location and orientation of each successive layer, thus eliminating much of the error in hand layup. However, variations between specified and as-manufactured orientation will always occur.

The cutting of plies can be automated to increase efficiency and quality. Techniques include water jets, lasers, reciprocating knife, and die cutting. Using these methods, intricate plies can be cut repeatedly with no limitation on orientation of the reinforcement. A water jet introduces moisture to the uncured composite, and extended exposure needs to be avoided. Laser cutting results in a heat-affected zone and may alter the local mechanical properties.

The contour of the tool is of great concern when using preimpregnated tapes and fabrics. Whenever there is a double radius of curvature, flat materials cannot be used without stretching or cutting and overlapping. The

inverse problem is to take any shape with a compound curvature such as a hemisphere and flatten it without excessive straining of the surface (Fig. 2a). One can see that the initial planar material requires many discontinuities. Even if cutting is reduced to a minimum as in the cone in Fig. 2(b), the orientation about the structure cannot be prescribed. Thus, a requirement for all of the fibers in a layer of a cone to be in one direction and only have one joint per ply is impossible. The orientation of fibers in structures with realistic surface contours is a continuum problem that the designer must be aware of.

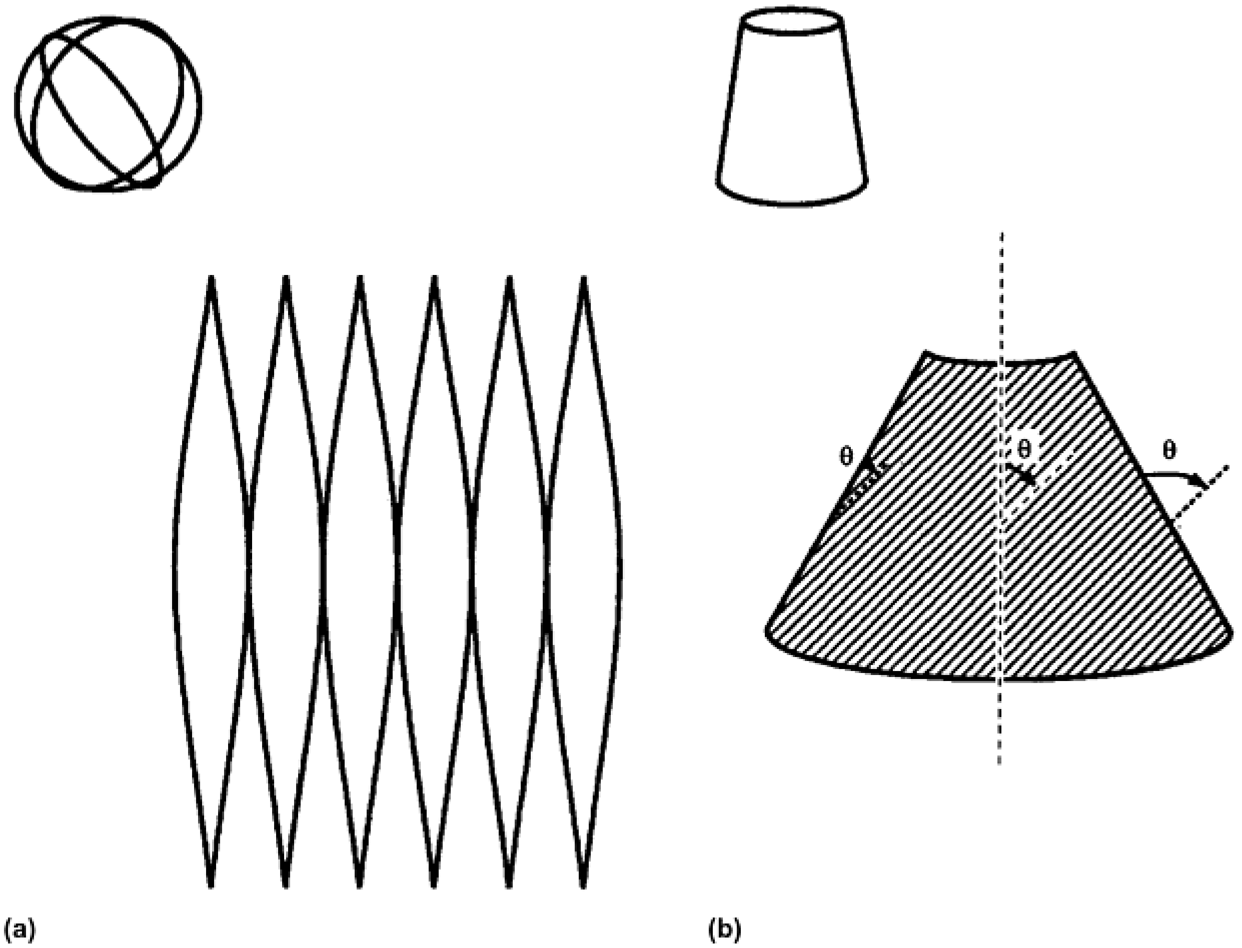

Fig. 2 Flattened contours. (a) Sphere. (b) Truncated cone

Many of the restrictions mentioned above can be overcome by using tow placement. Individual tows or strips of preimpregnated material can be laid down using a multiaxis, multi-degree-of- freedom robot arm. The material is tacked to the tool by applying pressure through the head of the tow placing arm. If this head is heated or an external heat source such as a laser is used, then thermoplastics can be used. Individual strips can be placed on the tool in the desired orientation. This process removes the variations inherent in hand processing, although it requires extensive programming and expensive fabrication equipment. Errors in orientations caused by the surface contour are limited by the width of the tow or strip being used.

Because most laminated structures are placed in a vacuum bag and cured with additional autoclave pressure, major concerns are maintaining the integrity of the bag during the forming process and proper transfer of the applied pressure to the part. In any concave portion of the part, the vacuum bag can form a bridge if it is locally of inadequate size. Thus, insufficient consolidation will occur in that section. One approach that reduces this effect is a reusable silicone rubber bag. The bag is originally formed on the tool. Even if the bag conforms as it should, a fillet should still be allowed in a corner; however, the fiber volume in the fillet will be lower than that in the surrounding material. For example, if an I-beam is constructed by laying up two separate C-channels, placing them together, and applying additional plies on the flanges, a small resin-rich pocket will form (Fig. 3a). To alleviate this resin- rich zone, additional material can be placed in that area to maintain the same fiber-volume fraction (Fig. 3b). In some cases, this remedy cannot be applied. Because plies have discrete thicknesses, the thickness of a part is changed using terminating plies, resulting in a resin-rich area that cannot be filled. A possible remedy is the use of a preform or bulk molding compound partially staged that can be cured with the overlaid flange plies.

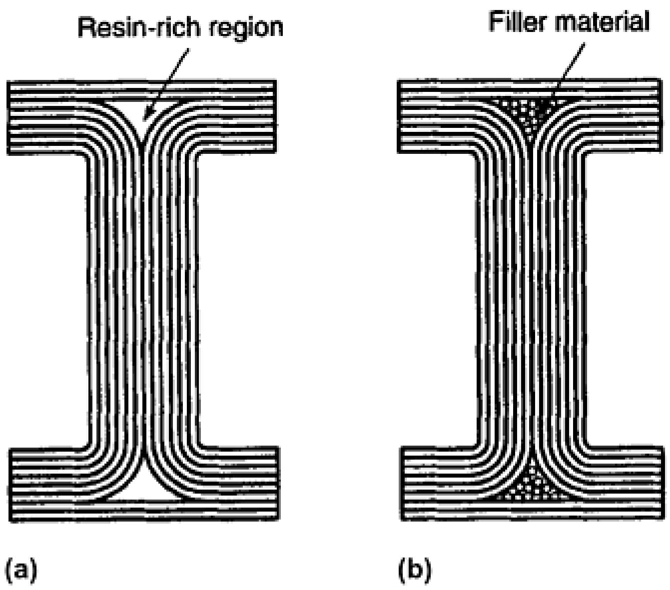

Fig. 3 Schematic drawing of a C-channel (a) with a resin-rich region and (b) with filler material to maintain fiber volume fraction

Dry Fibers and Broad Goods. One major disadvantage of using preimpregnated tapes and fabrics is that they require batch processes that involve significant hand labor or, in the case of automated tape laying and fiber placement, significant programming and capital investment. Mixing the reinforcement with the resin system in situ during the fabrication process allows for three-dimensional reinforcements or continuous processing while increasing material utilization.

In wet filament winding, fibers are drawn through a resin bath and wound on a rotating mandrel. This is the primary manufacturing method for cylindrical or spherical pressure vessels, because continuous fibers can be easily placed in the hoop direction. Low-cost constant cross-section components can be made using a filament winder with two degrees of freedom, the rotation of the mandrel and the translation of the payout eye. Increasing the number of degrees of freedom in the process increases its complexity as well as the complexity of parts that can be created. Additional payout eyes increase the speed of the process as well as introduce the possibility of performing braiding in the process. Variations to the winding process can include varying cross-sectional geometries, post-winding forming that can alter a convex outer surface to an I-beam shape as in Fig. 4, and inclusion of fittings and bosses.

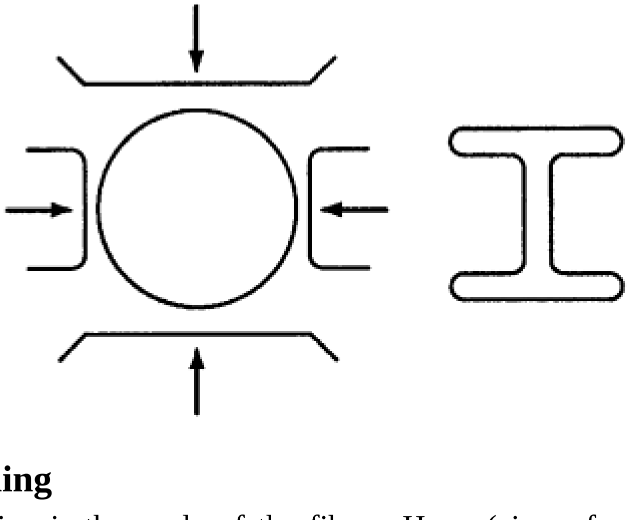

Fig. 4 Post-winding forming

One concern in filament winding is the angle of the fibers. Hoop (circumferential) winding involves laying fibers at nearly 90° with respect to the longitudinal axis of the mandrel. This results in a cylinder with high hoop strength. Helical (off-axis) or polar (axial, near-longitudinal) windings provide reinforcement along the length of the structure. As these fibers are wound, they have a tendency to slip. One exception is the geodesic path, which is a straight line on the flattened equivalent surface. As the part is formed, its thickness will increase, thus changing the geometry of the process. Additional information on design considerations with this process is provided in the article "Filament Winding" in this Volume.

Pultrusion is used to produce indefinite-length constant cross-section components. Fibers, fabrics, and mats are pulled through a die with resin introduced at one end. The die is tapered to apply hydrostatic pressure to the resin, resulting in fiber wet-out. An exothermic reaction can occur or heat is added to result in curing of the component. Design limitations include the need for a large proportion of reinforcement in the longitudinal (axial) direction to enable the process to be run. Annular cross sections or holes increase the complexity and cost of the die; however, it is better to have them formed in the part rather than added by post-forming machining. (It should be noted, though, that holes can be formed only in the pull direction of hollow closed sections.)

Molding Processes. The last set of forming processes involves forming with a closed mold. Such processes include matched-die molding and resin-transfer molding. These processes frequently are used to fabricate parts in large quantities with short cycle times.

The constraints that are posed by the forming process are the methods by which the resin is introduced into the mold and how the chemical reaction is to occur. The flow characteristics are often non-Newtonian. Mold design is based on specialized design experience and may utilize sophisticated software to locate resin entry and exit ports and to account for flow patterns, velocity, shrinkage, and thermal expansion. Often the resin is curing as it is being introduced into the mold; thus its rheology is a nonlinear function of time. Clearly, there are limitations in the shape of the component. A high degree of compartmentalization of the mold increases the need for many entry ports.

The dry reinforcement is placed in the mold before the resin is introduced. Fabrics, mats, and preforms of various cross sections and geometries are possible by employing the expertise of textile engineers.

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Post-Processing and Fabrication

Once the consolidation process is completed, the component usually requires additional fabrication steps to complete. The part is trimmed and holes are drilled. The surface may be prepped and painted. In addition, several parts may be bonded together to form a larger component, or secondary bonding is performed to yield a sandwich structure. The design of the component must also consider these steps and anticipate possible adverse effects.

Machining. The final shape and form of a metallic structure is realized in the machining process. Composite structures are formed prior to being machined. Machining is necessary to facilitate mechanical joints, cut small parts from stock items, and remove excess material. To avoid damage, composites should not be machined using metal techniques that use cutting, tearing, or shaving tools. Thus, if a cavity is required, it should be formed in the consolidation process and not by machining unless it is a thick- walled shape or has a “strong-back” composite or metal liner bonded in the cavity.

Cured composite materials can be cut using a number of techniques including mechanical methods and water jets. Mechanical methods require an increase in tool speed, a decrease in the feed rate, and a cooling lubricant. Often, carbide tip tooling is used; however, to prevent excessive damage or delamination to the composite structure, diamond-grit tooling should be used. Thus, the composite structure is machined using abrasives. Care must be taken to allow for particle removal and to prevent heating the part.

Water jets provide for a greater amount of complexity in cutting. Water jets can cut through a 25 mm (1 in.) thick structure at relatively fast feed rates (1.5 m/min, or 5 ft/min) and can be used for intricate details. The starting point of the water jet must be away from the part edge because of the possibility of delamination.

Because of the potential threat of damage during machining, designs should limit the amount of post-fabrication forming. Near-net-shape fabrication can result in a minimum amount of machining. Whereas holes can be drilled effectively, it is often better to incorporate a fixture into the component during its forming rather than to attach it through mechanical means later. However, difficulties arise when cocuring metal parts into composite parts due to the differences in CTEs.

Bonding. The ability to reduce the number of parts in an assembly is a clear advantage of using composite materials. Yet, if the manufacturing and design processes are developed independently of each other, this advantage will be severely diminished. An illustrative example of the choices available is a stiffened plate. In Fig. 5(a), the plate is made in three separate steps. The skin is fabricated, and the stiffener is fabricated. A secondary bond is performed. Although the stiffener fabrication may make use of a high-yield low-cost method such as pultrusion, performing the secondary bond reduces some of the cost benefit. One alternative is to cocure the stiffener with the skin. Film adhesive that has a similar cure cycle as the resin can be used to increase the integrity of the bond line. In Fig. 5(b), the stiffener may or may not be precured. A second variation has the stiffener now integrated with the skin. In Fig. 5(c), the macroscale of the design has increased, resulting in additional specifications on the microscale. Finally, the whole concept of skin with a blade stiffener can be abandoned, replaced by either a foam-filled hat section (Fig. 5d) or a sandwich construction.

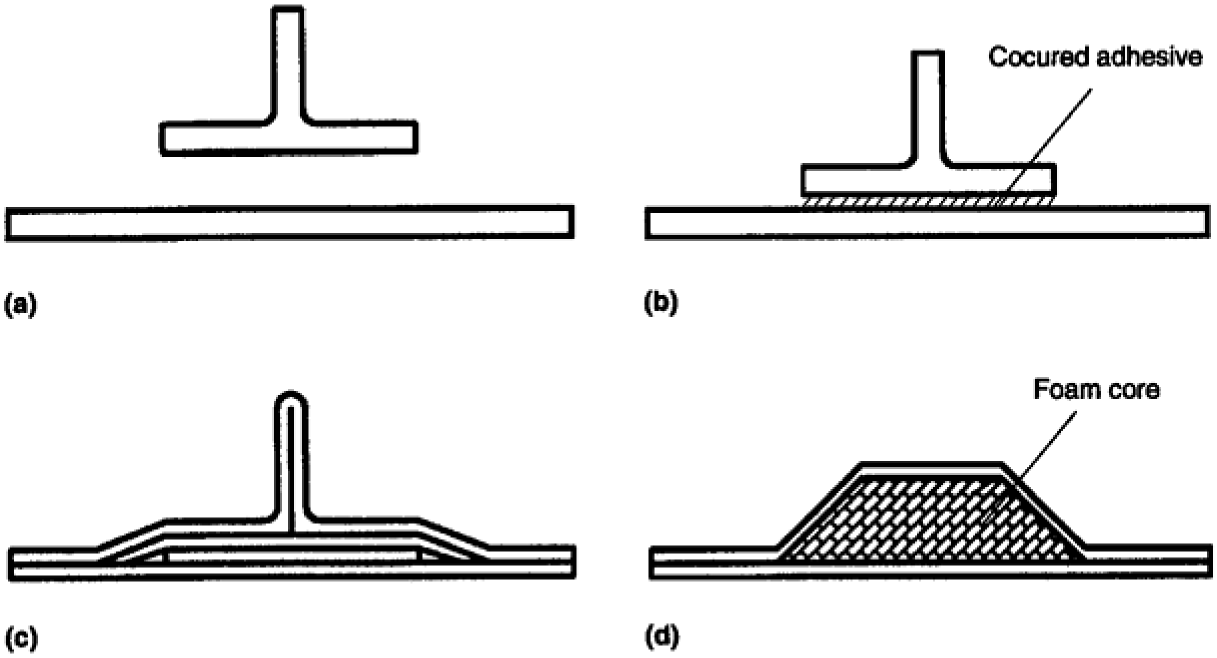

Fig. 5 Integration of stiffener and skin. (a) Mechanical/adhesive attachment. (b) Cocured. (c) Integrated lay-up. (d) Redesign

Again, if one approaches a composite structure with the same limitations imposed by metal construction, the potential of the composite material is not achieved. For example, an aircraft fuselage is constructed using thin skin stiffened by longerons along its length and hoop stiffeners about its circumference. The intersections of these stiffeners are at right angles, out of fabrication necessity. This limitation is imposed primarily because the metal structure must be made in many pieces and assembled. The true design objective of flexural and torsional stiffness can be met more efficiently with a composite structure if the artificial constraint of right-angle stiffeners is removed and stiffness is achieved through other means (such as sandwich construction).

Sandwich structures provide high bending stiffness at low weight. Various core materials are used such as expanded polymer foam, balsa wood, aluminum or Nomex honeycomb, or syntactic closed-cell foams. The face sheets can be formed separately and bonded to the core, cocured with the core, or cured in separate steps layer by layer. Forming core to different contours requires additional fabrication. Foam and honeycomb cores can readily conform to flat and cylindrical sections, although anticlastic deformations may cause problems on relatively small radius-to-thickness ratios. Compound curvatures are more difficult to attempt. The core material determines the minimum radius of curvature. Lower density core materials tend to conform easily but may offer lower shear stiffness and strength. The use of in-place foaming, overexpanded honeycomb, or scored-foam boards allows complex curvature or shapes while maintaining structural integrity.

The manufacturing process will determine the consolidation pressures seen by the face sheets during their forming process. If cured separately, high pressures can be used. Secondary bonding then occurs at temperatures equal to or lower than the cure temperature of the face sheets and at significantly lower pressures so as not to compromise the core material. Curing face sheets on the core directly results in a slight dimpling and reduced mechanical properties if honeycomb cores are used. If a resin infusion method is being used, nonporous core material must be used.

When using sandwich structures, most applications require that the edges must be closed out to allow for joining and to prevent damage and water intrusion. Several techniques are used, and some require machining of the core. Solid cores such as foam and balsa wood can be readily cut or sanded into the desired shape. Honeycomb cores require special cutting tools. In some cases the machined-out core is then backfilled with a resin/filler edging compound and cured to create a closeout. In other cases a specially fabricated metal or composite edge member is cocured or postbonded in place.

Anthony J. Vizzini, University of Maryland

Repair

An often-overlooked aspect of manufacturing with composites is repair. In addition to repair of damage inflicted in service, repair (or rework) is necessary if the component is damaged during manufacture or if a quality assurance check indicates that certain specifications are not met. The choice between repair or rejection depends on the ability to repair the structure effectively. This requires both access and proper procedures. Clearly, a proper design would anticipate likely damage events such as delicate areas being overstrained prior to final assembly or a tool drop on a composite surface. Poorly designed manufacturing processes yield a systematic flaw that may go undetected until the component is in the field.

General guidelines apply for composite repair as they do for repair of metallic structure. Convenient access should be provided. Thus, there is a trade-off between fully integrated structures and structures that are assembled with mechanical fasteners. Composite repair requires significant surface preparation. The damaged material is first removed, and the surrounding area is scarfed. A filler or a partially staged or cured bonded preform and a surface patch of several plies of fabric/resin prepreg is applied to return the strength and stiffness, to restore the contour of the surface, or to prevent water intrusion. Application is accomplished using a portable heating and vacuum bag unit. The core of sandwich structures is replaced if it is damaged. This necessitates an additional bonding cycle.

Design, Tooling, and Manufacturing Interaction

Anthony J. Vizzini, University of Maryland

Conclusions

The scale of design of a composite structure is substantially broader than an equivalent metal structure. This in turn increases the difficulty in the design process and is partly attributable to some of the advantages of composites, notably the ability to tailor the microstructure of the component and to integrate individual components into a single structure. This additional complexity is compounded by the relative scarcity of individuals who have knowledge of or experience with such materials. In addition the level of instruction at leading universities in manufacture of composite structures as compared to mechanics corresponds to the perception that research in manufacturing is less noble than research in mechanics. However, the recent emergence of texts specifically in integrated design may indicate a gradual reversal of this perception and an increase in awareness and research activity.

A vast pool of readily available experience aids the design of metallic structures. Clearly, the manufacturing practices of today involving milling machines, lathes, and drill presses have been honed in the preceding decades. Advanced composite materials are relatively new materials that pose new challenges to engineers. Moreover, it is unlikely that within an organization, the necessary expertise in materials, structures, and

manufacturing will reside in a single individual. Even simple components may require a design team and consultants to cover adequately the many facets involved in the process.

A key point is the need to codesign the manufacturing process and tooling with the component. Failure to coordinate both activities results in higher costs and poorer performance. Indeed, manufacturing may offer alternatives to the design that an engineer biased by his or her experience with metals may not contemplate. The emergence of composite tooling for composite components clearly indicates the limited ability for conventional materials to be formed in other than conventional shapes.

One drawback of using composite materials is the apparent lack of guidelines to assist in the design for manufacturability. New applications result in new challenges with little or no previous experience on which to build. An exposition in composite materials (International Composites EXPO '97 in Nashville, TN) displayed many new products in major and emerging end-use markets. Examples included a front-end apron for passenger cars that replaces 44 steel parts at a 25% weight savings and a sheet molding compound, cross-vehicle beam that consolidates 20 steel and plastic pieces with a 10% weight savings. Such examples indicate the advantages of integrating large structures through the use of composites.

Almost all processes can be improved once implemented by controlling key parameters that affect the occurrence and development of defects. Temperatures and pressures can be monitored and controlled to reduce process variations, yet mechanical performance may not be as sensitive to the processing variables as it is to the process itself. Care must be taken not to simply incrementally progress along a given path for an old process, but also to explore alternative manufacturing methods. New raw materials, processing materials, and methods are continuously being developed. The increased role of textile science due to the emergence of braided preforms is an example of how advantages can be seen by those who are willing to exploit both old and new technology in different areas.

Cost Analysis

Stephen Mitchell, General Electric Aircraft Engines; Rebecca Ufkes, Ufkes Engineering

Introduction

AFFORDABILITY is the key issue facing design engineers and manufacturers of composite components for current and next-generation aircraft, spacecraft, propulsion systems, and other advanced applications. To realize affordability goals, it is vital for engineering and manufacturing to accurately estimate manufacturing costs and risks at any stage of a program, but especially in the concept and preliminary design stage. Although the concept and preliminary design stages typically consume only 10% or less of program budget, over 80% of product cost is committed in these early stages.

In addition, lead times for design and fabrication of composite components often pace the development cycle. Consequently, a major priority is to reduce design cycle time and still produce the most efficient, lowest-risk component possible. Understanding the impact of critical cost elements on design features is a key step in reducing the overall cost of a component. It is critically important for the manufacturer to also quantify the cost elements of the manufactured part in order to reduce costs and simplify the manufacturing processes.

This article describes software tools available for modeling and analyzing costs associated with design and manufacturing options for advanced composites programs. An example is given of a composite exhaust nozzle shroud where the design and manufacture options were analyzed and adjusted, based on the use of cost analysis tools.

Composite Cost Tools

For decades, engineers have conducted their work without the benefit of fast cost feedback of their design concepts. However, over the past several years, a number of programs funded by the U.S. Air Force have resulted in the development of a variety of computer-based tools that allow for quick feedback of process cost. Two commercially available programs that have been used in recent Air Force-funded programs to develop composite process cost models are Cost Advantage by Cognition Corporation and SEER- DFM by Galorath Incorporated. Although a variety of software programs exist, most commercially available software can be categorized as either an open architecture, requiring user-provided rules and data, or a populated module with predefined equations based on industry standards.

In the Design and Manufacture of Low-Cost Composites for Engines (DMLCCE) Air Force program, General Electric Aircraft Engines (GEAE) used Cost Advantage as a framework to develop custom process cost models for filament winding and braiding of engine bypass ducts. In the DMLCCE program, GEAE directed the braiding and filament winding of a number of prototype composite ducts and captured the process steps and manufacturing data for each feature of the duct. These data were consolidated into algorithms, rules, and supporting data tables and programmed into Cost Advantage. The Cost Advantage software provides an architecture, or shell, to accept the rules, equations, and limits established by the engineer and manufacturer.

The flowchart of the desired model must be structured in the Cost Advantage software using the Process, Material, and Feature categories. The resulting flowchart for the General Electric Aircraft Engines DMLCCE composite model is shown in Fig. 1. Each node can have its own series of branches; however, it is impossible to show all branches, or paths, at one time in this view. Once there is an established flowchart, the model builder creates characteristics and corresponding relationships at various “contexts” within this framework. Figure 2

illustrates the interface for a model builder creating a characteristic for the braiding process. This example shows the interface for creating a default or programmed calculation. Note that this particular variable is not displayed to the user, but is derived using several existing user inputs. The true tow width of the braided tow is the value being calculated.

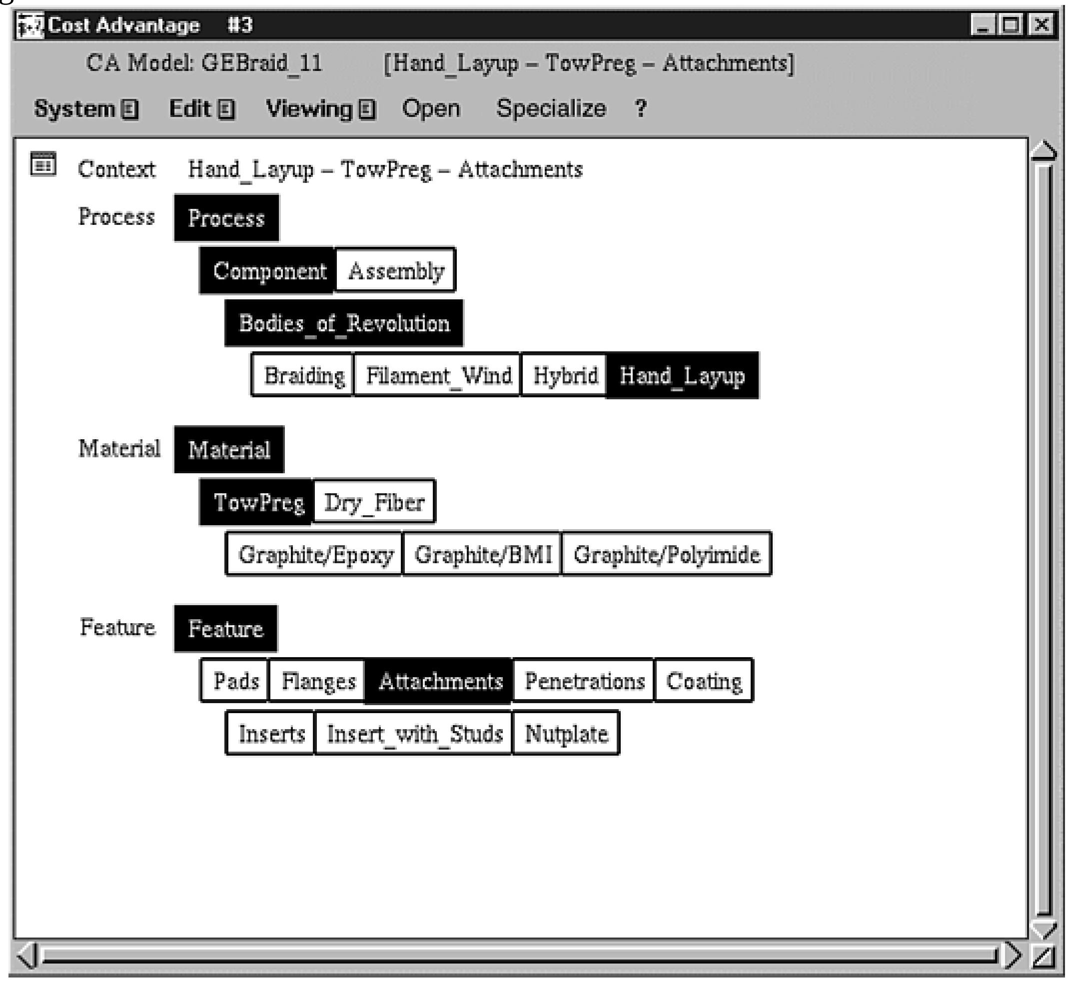

Fig. 1 Developed model hierarchy using Cost Advantage software

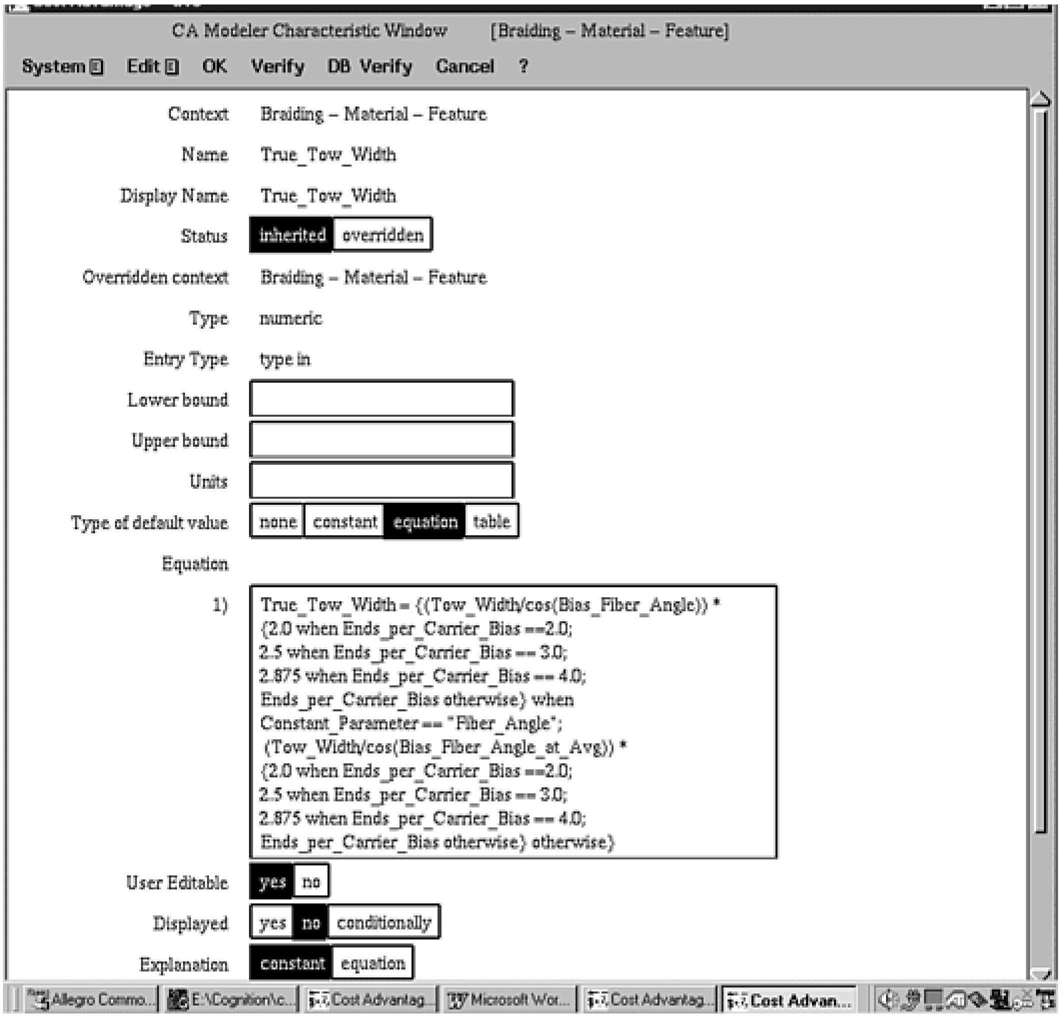

Fig. 2 Default model calculation for the braiding process, as created by a model builder

Once a model is completed and released by the "model builder," users can query the model. The resulting interface for the braid process as defined in the process windows can be seen in Fig. 3. The items noted with the sigma symbol (∑) indicate that the variables are system defaults or system calculations.

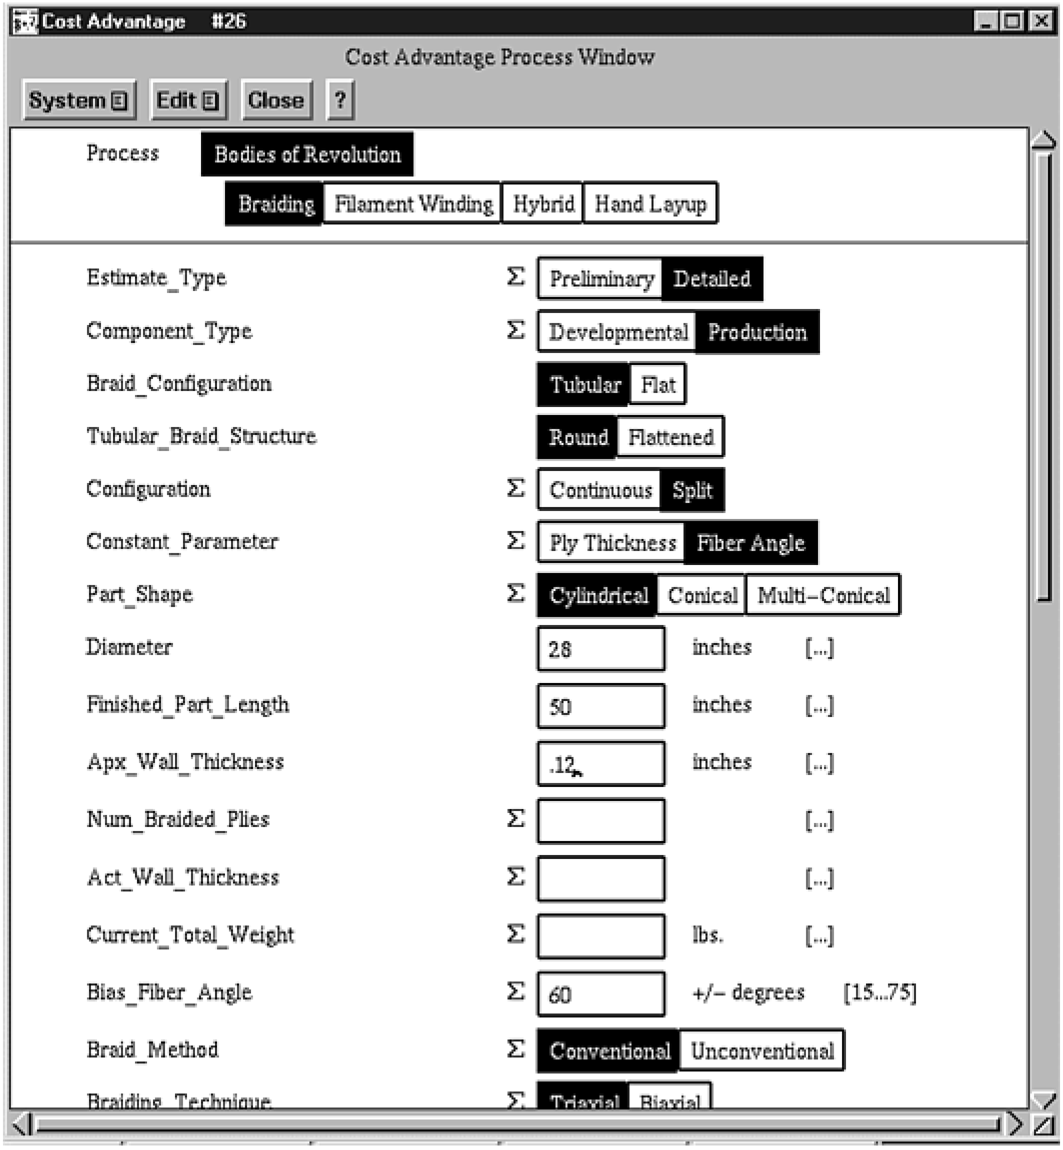

Fig. 3 Braid module process input window

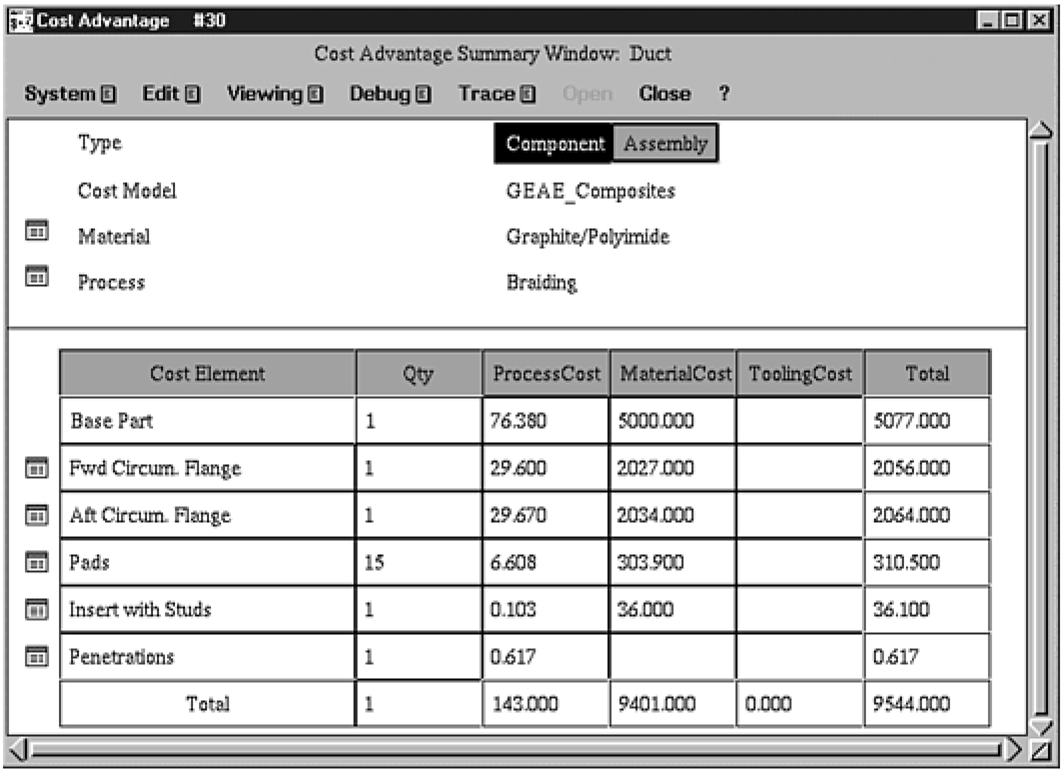
Based on inputs and model calculations, rules and restrictions may be invoked to alert the user of a problem concerning the design and/or the manufacturing process. The alert may offer guidance to the user, for example: "Warning: A single end per carrier is not meeting your coverage requirements for this part. Please increase the Ends per Carrier Bias variable or modify your coverage requirements."

Once the analysis is complete, the user is provided with a comprehensive summary. This summary identifies the total labor hours and material dollars as well as a cost breakdown per feature. This allows the user to quickly identify cost drivers. A summary window is shown in Fig. 4.



Cost Element	Qty	ProcessCost	MaterialCost	ToolingCost	Total
Base Part	1	76.380	5000.000		5077.000
Fwd Circum. Flange	1	29.600	2027.000		2056.000
Aft Circum. Flange	1	29.670	2034.000		2064.000
Pads	15	6.608	303.900		310.500
Insert with Studs	1	0.103	36.000		36.100
Penetrations	1	0.617			0.617
Total	1	143.000	9401.000	0.000	9544.000

Fig. 4 Output format from a Cost Advantage model

Under the U.S. Air Force-funded Composites Affordability Initiative (CAI), industry members from Boeing, GEAE, Lockheed Martin, and Northrop Grumman used SEER-DFM to develop comprehensive cost models for over 20 composite processes. Under this program, the CAI team members developed cost modules that plug into the existing SEER-DFM commercial software. This tool also guides the engineer through the composite process and, in many cases, identifies changes needed to avoid manufacturing problems or optimize manufacturing conditions. This software provides a variety of user-friendly features, such as a standard interface and detailed descriptions, graphics, pictures, and narrated videos. Figure 5 shows the standard interface for SEER-DFM.

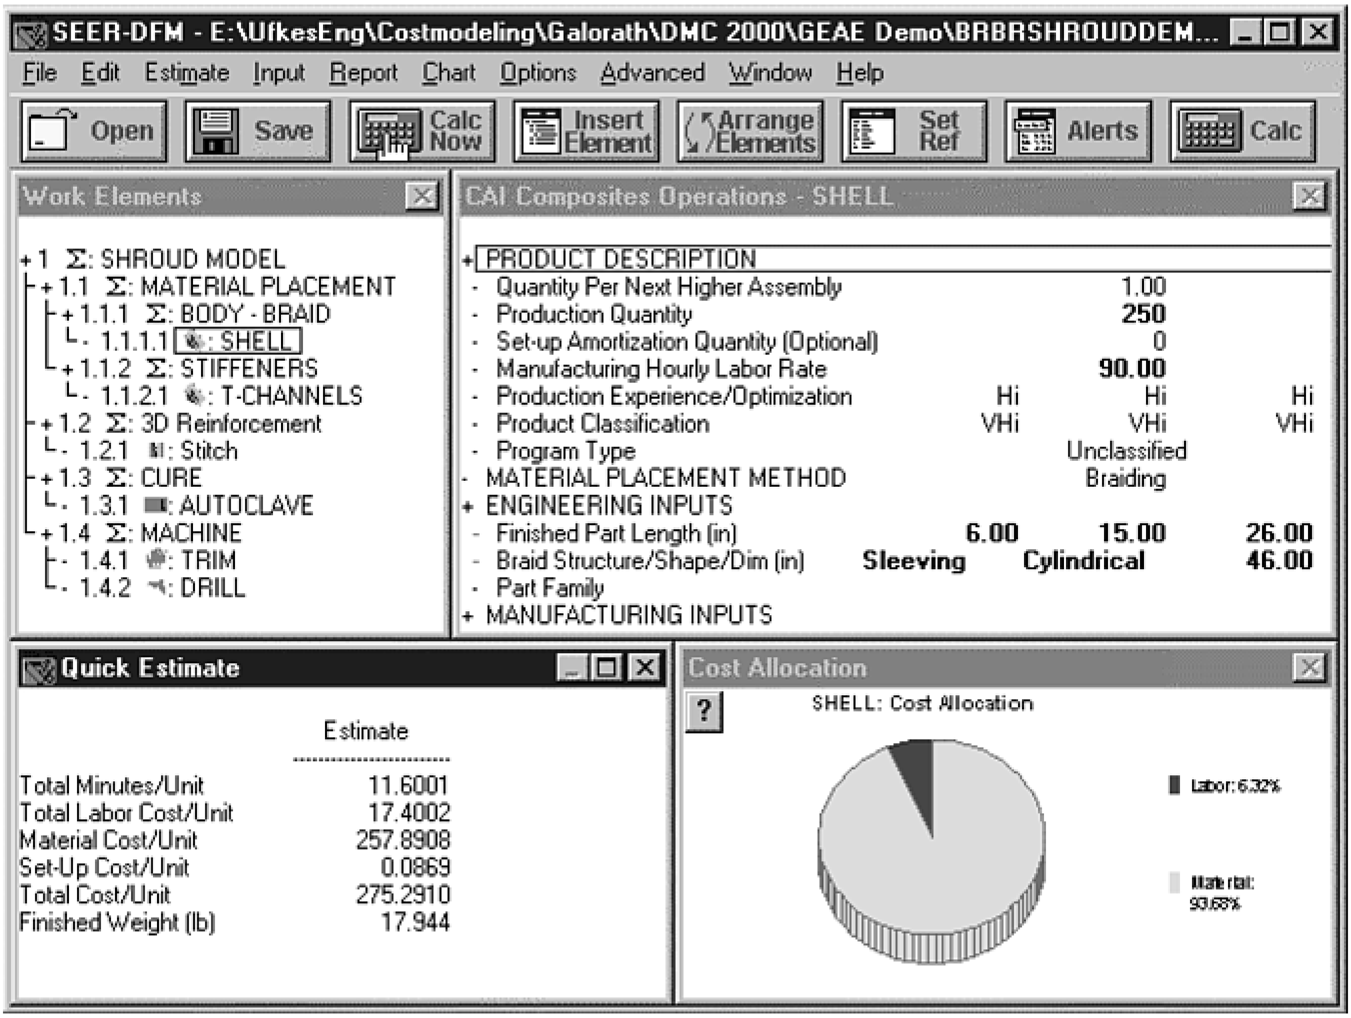


Fig. 5 Standard interface for SEER-DFM cost modeling software

The upper left corner allows the user to create a work breakdown structure for the part. Each work element, or process, has a specific parameter input window, as shown in the upper right corner. Outputs, reports, and charts are provided in the lower half of the screen.

The parameter window in Fig. 6 corresponds to the shell work element highlighted in Fig. 5. In this example, braiding is selected as the material placement method, and all of the required inputs for braiding are displayed.

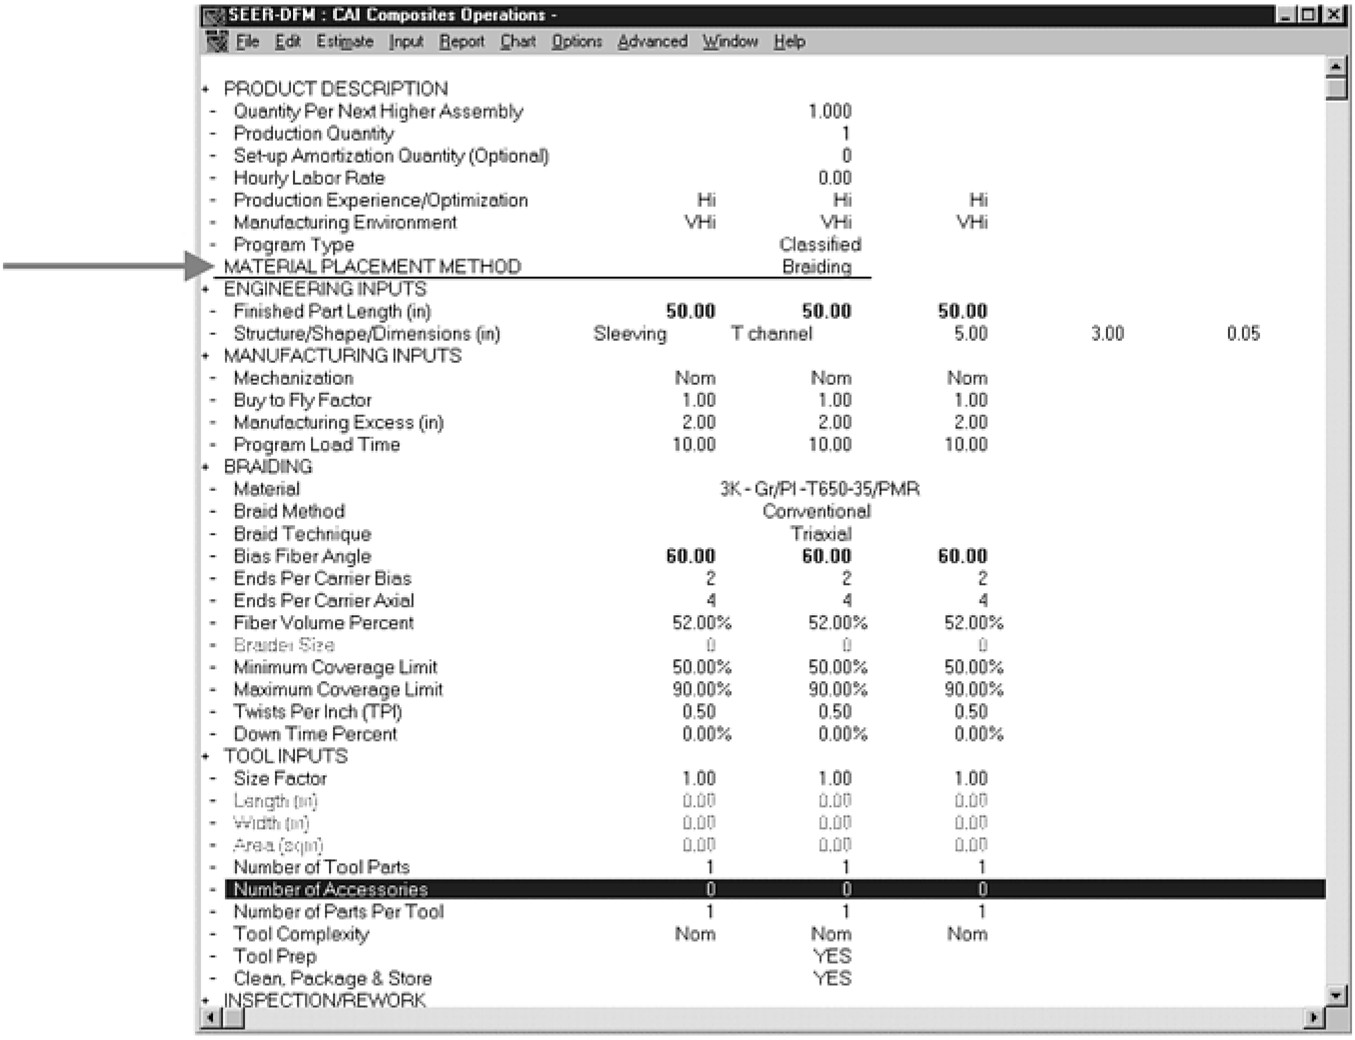

Fig. 6 Braiding parameter input window in SEER-DFM software

Note that various inputs can be “bounded” by a range of values. This allows a user to perform a risk analysis on one or more variables, in the event that exact inputs are not known or defined at that time. Many of the values appearing in the window are system defaults derived from tables or equations; however, these values can be modified as needed.

Each variable in the parameter window will open into an input screen when selected. This screen will provide additional information to the user regarding the specific variable. Figure 7 shows graphical assistance to the user for the structure/shape/dimension variable shown in Fig. 6. In this case, the engineer has selected a “T”-channel as a stiffener by clicking the appropriate icon at the top of the screen.

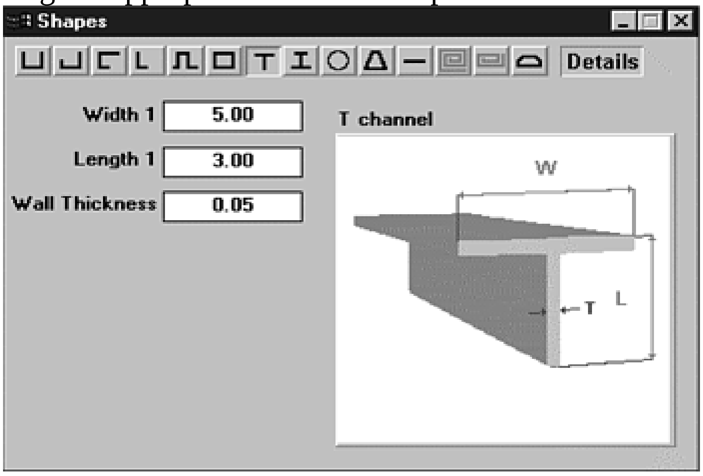

Fig. 7 Geometry input interface in SEER-DFM software

Help modules are available throughout the model. The SEER-DFM software also has alerts built into the program that provide guidance to the user. A defined “Alert” button identifies all invoked alerts in red.

The output of the model can be displayed in report or graphic format. Output can be generated for either the top component level, the subassembly level, or the individual work element level. The software also includes a built-in “set reference” capability that allows the engineer to perform trade studies and sensitivity analyses relative to a baseline. An example of one of the detailed reports can be seen in Fig. 8.

Fig. 8 Detailed output report from SEER-DFM software

Both Cost Advantage and SEER-DFM cost model software allow the engineer to evaluate different composite processes and can provide immediate cost feedback during all phases of design. The tools can also provide manufacturing and producibility guidance, assisting the engineer in designing affordable, low-risk designs. A key objective of implementing cost model software is to provide the engineer with electronic data concerning the manufacturing process and its critical elements so that smart, affordable decisions can be made early in the program in order to reduce downstream manufacturing costs.

Cost Savings

Cost modeling software makes it easier for engineers to perform cost estimates and choose among design alternatives, with the result being lower-risk, affordable components with reduced time-to-market. Figure 9 depicts the results of a trade study for an engine shroud where the advantages of braiding were compared against hand lay-up. The component is a continuous shell with integral internal "I-beam" stiffeners. The cost model allowed the engineer to examine the benefits of each process for both the shell and the stiffeners. Figure 10 shows the GE F110 composite exhaust nozzle shroud braided by A&P Technology using the lowest-cost process identified in the study.

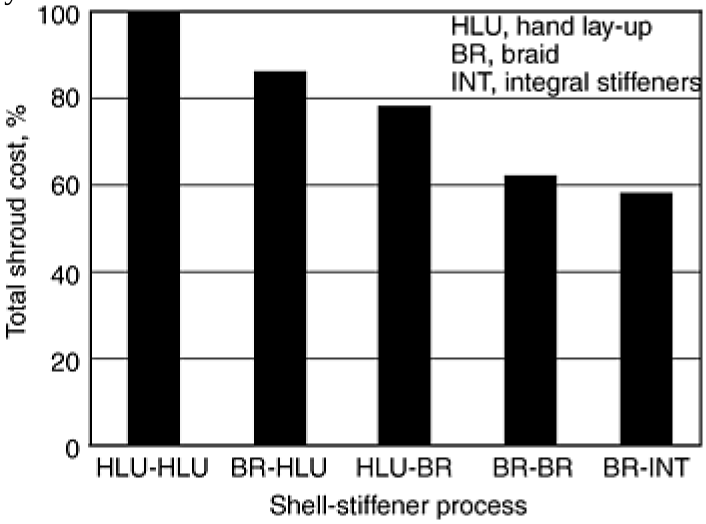

Fig. 9 Cost comparison (trade study) of different processes for manufacturing a composite shroud

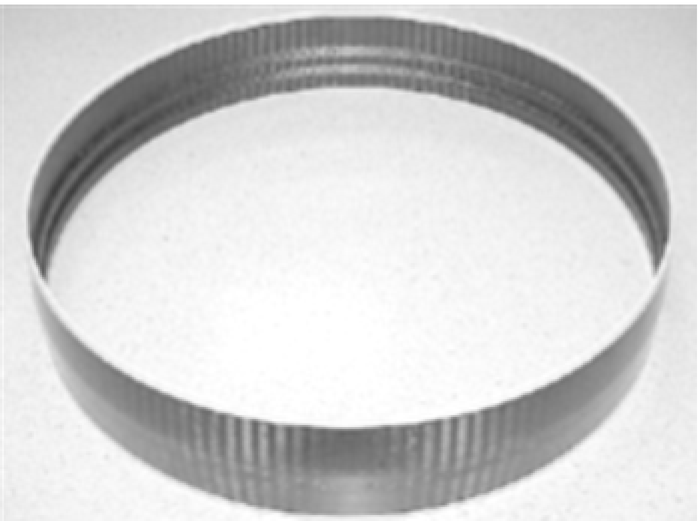

Fig. 10 Braided shroud with integral stiffeners. Approximately 1.2 m (4 ft) in diameter.

In addition to component savings, a variety of significant program savings can also be realized through the use of cost models. The following lists some of the attributes found in various cost modeling software and the potential cost benefits:

Attribute	Cost benefit
Knowledge of critical process steps	Lower cost and faster development
Knowledge of alternative processes	Lowest-cost design
Design advice	Fast demonstration of performance
Manufacturing warnings and alerts	Reduced cost through reduced risk
Fast, user-friendly software	More studies per program dollar

Industry has also documented a variety of savings within their respective companies. One key savings results when the engineer is provided electronic knowledge of alternative manufacturing processes and their critical elements. This up-front knowledge reduces program risk and downstream manufacturing costs. Another cost savings is the result of conducting cost studies faster than conventional methods. During the CAI validation phase, the CAI team documented several time savings that ranged from 88 to 95%. The trade study depicted in Fig. 9 was conducted using SEER-DFM in 10% of the time required for conventional consultation or quotation approaches.

Although the benefits are difficult to quantify, another cost savings is the ability to conduct more cost analysis trade studies within a fixed conventional schedule allocation. Some companies identified "10 times as many cost analysis trades" performed in the same time frame. Finally, the cost savings resulting from risk avoidance could provide significant benefits through fewer manufacturing iterations and faster development cycles.

Rapid Prototyping

Introduction

RAPID PROTOTYPING (RP)—also known as solid freeform fabrication, automated fabrication, layered manufacturing, and so forth— consists of a range of technologies that are capable of taking computer-aided design (CAD) models and converting them to a physical form or part. This process is automatic, generally independent of the model geometry, and does not require special tooling or fixtures. Complex, three-dimensional (3-D) contours are quantized in the form of stacks of two-dimensional, finite thickness layers or cross sections. If these layers are very thin, then the parts made will be sufficiently accurate to suit a range of applications. Nearly all RP parts can be characterized by a stair-step effect that approximates the original shape, which is most obvious on shallow slopes and curves. A most comprehensive classification of RP processes was proposed by J.P. Kruth (Ref 1), in which the focus is on the initial state of the raw materials used, namely solid, liquid, and powder-based manufacture. Other sources for more detailed information are included as 2, 3 4, 5 6.

Review of Processes

Photopolymer Systems. Stereolithography (SLA) (Ref 7) is regarded as the first commercial RP process and uses liquid-based photopolymer resin as the raw material (Fig. 1). Polymerization occurs at a specific frequency of light, supplied by a laser source, which scans across the surface of the photopolymer. The laser intensity is matched to the absorption of the photopolymer so that solidification is limited to a short depth, representing the layer thickness. Parts are built on an elevator platform, which increments down from the surface as layers are added. Stereolithography was first commercialized by 3D Systems and is registered to their machines. There are, however, a number of variations from other companies that also use photopolymer resins. Parts made using SLA are surrounded by liquid resin during the build so there is a need to ensure that all layers, and parts of layers, are connected to each other and to the build platform at all times during the build process. Overhanging part features must therefore be connected using additional support structures, which are fabricated at the same time.

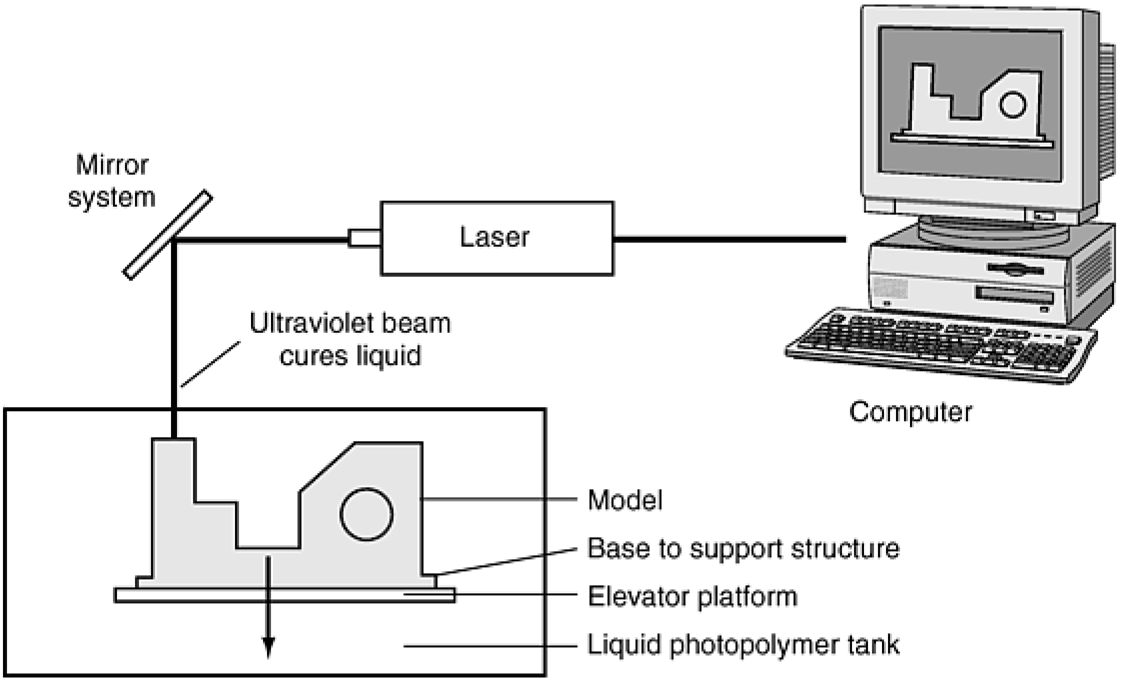

Fig. 1 Stereolithography (SLA) rapid prototyping system. Courtesy of Milwaukee School of Engineering

Powder Sintering. Selective laser sintering (SLS) uses powder as the raw material (Fig. 2). Parts are built on a platform, which indexes downward as more powder is added at the top. A laser melts or sinters the powder particles according to the cross section at a particular layer. Each layer cools rapidly, and laser penetration is such that it thermally bonds to the layer below. The powder material must therefore be thermoplastic in its behavior. The use of powders means that part surfaces have a granular texture, and there is also a tendency for parts to be porous. Loose powder surrounds the solid part, thus eliminating the need for specific support structures. Thermal processing also leads to very good part strength. Selective laser sintering is registered to

machines manufactured by DTM Corporation (Ref 8), but similar machines are also made by EOS GmbH in Germany (Ref 9).

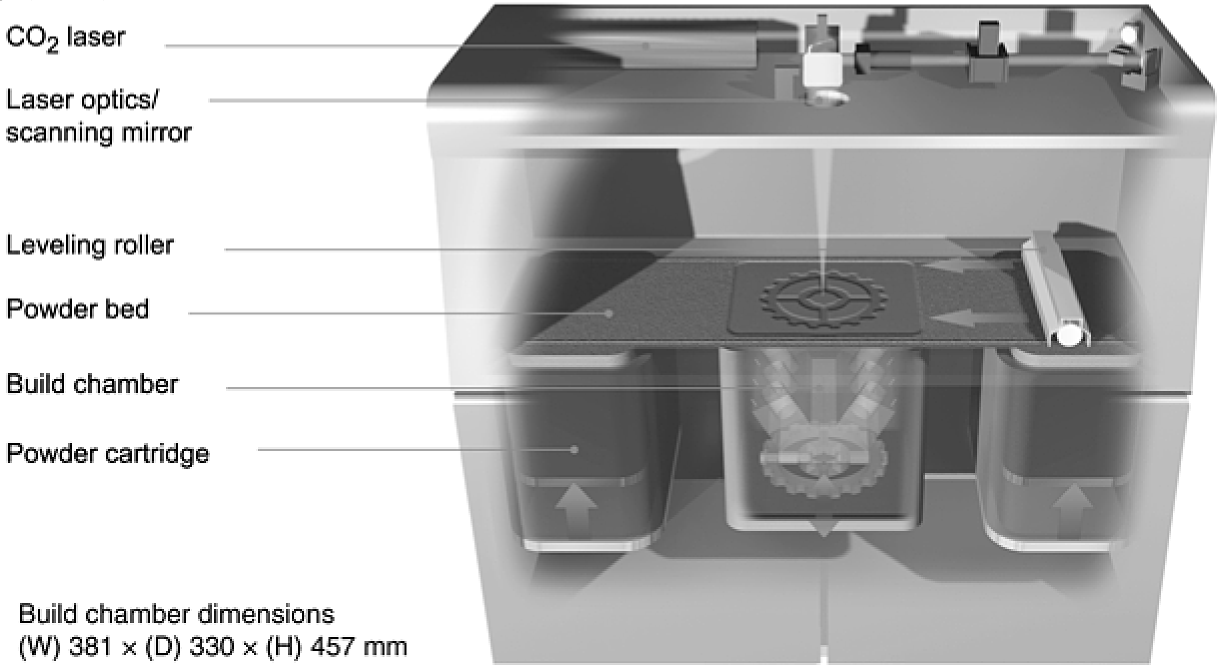

Fig. 2 Selective laser sintering (SLS) rapid prototyping system. Courtesy of DTM Corporation

Hot Melt Extrusion. Fused deposition modeling (FDM) material comes in solid form as a filament. This is extruded through a heated nozzle, which deposits a thin "road" of material (Fig. 3). First, roads are extruded to form the outline of the part. These roads are then filled in to complete the layer. Since the material is optimally softened and not fully liquefied when it exits the nozzle, FDM generally uses amorphous polymers. Fused deposition modeling must also use support structures for overhanging features. Supports are extruded through a second nozzle and can therefore be held at a different temperature or made from a different material. This allows the supports to come away from the part easily. A recent development is the use of a soluble support material that can be removed with a minimum of mechanical damage to the part. Fused deposition modeling is currently commercialized by Stratasys Inc. (Ref 10).

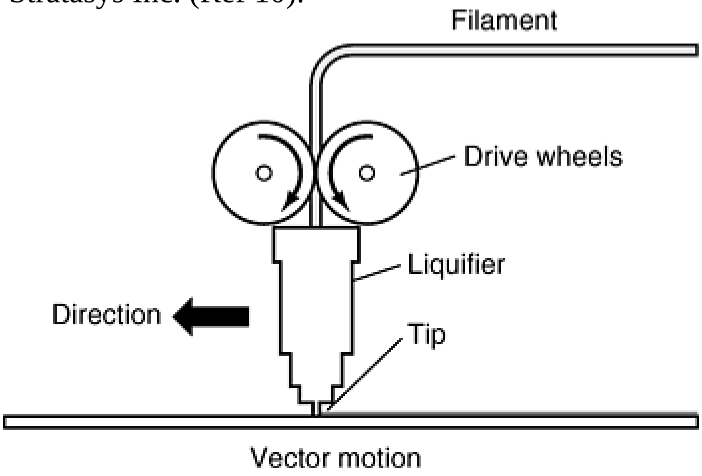

Fig. 3 The fused deposition modeling (FDM) hot melt extrusion process. Courtesy of Penn State University

Sheet Lamination. Laminated Object Manufacturing (LOM) (Ref 11) uses solid sheets of material, which are sequentially bonded together and cut to form the part (Fig. 4). The thickness of the sheet material, which is normally paper, represents the layer thickness. After each layer is bonded and cut, the part is separated from the feed material by cutting it around the outline. Further cuts or "cross hatches" are required to permit easy removal of the waste material after the entire part is complete. Thus, LOM parts are surrounded by solid material and do not require support structures during the building process. LOM was first commercialized by

Helisys Inc., which used the approach described previously to cut and bond adhesive-backed paper that was delivered on a continuous roll. Another laminating machine, which uses single sheets of paper for each layer, photocopying technology to apply the adhesive, and a blade to cut the part outlines, is made by Kira in Japan (Ref 12).

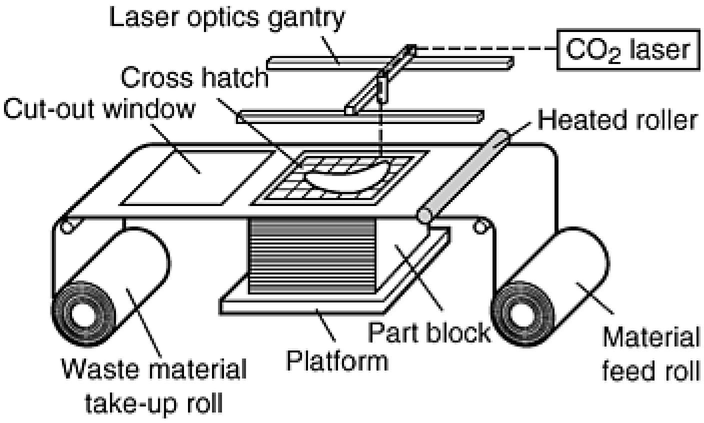

Fig. 4 Sheet lamination using the laminated object manufacturing (LOM) process.

Solid Ground Curing (SGC) (Ref 13), a process developed by Cubital in Israel, also fabricates parts from photopolymer resins but in a different way than stereolithography (Fig. 5). Resin is spread onto a platform, which is then exposed to ultraviolet light through a mask, which is printed from the layer data onto a glass plate. Uncured resin is vacuumed away, and the space is filled with molten wax. The wax solidifies and the whole layer is machined, level to the required layer thickness. Parts are therefore a combination of resin and wax and do not require supports. Wax is removed using a chemical bath or autoclave. Solid ground curing can be considered a hybrid system since it uses solid wax and liquid resin.

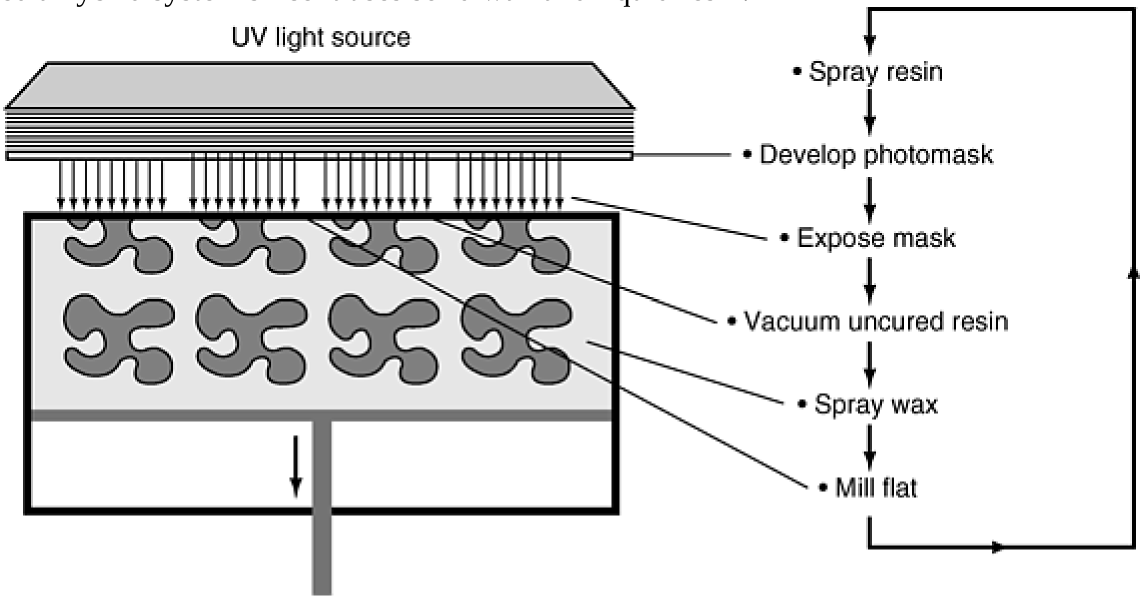

Fig. 5 The solid ground curing (SGC) process from Cubital. Courtesy of Penn State University

Three-Dimensional Printing (3DP). Developed and licensed by the Massachusetts Institute of Technology (Ref 14), 3DP can be found in a number of commercial forms. Powder is spread onto a build platform (Fig. 6). Liquid is then printed from an ink-jet print head. The liquid dries and binds the powder particles together to form the layer. 3DP is therefore another hybrid process using powders and liquid. Like SLS, the use of different powders results in different applications. The most common machine is the Z402 from ZCorp, which uses multiple nozzle ink-jet print heads to print large areas in one pass, making it possible to create parts quickly. Like SLS, parts exhibit a granular texture and are porous. Three-dimensional printing parts generally require strengthening using a resin- based infiltrant.

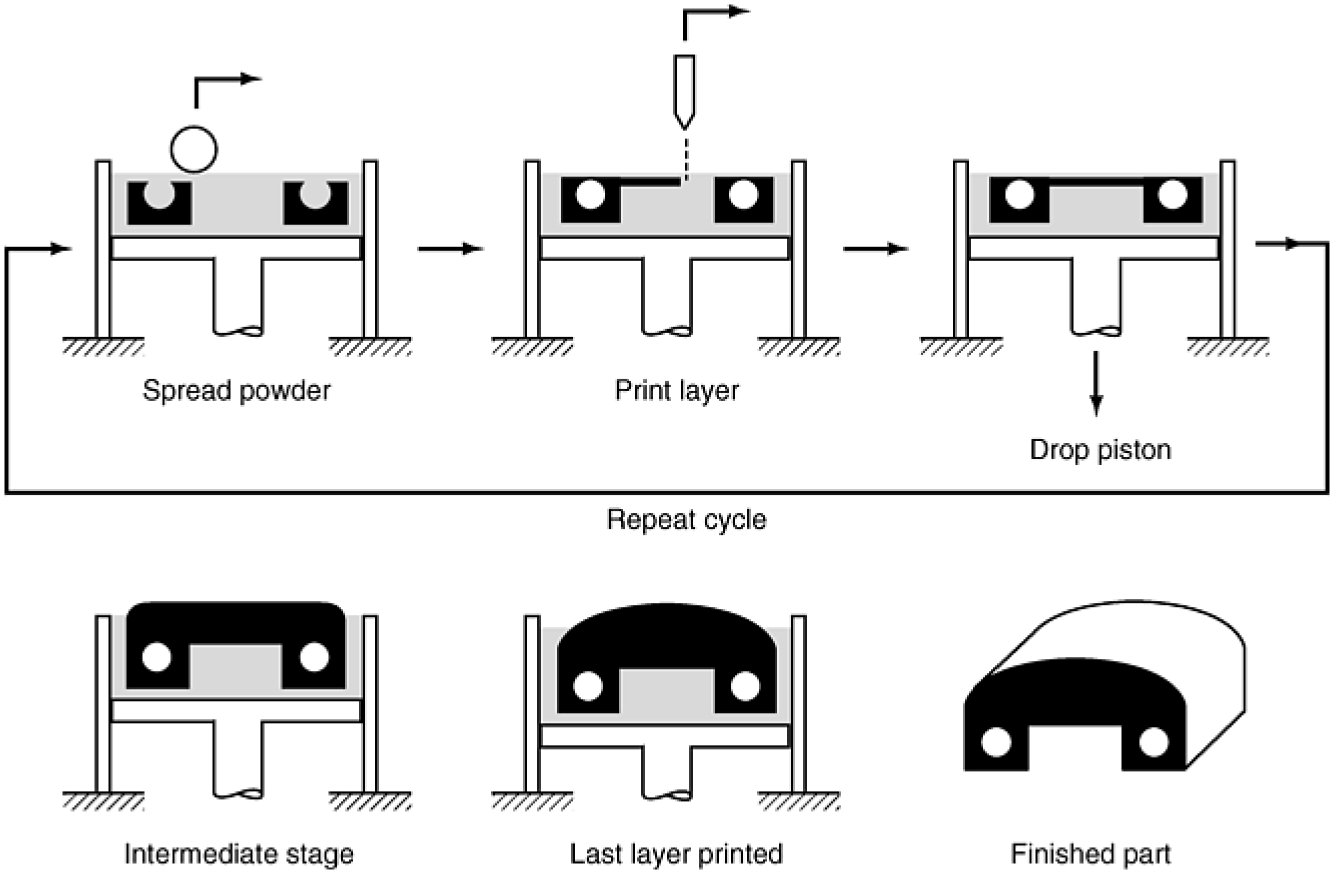

Fig. 6 The basic three-dimensional printing (3DP) process. Courtesy of MIT

Drop-on-drop systems, like 3DP, FDM, and others, use nozzles to create parts. The Sanders ModelMaker (Ref 15) (Fig. 7) and Thermojet (registered to 3D Systems) processes deposit material in a molten droplet form. This material then solidifies rapidly to allow further droplets to be applied. These processes generally use wax as the raw material. Sanders machines use two types of wax, one for support structures that can be removed from the part material at low temperature. Thermojet systems create supports from the same material, resulting in comparatively rough, down-facing surfaces.

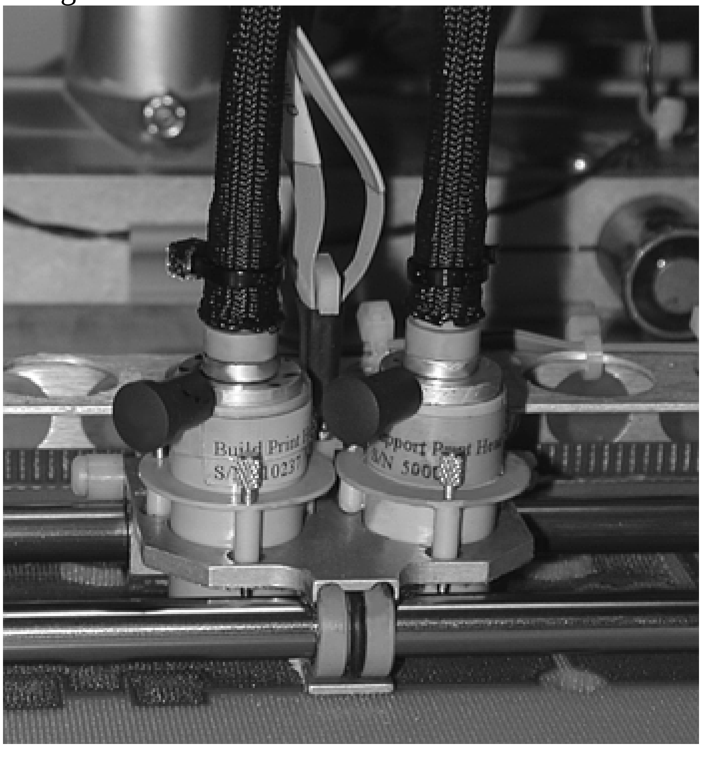

Fig. 7 Drop-on-drop system (Sanders ModelMaker) print jets, showing the two jetting heads above sample parts. Courtesy of Sanders Prototype International

Metal Systems. All of the above commercial systems concentrate on polymeric materials or materials with low melting points. A number of processes have been adapted so that they can process metals, but few of them have reached commercial status to date. It is not difficult to see how FDM, LOM, and SLS can be developed into metal systems. Direct sintering of metal powders is possible with the EOSint M machine, although the metals are, admittedly, relatively low melting point. The Laser Engineered Net Shape (LENS) directed material-deposition process commercialized by Optomec, Inc. (Ref 16) feeds metal powder into a head, which then melts and deposits in a similar manner to FDM. StratoConception (Ref 17) uses machining to create metal sheet laminates, which are bonded together like LOM. Obviously, high power, temperature, and atmosphere considerations make these direct methods difficult tasks to achieve.

Direct Fabrication of Composite Structures

Significant advances in the technology of rapid prototyping during the 1990s have produced a new capability for directly fabricating advanced material prototypes and end-use components. The list of advanced materials

includes particulate and fiber-reinforced polymer, ceramic-matrix composites (CMCs), and metal- matrix composites (MMCs). Adapting the various RP processes for direct fabrication of ceramic materials has received the most effort because, compared to techniques for fabricating metals and polymers, traditional techniques for small-lot fabrication of complex-shaped ceramic components are difficult, time consuming, labor intensive, and expensive. Thus, RP technology was expected to yield the earliest and greatest payoff for direct fabrication of ceramic materials. Great strides, however, were also made with direct fabrication of polymer and metal components during this time period. Currently, a wide variety of RP processes exists for direct fabrication of particulate and fiber-reinforced composites.

Fiber-Reinforced Composites. Of all the RP techniques, LOM is the only one well-suited for direct manufacture of fiber-reinforced composites. Because LOM is essentially a sheet-processing method (Fig. 4), it is capable of handling common sheet preforms such as fabrics and prepregs that are traditionally used in composite fabrication.

Recent research efforts have established the viability of LOM for direct fabrication of continuous-fiber reinforced polymer-matrix composites (PMCs) and CMCs. With PMCs, a full discussion of the various issues involved is given elsewhere (Ref 18, 19). The general approach is to use the LOM machine to lay up and shape a green (partially cured and consolidated) composite, followed by additional off-line consolidation and cure using a heated vacuum bag or autoclave. Glass fiber/epoxy composites made with LOM using a commercially available prepreg, Scotch Ply (3M), exhibited approximately 85% of the strength (tension, compression, flexure, and interlaminar shear) of an autoclave cured panel. Figure 8 is a photograph of some PMC parts. The standard CO_2 laser of the LOM machine can be used without modification to cut glass fiber/epoxy prepregs. However, for higher performance fibers such as carbon or silicon carbide, an entirely different cutting mechanism is required. To this end, researchers have demonstrated high-quality cutting of continuous silicon-carbide (SiC) fibers via photoablation using a copper-vapor laser in a bench-top LOM process (Ref 20).

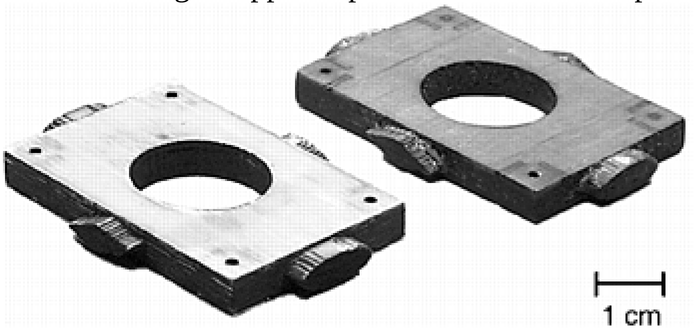

Fig. 8 Parts made with glass fiber/epoxy prepreg using laminated object manufacturing (LOM). The part on the right has been fully cured.

For CMCs, the LOM machine is used again only to lay up and shape a green composite. Ceramic-matrix composite prepregs must contain a polymer-ceramic precursor resin of sufficient tack, or a tackifier can be used in between prepreg layers. One study demonstrated the use of a novel preform comprised of a layer of SiC fiber/furfural unidirectional prepreg adhered to the top of a SiC ceramic tape (Ref 21). Regardless of the preform type, the green CMC must undergo significant postprocessing involving high- pressure consolidation, high-temperature resin- to-ceramic conversion, and possibly infiltration or reinfiltration with additional ceramic precursor resin or liquid metal.

Regardless of the material type, LOM and other RP processes are limited to building with flat, horizontal layers. While it is true that complex, curved geometries can be created with this process, they must be built up from thin, flat layers and then postmachined to get the final part. Thus, flat-layer RP processes are incapable of addressing the larger geometrical issues involved with fiber composite fabrication, namely fiber orientation and continuity. In response to this need, the first curved-layer RP process was developed. The new process, referred to as curved LOM, was motivated by the need for rapid fabrication of fiber-reinforced structures containing sloping, curved surfaces, especially thin curved-shell components. It is crucial to maintain fiber continuity along the curved surfaces of these components.

Details of the curved layer process are found elsewhere (Ref 22). It begins with production of a matched tool or mandrel for the intended part. This tool can be generated by any of several other RP processes, including the standard LOM process using LOM paper. The finished LOM mandrel is mounted to the flat building platform in the curved LOM machine. Size limitation is approximately 30 by 30 by 5.5 cm (12 by 12 by 3 in.). Sheets of

the desired build material (e.g., composite prepreg) are loaded onto an external, rotatable feed table, picked up with a vacuum chuck, and shuttled to the mandrel. A flexible thermoforming mechanism laminates each new layer to the curved mandrel with steady, uniform vacuum pressure and heat. After the laminator retracts, a CO_2 laser cuts each layer, accounting for the sloped surface. The fiber orientation can be varied from layer to layer by programming the rotatable feed table. The process proceeds one layer at a time until the part is finished. If necessary, the laminator can be used to provide additional post cure to the final part. Subsequently, the part is removed from the mandrel, and the excess material is manually stripped away (decubed). Suitable postprocesses are then performed to obtain a fully consolidated, cured, and/or densified PMC or CMC.

The viability of using curved LOM for production of PMC (Ref 23) and CMC (Ref 21, 22) structures has been established. Curved-layer CMC components are shown in Fig. 9. Widespread industrial use of LOM or curved LOM for direct fabrication of PMCs had not occurred by the year 2001, most likely because of size limitations and the availability of automated tape placement (ATP) machines (Ref 24) used in the aerospace industry (see the article "Automated Tape Laying" in this Volume). However, compared to ATP, the cost and ease of use of LOM machine is favorable for production of small (e.g., 60 by 30 by 15 cm, or 24 by 12 by 6 in.) articles. Thus, with regards to PMCs, LOM holds the most short-term potential for the consumer-goods industry. Ceramic and CMC articles are often not as large as PMC structures, and thus the potential benefits of LOM for these materials still remain for all applications.

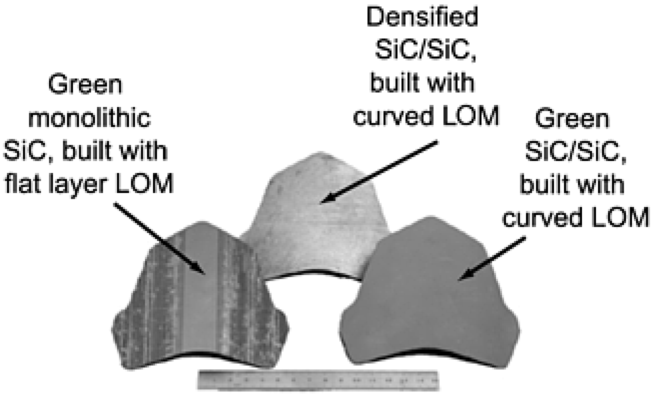

Fig. 9 Aircraft engine flame holders. The piece on the left illustrates the poor surface finish obtained with the flat-layer LOM process compared to the curved layer LOM process.

Particulate-Reinforced Metal- and Ceramic-Matrix Composites. Processing of MMCs and CMCs presents unique opportunities for RP techniques due to the inherent nature of high-cost, low-volume production needs of value-added products. Net-shape fabrication of controlled microstructure parts has already been demonstrated, utilizing some of the commercial RP systems. Although extensive research and development work is still pending for tailoring these approaches to mature commercial techniques for industrial-scale production, some of the initial results show significant promise and are herein discussed.

Magnesium/Silicon Carbide Composites. Wohlert and Bourell (Ref 25) utilized the SLS process to fabricate particulate Mg/SiC metal- matrix composites (Fig. 10). In their approach, polymer-coated commercial SiC powders were used to produce porous SiC ceramic preforms. Preforms were binder removed and sintered, prior to metal infiltration. Porous SiC preforms were infiltrated with commercial die-casting AZ91D magnesium alloy under controlled nitrogen environment via pressureless metal infiltration. Composites with fine features having 40 to 50 vol% of SiC particles were successfully processed via this approach. The Mg/SiC composite microstructure showed little or no residual porosity for structures where the pore sizes were uniform and smaller in size. One of the problems in this two-stage approach is the selection of metal-ceramic combination. For the pressureless infiltration process to be successful, the surface tension of the liquid infiltrant must be lower than the surface energy of the solid matrix. Usually the surface energies of the ceramics tend to be quite low, causing difficulties in selecting the matrix metal for preforms of different ceramic compositions.

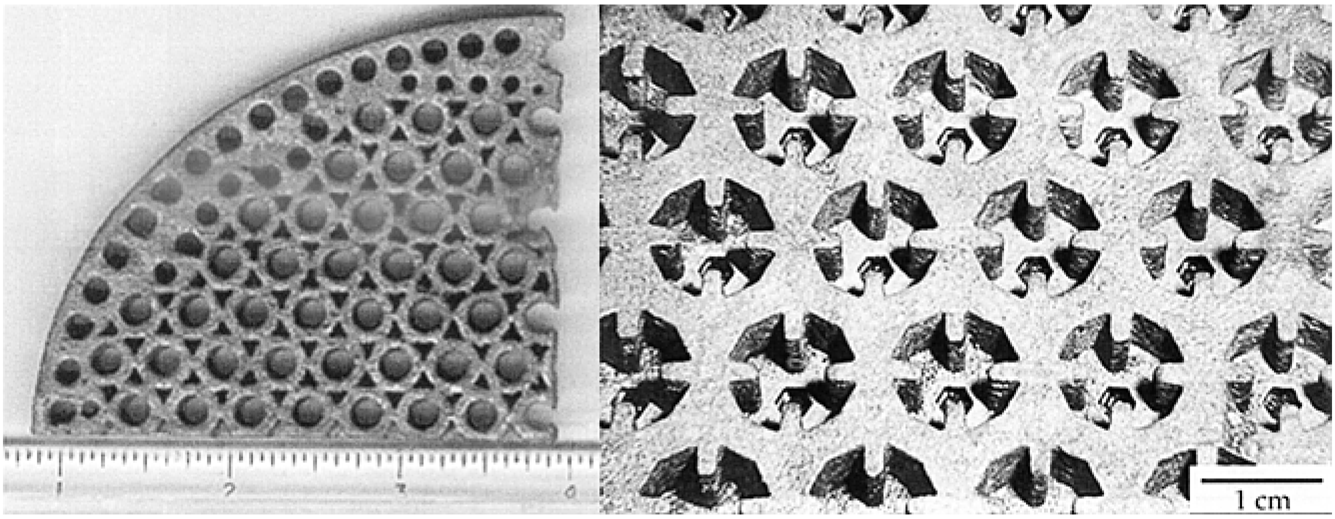

Fig. 10 Particulate composite parts produced by SLS processing of SiC preforms followed by liquid-metal infiltration of a magnesium alloy. Source: Ref 25

Metal-Ceramic Composites. Bandyopadhyay et al. (Ref 26, 27) reported the fabrication of interpenetrating phase metal-ceramic composites using FDM. Interpenetrating phase composites are those where both the metal and the ceramic phases are connected to itself in all three directions. In this approach, controlled porosity ceramic preforms were fabricated using the indirect FDM. Polymeric molds of desired parts were fabricated using ICW wax with different tool path variations. Molds were infiltrated with mullite ($Al_6Si_2O_{13}$) ceramic slurry or gel, and dried. The structures were then subjected to a binder removal and sintering cycle. The polymeric roads of the mold formed the pores in the controlled porosity mullite preform. By varying the tool path and the slice thickness of the mold, size, shape and distribution of the pores in the ceramic preform can be varied. Mullite preforms were then infiltrated using an Al metal via pressureless reactive metal infiltration to form mullite-Al or alumina-Al composites in which the metal phase filled the designed pores of the preforms. Uniform and functionally gradient composites with 20 to 50 volume percent metal contents were fabricated having various shapes and sizes. By varying the metal and the ceramic phases in the composites, the properties of the final part could be tailored for specific application.

Ceramic-Matrix Composites. Ceramics are hard and brittle, difficult to machine, and have low-volume production in numerous applications. During the mid- to late 1990s, extensive research was focused in the development of direct RP systems for ceramics and ceramic composites. The SLS is one of the commercially available processes where ceramic parts can be produced directly using polymer-coated ceramic powders. The parts require postprocessing, such as binder removal and sintering. In fused deposition of ceramics (FDC) (Ref 28), ceramic particle loaded thermoplastic filaments were used with commercial FDM systems to directly produce green ceramic components. In situ reinforced Si_3N_4, alumina, and lead zirconium titanate (PZT) are some of the ceramic materials that have been produced using this process. Postprocessing such as binder removal and sintering is necessary for the green FDC parts. Due to high volume fraction of thermoplastic binder content of the green part, parts greater than 15 mm (0.6 in.) thick are difficult to binder remove. The 3DP process was utilized to fabricate different structural, electronic, and bioceramic monoliths and composites. For small parts, most of these direct- deposition techniques are capable of achieving >98% theoretical density, but cracking and warpage during full densification of complex- shaped, large-size parts are still serious concerns. Attempts have also been made to directly produce functional ceramics and composites using other RP processes, and some of the efforts are still continuing for numerous applications.

Freeform Tooling for Composite Part Lay-Up

While some inroads have been made in the area of composite part production using freeform techniques, another strong area of application of these technologies is in production of tooling for composite part lay-up. This has been alluded to earlier in this article with the treatment of curved LOM. In the commercial sector, tools for injection and compression molding of composites represent a significant process expense, and limited success has been achieved in the application of toolless manufacturing processes to tool production. One example is SLS of epoxy-infiltrated metal molds (Ref 29). Freeform fabrication may also be used to produce tools for a large number of "half-mold" processes including hydroforming, diaphragm forming, vacuum forming, resin- transfer molding, manual/mechanically-assisted lay-up and electroformed nickel tooling.

Virtually any freeform fabrication technique may be used to produce short-run tooling. Epoxy-backed SLA molds have been demonstrated for aerospace applications in a resin transfer molding (RTM) operation (Ref 30), and SLA parts have been used for a variety of soft tooling mold applications including RTM and vacuum forming (Ref 31, 32).

A limited number of commercial freeform- fabrication techniques are capable of producing metallic tools that can be operated for extended numbers of parts. These include selective laser sintering (DTM Corporation, EOS GmbH) and direct metal deposition (Optomec) (Ref 33). A sample tool is shown in Fig. 11. Here, Type 420 martensitic stainless steel powder is coated with a polymer binder and SLS processed. The part, composed of approximately 60% metal, is fired to burn off the binder and to infiltrate with a bronze alloy. The final part has tolerances as high as 0.51 mm (0.020 in.), so critical surfaces must be finished by some form of machining operation.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Introduction

DESIGNERS have more freedom when using composite construction than they do when using other materials, because with composites they are free to select different fibers, flakes, or particles and to combine them with a choice of different resins, ceramics, or metals. The skin can be different than the core. The designers are free to determine the amount and distribution of the constituents. A composite laminate may be built to any thickness, and the fibers may be oriented to achieve the desired strength and stiffness. This article addresses the basic guidelines considered in designing a composite structure. More detailed information on many of the topics addressed in this article is available in other articles in this Volume.

In the materials selection part of the design process, a broad choice can be made between the use of composite construction, metals, unreinforced polymers, and natural materials. As a general guideline, if a part can easily be fabricated from traditional materials, such as aluminum, steel, wood, or plastic, this choice may represent the lowest-cost solution. Composite construction has many advantages, including weight reduction, high stiffness, and corrosion resistance in polymer-matrix composites (PMC), hardness and high service temperature in ceramic-matrix composites (CMC), and improved strength and stiffness in metal-matrix composites (MMC). It is also relatively easy to mold large, complex shapes, which often result in lower costs than metal fabrication. A comparison of typical materials properties is given in Table 1.

Table 1 Comparisons between typical properties of epoxy resin with various reinforcements and various metals

Material	**Density**		**Ultimate unidirectional strength**				Unidirectional tensile modulus	
			Tensile		**Compressive**			
	g/cm^3	**lb/in.^{3}**	**MPa**	**ksi**	**MPa**	**ksi**	**GPa**	10^6 psi

Composite properties are for general quasi-isotropic laminate and are dependent on fiber orientation.

This is a general introduction to composites; it is intended to familiarize the reader with the general considerations necessary to design and construct a composite part. For convenience, many of the terms common to composites are defined in this article. A complete glossary is in the back of this Volume.

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Definition of Composites

A composite material can be defined as a macroscopic combination of two or more distinct materials having a recognizable interface between them. However, because composites are usually used for their structural properties, the definition can be restricted to include only those materials that contain reinforcement (such as fibers or particles) supported by a binder (matrix) material.

Figure 1 shows a generalized diagram to illustrate the stress-strain relationship in a typical composite. Composite laminates can fail suddenly when the fibers break, unlike most metals, which have a plastic deformation region beyond the straight line “Hooke's law” relationship. Therefore, the strain limit of the fibers will determine the failure of the composite laminate.

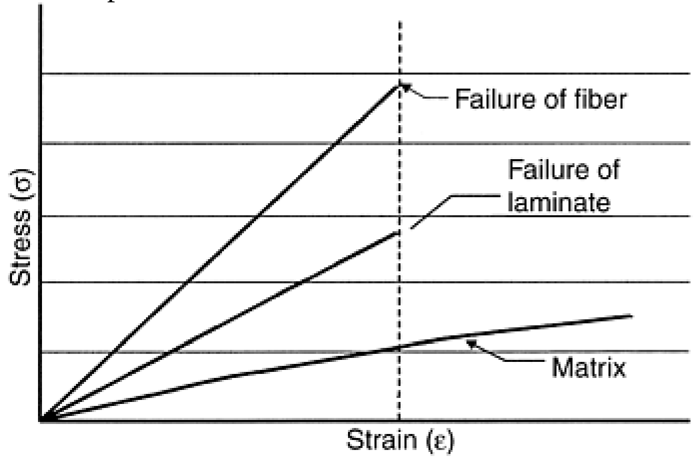

Fig. 1 Stress-strain relationship in a composite

Following are definitions of terms that apply to composites in general (additional definitions can be found in the “Glossary” in this Volume):

matrix.
: The essentially homogeneous resin, polymer, or other material in which the fiber system or other reinforcement of the composite is embedded. Both thermoplastic and thermoset resins may be used, as well as glass, ceramics, and metals.

reinforcement.
: The primary load-carrying or reinforcing element, usually fiber, embedded in the matrix. Chopped fibers, whiskers, particles, and flakes may also be used.

lamina.
: A single ply of a layered composite material

laminate.
: A product made by bonding two or more lamina to form a composite material. Figure 2 shows a typical balanced laminate of five lamina of plain weave cloth.

fiber orientation.
: The directional alignment of fibers in a composite. In composite construction, the designer has the freedom to align the fibers in any particular orientation to achieve specific laminate properties. The terms *isotropic*, *anisotropic*, and *quasi-isotropic* are used to describe the resulting laminate properties.

isotropic.
: A material having uniform properties in all directions, typically a metal

anisotropic.
: A material having varying properties in different directions, typically a composite laminate. By orienting the fibers in a prescribed manner, the properties can be tailored to the exact loading and

stiffness requirements of the design. Table 2 shows the directional properties of carbon fibers, which can be used to the designer's benefit to build an efficient structure.

quasi-isotropic.

A material approximating an isotropic material, typically a composite laminate with the fibers orientated in the 0^o, 90^o,$+45^o$,$–45^o$ to simulate isotropic properties.

Following are a list of common definitions relating to fibers and fabrics:

fiber.

Basic unit of fibrous material

tow.

An untwisted bundle of continuous fibers

roving.

A number of tows collected into a parallel bundle with little or no twist

yarn.

A number of twisted fibers assembled into a continuous length and suitable for weaving into a fabric

sizing.

Finish applied to fibers that allows the resin matrix to adhere to the fibers

tape.

Parallel tows of fibers held together in a prepreg or cross-stitching to form standard widths of unidirectional fibers

fabric.

A textile structure produced by weaving tows of fibers. Figures 3, 4, and 5 show common fabric weaves.

warp.

Longitudinal fibers of a fabric. The warp is the high-strength direction, due to the straightness of the fibers.

fill.

Fibers running over and under the warp fibers at an angle of 90^o to the warp direction. Also called woof and weft. The fill-direction is the lower-strength direction, due to the curvatures of the fibers.

nonwoven.

A textile structure produced from a collection of tows in a random mat

prepreg.

Typically fabric or tape that is preimpregnated with a resin and stored for use. The resin is partially cured to a “B” stage. This is an intermediate stage in the polymerization reaction of thermoset resins. A prepreg must be stored in a freezer and has a limited shelf life (usually six months).

The following terms apply to the resin used as a matrix as well as impregnating resins:

thermoset.

A resin that is substantially fused and insoluble after being cured by either heat or chemical means

thermoplastic.

A resin that can be softened by heating and hardened by cooling through a characteristic temperature range

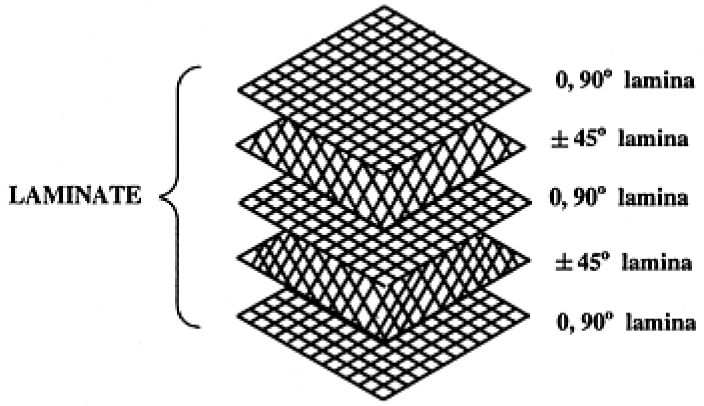

Fig. 2 Typical balanced-symmetric laminate

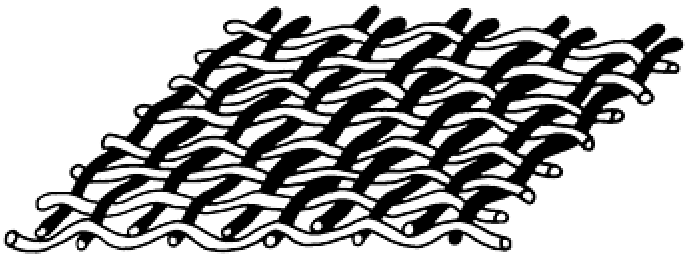

Fig. 3 Plain weave, yarn interlacing

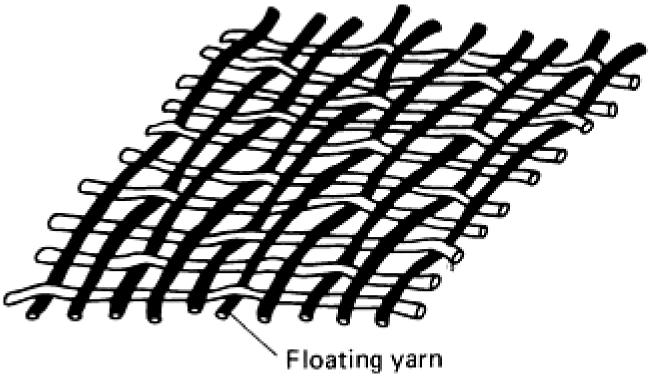

Fig. 4 Fiber-harness satin weave, interlacing

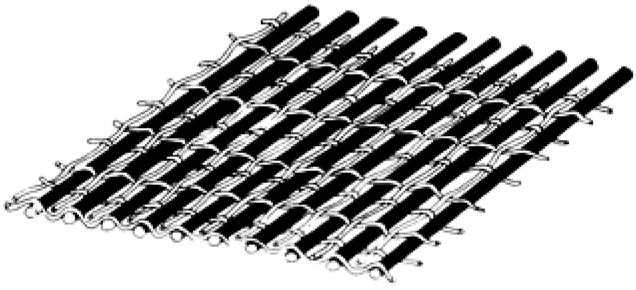

Fig. 5 Unidirectional weave

Table 2 Properties of carbon fiber

Direction	Modulus		Ultimate unidirectional strength				Coefficient of thermal expansion	
			Tensile		Compressive			
	GPa	10^6	MPa	ksi	MPa	ksi	10^{-6}/K	10^{-6}/°F
Axial	160	23.1	1724	250	1365	198	0	0
Transverse	11	1.6	41	6	228	33	22.5	12.5

For some carbon fibers, the axial coefficient of linear expansion is negative.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Analysis of a Composite Laminate

There are a number of computer programs that may be used to analyze a composite laminate. These programs generally fall into two groups:

- *Group 1 codes:* These allow the user to specify the composite lay-up. The code will then predict the laminate properties. These properties may then be used in a typical finite- element analysis (FEA). This form of analysis is quick and is often used during the preliminary design of a composite structure. Because this form of analysis is dealing with the global laminate properties, it is not possible to predict the laminate failure conditions, such as interlaminar shear.
- *Group 2 codes:* These allow the designer to input the composite lay-up ply-by-ply directly into the FEA model of the complete structure. These codes have the advantages of making it possible to predict the detailed performance of each ply within the laminate and to calculate failure criteria, such as maximum strain, maximum stress, Hill-Tsai, and Tsai- Wu. The ply-by-ply approach leads to large models and is consequently used after the preliminary design has been established.

While these codes are available, it is always essential to have a good grasp of the basic equations governing the laminate performance, because this will aid the designer with a basic understanding essential to the design of an efficient structure. The basic laminate equations are presented in the following paragraphs.
Stress-strain relationships for metals and composites are defined below. For metals:

$$\sigma = E\epsilon$$

where σ is stress, ϵ is strain, and *E* is Young's modulus. For composites:

$$\sigma_{ij} = Q_{ij}\epsilon_{ij}$$

where Q_{ij} is the lamina stiffness.
The stiffness matrix for plane stress is called the reduced stiffness matrix, where, *ij*= 1, 2, and 6:

$$[Q] = \begin{bmatrix} Q_{11} & Q_{12} & Q_{16} \\ Q_{21} & Q_{22} & Q_{26} \\ Q_{16} & Q_{26} & Q_{66} \end{bmatrix}$$

$$= \begin{bmatrix} \dfrac{E}{1-\nu} & \dfrac{\nu_{12}E_{22}}{1-\nu_{12}\nu_{21}} & 0 \\ \dfrac{\nu_{21}E_{11}}{1-\nu_{12}\nu_{21}} & \dfrac{E_{22}}{1-\nu_{12}\nu_{21}} & 0 \\ 0 & 0 & G_{12} \end{bmatrix}$$

where ν is Poisson's ratio, *E* is Young's modulus, *G* is shear modulus, and $Q_{16} = Q_{61} = Q_{26} = Q_{62} = 0$, for principal fiber directions.
Stress-Strain Load Relationships. The general stress-strain relationship is:

$$\sigma = E\epsilon$$

For tension, compression, and shear:

$$\sigma = N/A \rightarrow E\epsilon = N/A \rightarrow N = (EA)\,\epsilon$$

where *N* is the stress resultant and *A* is the unit area. For bending:

$$\sigma = Mc/I \rightarrow E\,\epsilon = \mathrm{Mc/I} \rightarrow M \rightarrow (EI)\epsilon\,/\,c$$

$$\rightarrow M = (EI)\,K$$

where *M* is the resultant moment, *c* is the distance from the neutral axis to the extreme fiber, *I* is the moment of inertia, and *K* is a curvature. The resultant stresses and moments are seen in Fig. 6.

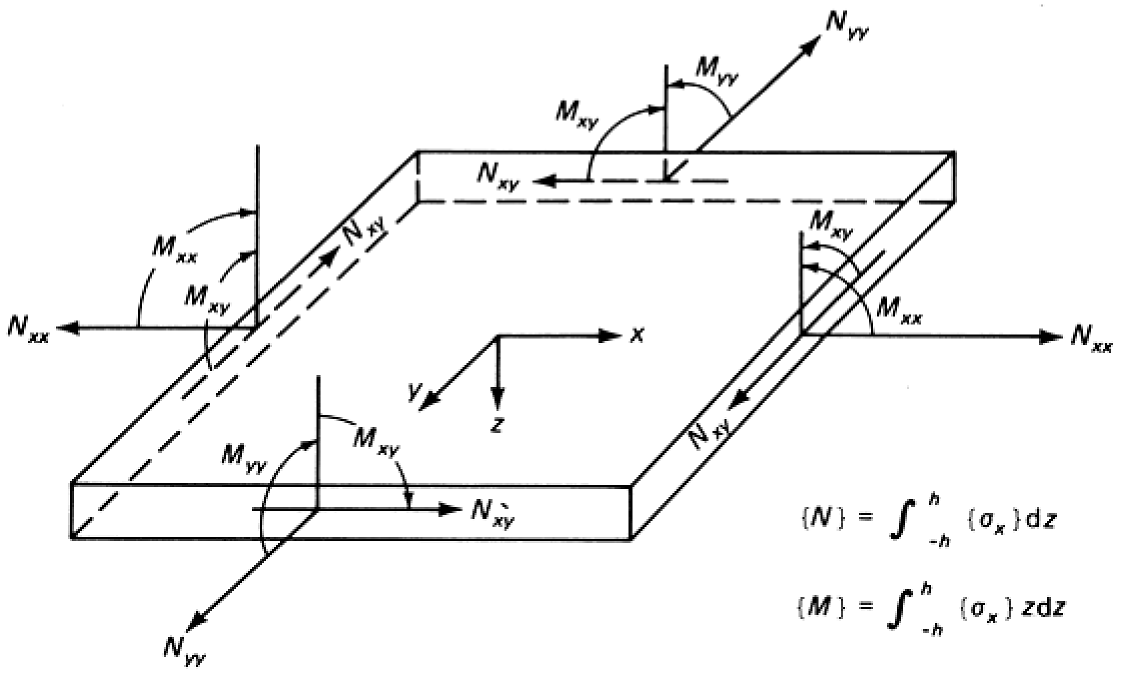

Fig. 6 Stress and moment resultants

General Load Displacement Case. These stress and resultant moments can be used, as is usual in plate theory, to develop a general load, strain, curvature relationship:

$$N = (EA)\epsilon$$

$$M = (EI)\,K$$

In matrix form:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_x \\ M_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & \vdots & B_{11} & B_{12} & B_{16} \\ A_{21} & A_{22} & A_{26} & \vdots & B_{21} & B_{22} & B_{26} \\ A_{61} & A_{62} & A_{66} & \vdots & B_{61} & B_{62} & B_{66} \\ B_{11} & B_{12} & B_{16} & \vdots & D_{11} & D_{12} & D_{16} \\ B_{21} & B_{22} & B_{26} & \vdots & D_{21} & D_{22} & D_{26} \\ B_{61} & B_{62} & B_{66} & \vdots & D_{61} & D_{62} & D_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_x \\ \varepsilon_{xy} \\ K_x \\ K_x \\ K_{xy} \end{Bmatrix}$$

where *N* terms are in-plane loads; *M* terms are moment loads; *A, B,* and *D* terms make up the laminate stiffness matrix; ϵterms are the mid- plane strains; and *K* terms are curvatures.

The terms of the stiffness matrix are:

$$A_{ij} = \sum_{k=1}^{N} (\bar{Q}_{ij})(z_k - z_{(k-1)})$$

$$B_{ij} = \frac{1}{2}\sum_{k=1}^{N} (Q_{ij})(z_k^{\,2} - z_{(k-1)}^{\,2})$$

$$D_{ij} = \frac{1}{3}\sum_{k=1}^{N} (Q_{ij})(z_k^{\,3} - z_{(k-1)}^{\,3})$$

where $\overline{Q}_{ij}$= Q_{ji} rotated into material coordinates from principal coordinate directions. The differences in *z* represent individual ply thicknesses, as seen in Fig. 7.

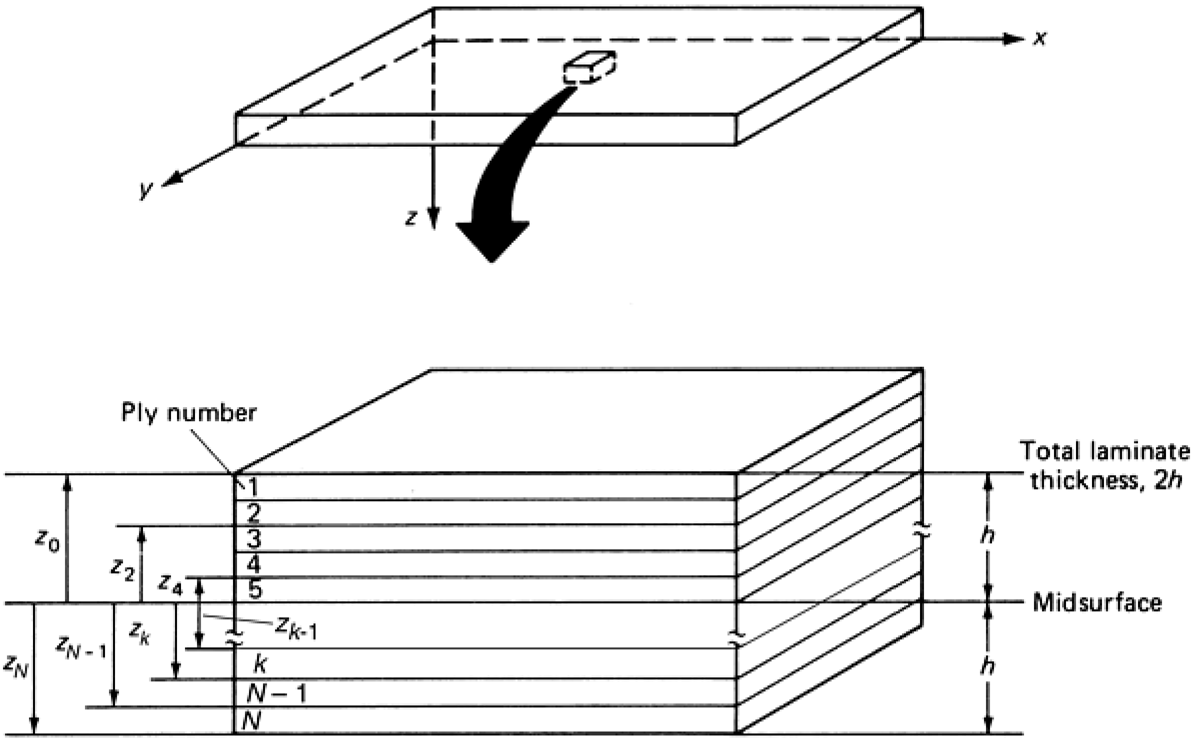

Fig. 7 Laminate construction with ply designations

The equations may be simplified for a symmetrical and balanced lay-up:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_x \\ M_{xy} \end{Bmatrix} \left[\begin{bmatrix} A_{11} & A_{12} & A_{16} & & & \\ A_{21} & A_{22} & A_{26} & & 0 & \\ A_{61} & A_{62} & A_{66} & & & \\ & & & D_{11} & D_{12} & D_{16} \\ & 0 & & D_{21} & D_{22} & D_{26} \\ & & & D_{61} & D_{62} & D_{66} \end{bmatrix} \right] \begin{Bmatrix} \varepsilon_x \\ \varepsilon_x \\ \varepsilon_{xy} \\ K_x \\ K_x \\ K_{xy} \end{Bmatrix}$$

where B terms = 0 for symmetrical laminate. The details of this characterization of a laminate composite using matrices is detailed in the article “Macromechanics Analysis of Laminate Properties” in this Volume.
Solution of General Load Case. The steps are:

1. Determine terms of modulus matrix, Q_{ij}, for *each* layer in lamina coordinates.
2. Transform Q_{ij} lamina into $\overline{Q}_{ij}$ laminate.
3. Calculate “*EA*” terms, A_{ij}, B_{ij}, D_{ij}, for laminate and set up stiffness matrix.
4. Set up load case, calculate strains and curvatures, then combine strains and curvatures to determine total strain of the laminate.
5. Transform laminate strains to lamina strains for *each* layer.
6. Calculate lamina stresses from lamina strains for *each* layer.
7. The use of computer codes greatly reduces the time required to solve these equations.

A two-stage approach for the analysis of composite structures is recommended:

- Use simple code to determine global laminate properties. These properties are then used for preliminary design and optimization.
- For design verification and structural analysis, the composite structure is modeled using a finite-element code in which each ply (lamina) will be modeled and the stresses and failure criteria determined.

Summary of Factors Affecting Composite Materials Properties and Allowables. Materials properties for composites are stated as design allowables that are statistically determined from test data. Factors affecting the materials property values for fiber-reinforced polymers include, but are not limited to:

- *Volume fraction (percent fiber to total volume):* Generally, the fiber volume will be in the range of 45 to 65%.
- *Temperature:* Generally, high cure temperatures are indicative of higher operating temperatures. The higher the cure temperature, the higher the cost of materials and processing. Therefore, it is important to understand the operational conditions and to specify the appropriate resin, to avoid adding unnecessary cost. Temperature differentials in processing and in service, combined with different coefficients of thermal expansion (CTE) of components, lead to internal thermal stresses.
- *Moisture absorption:* The matix, reinforcement, and their interface respond differently to moisture. This is called hygral behavior.
- *Orientation* of fibers in laminate
- *Test procedures*, number of tests, and analysis of data
- *Process control* relative to manufacture of composite laminate

Laminate Design. In order to minimize any residual thermal stresses caused during cure of the resin, it is always good practice to design a symmetrical, or balanced, laminate. Examples of balanced laminates are presented in Table 3. The first example uses unidirectional tape, and examples 2 and 3 are typical quasi-isotropic laminates fabricated from woven cloth.

Table 3 Symmetrically balanced laminates

Example	**Lamina**	Written as
1	$\pm45^o$,-45^o, 0^o, 0^o,-45^o, $+45^o$	**$(+45,-45, 0)_S$**
2	$\pm45^o$, $0^o/90^o$, $\pm45^o$, $0^o/90^o$, $0^o/90^o$, $\pm45^o$, $0^o/90^o$, $\pm45^o$	**$(\pm45, 0/90)_{2S}$**
3	**$\pm45^o$, $\pm45^o$, $0^o/90^o$, $0^o/90^o$,$\pm45^o$, $\pm45^o$**	**$([\pm45]_2, 0/90)_S$**

Table 4 presents examples of the effects caused by nonsymmetrical laminates. These effects are most pronounced in laminates that are cured at high temperature in an autoclave or oven, due to the thermal stresses developed in the laminate as the laminate cools down from the cure temperature to room temperature. Laminates cured at room temperature using typical wet lay-up or vacuum-assisted resin transfer molding (VARTM) do not exhibit the same degree of distortion, due to the much smaller thermal stresses.

Table 4 Examples of effects of nonsymmetry

Type	**Example**	Comments
Symmetrical, balanced	(+45,–45, 0, 0,–45, +45)	**Flat, constant midplane stress**
Nonsymmetrical, balanced	(90, +45, 0, 90,–45, 0)	**Induces curvature**
Symmetrical, nonbalanced	(–45, 0, 0,–45)	**Induces twist**
Nonsymmetrical, nonbalanced	**(90,–45, 0, 90,–45, 0)**	**Induces twist and curvature**

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Mold Design

There are many types of molds that can be manufactured in order to produce a composite part. The type of tooling chosen will vary, based on several factors. These factors include:

- Molding process used. This includes autoclave, resin transfer molding (RTM), VARTM, and wet lay-up, which is defined subsequently.
- Temperature of cure
- Surface quality desired on finished part
- Budget
- Number of parts being produced from the tooling
- Size and complexity of the parts

Once these factors have been addressed, the type of tooling required can be determined.

Master Model. Depending on the complexity of the composite part and the type of tooling to be made, there are different routes to the production of the mold. The master model can be a physical representation of the actual composite part, computer-aided design (CAD) data, or drawing of the part. How a master model is defined is necessary in creating the tooling.

Metal Tooling. If the mold is to be made of a metal, the metal tool can be directly machined to the desired shape and size using CAD data or a drawing of the finished part. If the mold will be going through a cure cycle, the differences of the CTEs will have to be taken into account when selecting the material and defining the size of the mold.

Composite Tooling. When considering composite tooling, a physical mold master will need to be created to make the mold. The master can be made from the materials listed in Table 5, which includes the advantages and disadvantages of each.

Table 5 Materials used as mold masters

Material	Advantages and disadvantages
Wood	**Only usable at low temperature** **Easily worked** **Inexpensive materials** **Not very accurate or dimensionally stable** **Surface requires sealing to produce suitable mold surface**
Urethane tooling block	**More accurate** **Relatively cheap** **More stable than wood—still short term** **Will take in moisture over time** **Requires surface sealing** **Reaction problem to epoxy prepregs** **Capable of withstanding autoclave cures** **Requires machining**
Epoxy tooling block	**Price is variable depending on grade of block, but expensive compared to wood or urethane** **Surface coating not always necessary** **High-quality block extremely stable**

	Capable of withstanding autoclave cures
Metal	**Can be steel or aluminum, cast or fabricated, or a combination** **Excellent surface finish. Surface sealing is not required.** **Extremely heavy** **Large thermal mass to heat up and cool down** **Cost is relatively inexpensive** **Long-term stability is good if protected from corrosion** **Welded joints can leak**

Tool Care. No matter what type of tooling is used, the quality of the parts produced from the tooling will be a direct reflection of how the tool is treated in the working environment. Some common faults that will lead to degradation of the tool surface and reduced life of the tool are:

- Incorrect application of release agent
- Cutting on the tool surface
- Cleaning of the tool surface with inappropriate materials or equipment
- Impact damage to the tool surface

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Matrix-Resin Selection

For resin-based composites, resin selection is an important step in designing the composite for use in a particular application. There are several general types of matrix-resin systems, and within each, there are countless variants that are commercially available. Selection of a basic resin group is based on general performance criteria of the application. It is important to note that a thorough investigation of a particular manufacturer's matrix-resin system must be undertaken prior to final selection and use.
The first step in the matrix-resin selection process is to determine the requirements of the final application. Requirements should be based on the envelope operation conditions of the application, including, but not limited to, the following:

- *Structural characteristics* of strength, stiffness, and toughness. While the reinforcement is the primary structural member, transverse properties, compression, and toughness requirements must be considered in resin selection.
- *Resistance* to corrosion, chemicals, moisture, and other environmental factors, such as ultraviolet radiation
- *Thermal characteristics,* including maximum and minimum temperatures, temperature differences, and thermal cycling
- *Fire, smoke, and toxicity*
- *Outgassing*

After the application requirements are defined, a number of fiber reinforcements and matrix- resin systems may satisfy them. A suitable matrix-resin system will have particular processing requirements and costs associated

with it that may preclude its use on a particular application. Table 6 cross-references resin systems with performance and processing methods to aid the selection of resin systems.

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Typical PMC Processes

Many different methods may be used to process composite components. A brief overview is presented in Table 7. The choice of processing method is determined by the materials and intended use of the composite part.

Table 7 Various manufacturing processes

Process	**Comment**	Typical applications
Hand lay-up	Low cost Lower strength components Large parts Relatively low-cost tooling	**Large commercial parts, where cost is more important than high strength or low weight**
Vacuum bag, oven cure	Similar to wet lay-up, but improved consolidation leading to higher strength	**Large commercial parts, where cost is more important than high strength or low weight**
Autoclave cure	High quality High strength Relatively high cost of tooling Size limited by autoclave	**High-performance military and aerospace components and thermal cores**
Resin transfer molding	High quality High strength Matched metal tooling Lower cost than autoclave	**Military and aerospace applications** **Large-volume commercial parts** **Small enclosures and keyboards**
Vacuum-assisted resin transfer molding	Room-temperature process Large parts High qualityLow cost	**Extensively used for Navy applications** **Large electronic equipment enclosures, operator consoles, etc.**
Compression molding	High-cost tooling High quality Complex parts Low part cost	**Electronic module covers and small electronic equipment enclosures**
Bonded metal	**Typically, aluminum honeycomb construction**	**Lightweight back planes and electrically conductive components** **Commercial applications**

Wet lay-up is used in low-stress applications where performance and weight are not critical, but lowest cost is very important. Wet lay-up parts can be fabricated using continuous woven fiber and a roller to spread the resin and completely wet-out the fiber. The fiber reinforcement may also be applied to the mold using a chopper gun that sprays a mixture of resin and fiber directly onto the mold. Because this process uses room-temperature cure resins, the mold tools may be manufactured from wood or glass fiber, with a gel coat to produce a high-quality finish.

The concerns for the tooling are not as great as for the other methods of manufacturing. The tool does not need to hold a vacuum, and there are no concerns of thermal mismatch. This leads to a relatively inexpensive tool.

Autoclave process is used to manufacture high-performance parts that are designed for the highest strength-to-weight ratios. It is necessary to use resins that require a high cure temperature; typically, the higher the operating temperature for the composite, the higher the cure temperature of a resin. Tooling is usually fabricated from metal or special tooling prepregs that can withstand the typical high-pressure, high-temperature cure cycles. Due to the high-temperature cure cycle, the tooling has to be designed so that it is dimensionally correct at the elevated-cure temperature rather than at room temperature. Special care must be taken to ensure that the part may be easily removed and will not become trapped as the tool cools.
When using an autoclave cure, the following factors must be considered:

- Thermal mismatch
- Thermal mass of the tool
- Number of parts being made from the tooling
- Budget
- Surface-quality requirements
- Tool must be able to maintain a vacuum

Resin transfer molding requires matched metal tooling. The cure can be done at room temperature. The resin may be heated to facilitate flow into the tool, so mismatched CTEs may be a concern.
Vacuum-Assisted Resin Transfer Molding. There are about 30 different variations of the process that have been developed to meet particular applications. In general, VARTM is used to fabricate very large components. Typically, the dry fibers and core material are laid into the mold, a vacuum bag is then used, and the air is sucked out. Once a good vacuum is achieved, resin is infused into the part. Balsa or foam cores are typically used; honeycomb core cannot be used. Because VARTM uses continuous fibers and is cured under typical vacuum pressure of 84 MPa (25 in. of mercury), the resulting laminate is very high quality, with properties similar to autoclave cure and with a lower void content. The process is limited by the resin selection to typically room-temperature resins with very low viscosity, to allow for infusion. New resins are presently being developed to achieve higher operating temperatures; the operating temperature of parts may be enhanced by postcuring the cured part in the oven. Because this process uses room-temperature cure resins, the mold tools may be manufactured from wood, or glass fiber with a gel coat may be used to produce a high- quality finish.
Besides surface-quality requirements for the finished parts, tooling design for VARTM must consider the number of parts being produced from the tooling, the cycle time, and the ability to maintain a sufficient vacuum throughout its life.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Electromagnetic Interference (EMI) Shielding and Electrostatic Discharge (ESD) Protection

Electromagnetic interference shielding and electrostatic discharge protection are required in numerous composite applications, such as computer cases to meet emission specifications, or aircraft wing structures to dissipate lightning strikes. Some common EMI shielding methods, with pros and cons, are listed in Table 8.

Table 8 Common EMI shielding methods

Protection method	Comment
Carbon fibers	**Carbon fibers are electrically conductive and, therefore, provide a low-level EMI shielding.**
Nickel-plated carbon fibers	**The electrical conductivity enhanced by nickel plating can provide higher levels of shielding, up to 70 dB. Good for ESD protection**
Metal mesh	**Metal meshes provide a high level of EMI shielding.**
Electrically conductive paint	**This is an effective method, but has the disadvantage that it is a surface**

flame spraying	**layer and needs to be protected from abrasion and corrosion.**
Metal plating	**See text**

Many published articles claim that very high shielding levels are obtainable for panels by using these methods. In all EMI and ESD protection schemes, grounding of the composite panel to the main structure is the area requiring the most attention. The major issue for the embedded EMI protection systems is that the surfaces are often resin-rich. This forms a good electrical insulating barrier and prevents electrical contact to the main structure. The resulting gap will act like a slot antenna and radiate at specific frequencies. Therefore, particular attention must be given during the design and fabrication to ensure that any embedded metallic layer is extended beyond the laminate matrix to provide a good electric bond to the metal.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Metal Plating

Metal plating is often used to provide enhanced corrosion protection and EMI protection for composite laminates. There are three considerations:

- Ensure the part will fit into the plating bath; this may exclude large parts.
- Choice of resin system
- Release agent used

The basic plating system is comprised of up to 20 baths, each containing a different chemical. The general process is to clean, etch, activate the surface, electroless plate the base metal, then plate other metals once a conductive metal surface is established. Conventional electroplating can be used to build up thickness. Typically, the etching process attacks the surface and provides microscopic sites where the metal molecules can form a mechanical bond to the composite laminate. In some plastics, such as acrylonitrile-butadiene-styrene, this is easy, and excellent plating can be achieved. The reflectors for car headlights are a good example. Typical epoxy resins are a long polymer chain that is very resistant to chemical attack. It is therefore very difficult to etch the surface to provide the molecular sites for the metal to mechanically adhere to the laminate. The simplest test to verify adhesion is to apply masking tape to the plated surface. When the tape is removed, it should be free of metal particles. There are several proprietary systems that claim to work. The author has achieved success with the McDermot system. Plating is not a trivial matter, and it is recommended that the composite fabricator works with the plater and carries out a number of trials to ensure the plated surface will meet specification.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Fire Resistance

Where composite structures are used in aircraft interiors, maritime applications, and mass transit applications, some degree of fire protection is normally required:

- Typically, the aircraft industry uses a standard that requires a composite structure to self-extinguish within 60 seconds of the flame being removed.

- Marine and mass transit industries require that a composite will not significantly add to a fire and that it retains structural integrity for at least 15 minutes.

Generally, the use of composites for aircraft interior applications is well established with a clearly defined test requirement. With the recent growth in the use of composites in the marine and mass transit industry, standards and acceptable laminate systems are still being developed.

There are two main approaches to the design of a fire-resistant laminate: resin selection and surface treatments.

Resin Selection. Because the glass fiber or carbon-fiber reinforcement does not burn, the resin selection is the element that determines the fire characteristics of the laminate. Typical specifications for aircraft interiors are specified in Federal Aviation Regulation (FAR) 25 or 23. These require that after exposure to a flame, a composite panel will self-extinguish within 60 seconds of the flame removal. This requirement is typically satisfied with a phenolic resin or an epoxy resin that has a flame retardant added. These resins are relatively expensive and require 120 to 175 °C (250 to 350 °F) cure cycle temperatures. They are not particularly suitable for use in large mass transit or marine applications, due to cost and cure considerations.

Surface Treatments for Laminates. Composite laminates may be coated with intumescent paints or have intumescent layers embedded into the surface of the laminate. When exposed to intense heat or flame, these coatings bubble into a foam that protects the material underneath. The advantage of intumescent paints is that they can be easily applied to the surface of the laminate once it is cured. However, they have the potential disadvantage that they can be abraded from the surface due to normal wear and tear, and hence reduce the fire protection. Embedding an intumescent layer into the laminate has the advantage that it cannot be easily worn off by normal use. However, it has the disadvantage that the intumescent material will absorb resin, which will burn off of the surface before the intumescent material begins to work.

The use of intumescent materials embedded into the surface of a low-cost vinyl ester resin structure is relatively new, but has been approved for use by the U.S. Navy for some shipboard applications. Further development to enhance the performance is presently being carried out by the marine and mass transit industries.

The graph presented in Fig. 8 shows typical cone calorimeter tests for two laminates protected by an intumescent layer.

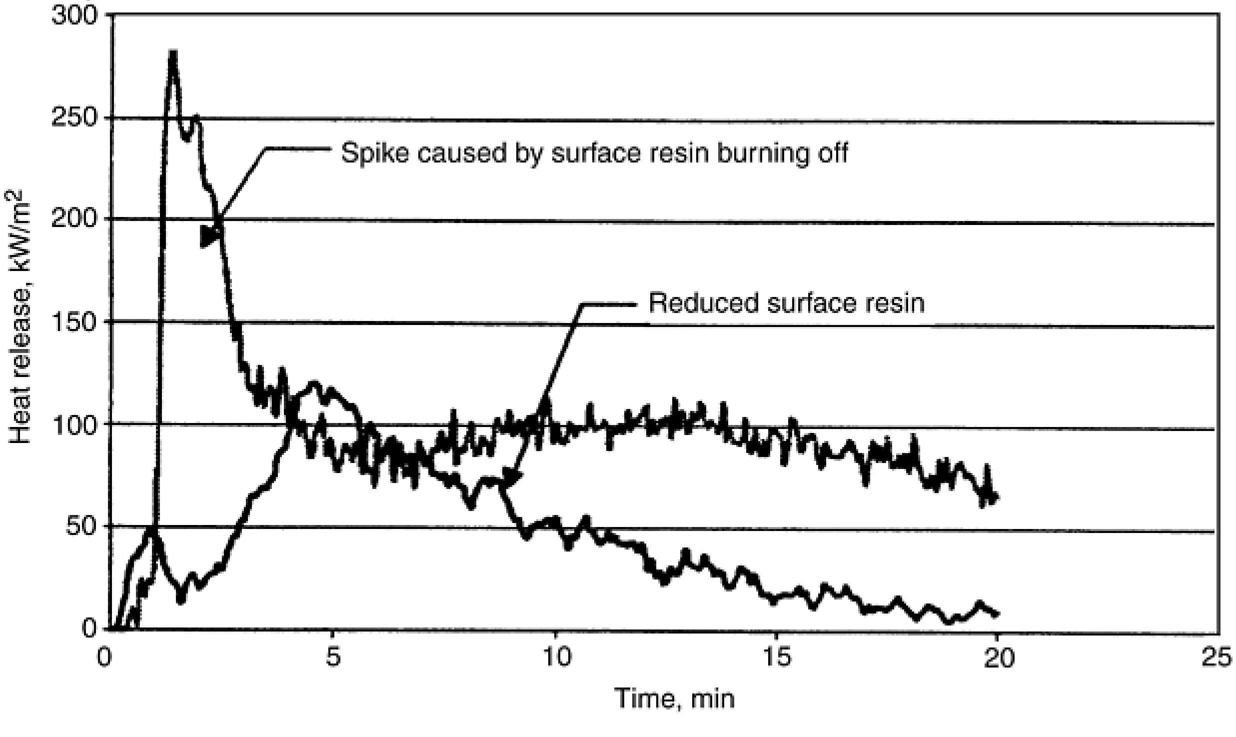

Fig. 8 Heat release averages from calorimeter tests for incident heat flux of 50 kW/m^2

Performance Verification. For typical aircraft applications, there is a considerable database of experience, and it is often possible to verify performance of a laminate by carrying out coupon testing as defined in Boeing specification BSS 7230. For marine applications, some form of hazard analysis to verify that the composite structure will not add significantly to a fire is often required. The general methodology is described in Fig. 9. The small-scale testing could involve carrying out cone calorimeter testing in accordance with ASTM E 1354, for example. Typically, the cone calorimeter testing is carried out at incident heat fluxes of 25, 50, and 75 kW/

m^2. The most important features for comparing the fire performance of laminates are the time to ignition and the heat released during the test. The results from the cone test are used as the input for a computer hazard analysis of the room where the composites are being used, to determine the effect of a fire on surrounding structures. If this analysis is inconclusive, then it will be necessary to carry out a full size test, typically an ISO 9705 corner test to determine the performance.

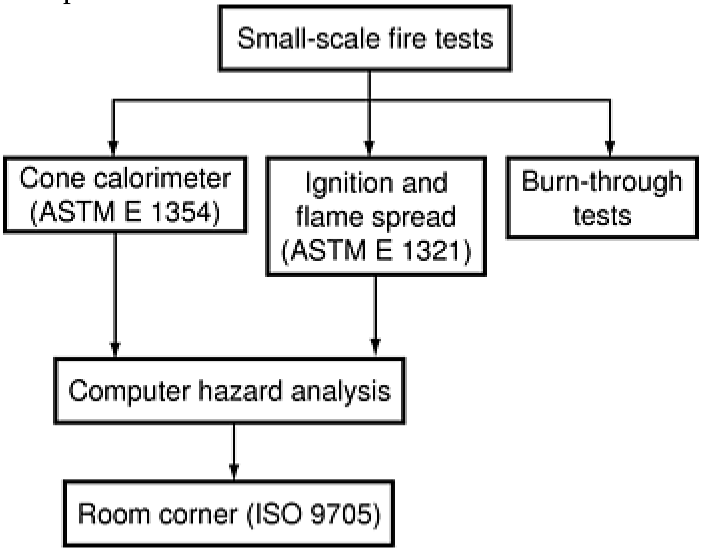

Fig. 9 Methodology for fire qualification

Table 9 lists a summary of some of the common fire-protection options and typical uses of each.

Table 9 Summary of fire-protection options

Resin	**Comment**	Use
Vinyl ester resins	Low cost Easy to process Low fire resistance	**Use intumescent coating to meet typical commercial and maritime specifications**
Epoxy resins	120 °C (250 °F) cure temperature	**Can use fire inhibitors, but these produce fumes when burned. Meets FAR 25.853**
Phenolic resins	**175 °C (350 °F) cure temperature**	**Typically used for aircraft interiors**

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Thermal Conductivity

Pitch-based carbon fibers offer considerably higher thermal conductivity (K_L) than metals and have a much lower density. This comparison is shown in Table 10. The main use of these fibers is in space applications and thermal cores for electronic modules. The in-plane thermal conductivity for a ply of carbon fiber is determined by the rule of mixtures and is given by:

$$K_x = K_{FL} \cdot V_f \cdot \sin^2\alpha$$

$$K_y = K_{FL} \cdot V_f \cdot \cos^2\alpha$$

where V_f is fiber volume, K_{FL} is the longitudinal fiber thermal conductivity, and α is the angle of fibers in a particular ply.

Table 10 Properties of various thermally conductive materials

Fiber	Manufacturer	Fiber thermal conductivity (K_{FL})		Tensile modulus	
		W/m · K	**Btu/h · ft ·°F**	**GPa**	10^6 psi
K1100	Amoco	1060	613	965(a)	**140(a)**
P120	Amoco	640	370	830(a)	**120(a)**
K13C2U	Mitsubishi	620	360	900(a)	**130(a)**
P100	Amoco	520	300	724(a)	**105(a)**
XSH-70A	Nippon	250	140	738(a)	**107(a)**
Aluminum beryllium	…	210	120	190	**28**
Aluminum	**…**	**187**	**108**	**70**	**10**

(a) (a) These are fiber values; the stiffness of a composite laminate will be less.

The thermal conductivity through the thickness of the laminate K_z, is dominated by the resin and is typically in the region of 1.5 W/m · K (0.87 Btu/h · ft ·°F). There are several equations to predict K_z, but presently they are approximations at best. It is recommended that the user base design calculations on previously measured data. K_z is dependent on the resin thermal conductivity and radial thermal conductivity of the fiber, $K_{FR.}$ The problem is that K_{FR} varies, depending on the plane through the fiber. Therefore, a statistical term must be included for K_{FR}. The result is that, for practical purposes, it is better to work from measured data. Recent work has demonstrated that it is possible to increase K_z up to about 4 to 6 W/m · K (2.3 to 3.5 Btu/h · ft ·°F) by adding boron nitride powder to the laminate.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Corrosion

Glass-fiber laminates exhibit excellent corrosion resistance and may be used with most common metals without using special precautions to prevent corrosion. When carbon-fiber laminates are used in conjunction with metal parts, special care must be taken to prevent bimetallic corrosion. Reference to the galvanic table, Table 11, shows that carbon fibers and aluminum are on opposite ends of the table, which indicates that particular precaution needs to be taken when aluminum fittings are to be used with a carbon-fiber structure. However, no special precautions need to be used when passivated stainless steel fittings are used.

Table 11 Galvanic series

Galvanized steel
Aluminum
Mild steel
Cast iron
Lead
Tin
Brass
Nickel
Copper
Titanium

Nickel (passive)
Stainless steels (passive)
Silver
Gold
Carbon, graphite
Cathodic (least active)

Typical methods to provide bimetallic corrosion protection are shown Fig. 10. The glass fiber barrier extends at least 0.1 m (4 in.) beyond the aluminum fitting when the fitting is in an external location and exposed to water. This distance may be reduced to 0.063 m (0.25 in.) when used in a dry, internal location. The fasteners are dipped in epoxy resin and installed wet, so that the resin will cure to form a tight moisture barrier.

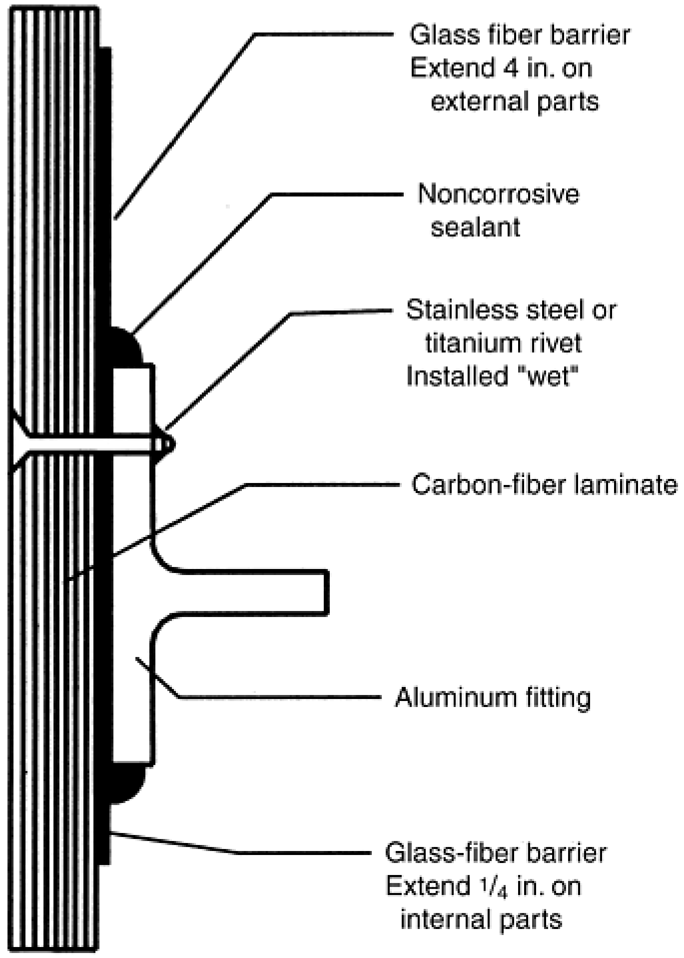

Fig. 10 Typical method of providing bimetallic corrosion protection

Aluminum mesh may be embedded into glass- fiber laminate to provide EMI shielding, but copper mesh or nickel-plated fibers should be used in carbon-fiber structures.

Design Guidelines

John Bootle, Frank Burzesi, and Lynda Fiorini, XC Associates, Inc.

Fasteners

There are a large number of proprietary fasteners that have been designed to work with composite laminates. It is also possible to use traditional helical coil inserts, key inserts, and nut plates. If the position of the threaded inserts is known before fabrication, then hard points may be embedded into the laminate prior to cure. The hard point may be fabricated by simply filling the hole in the core with glass-fiber cloth during the lay-up in

VARTM systems, or by embedding precured G10 or phenolic when using a prepreg system. This method is depicted in Fig. 11.

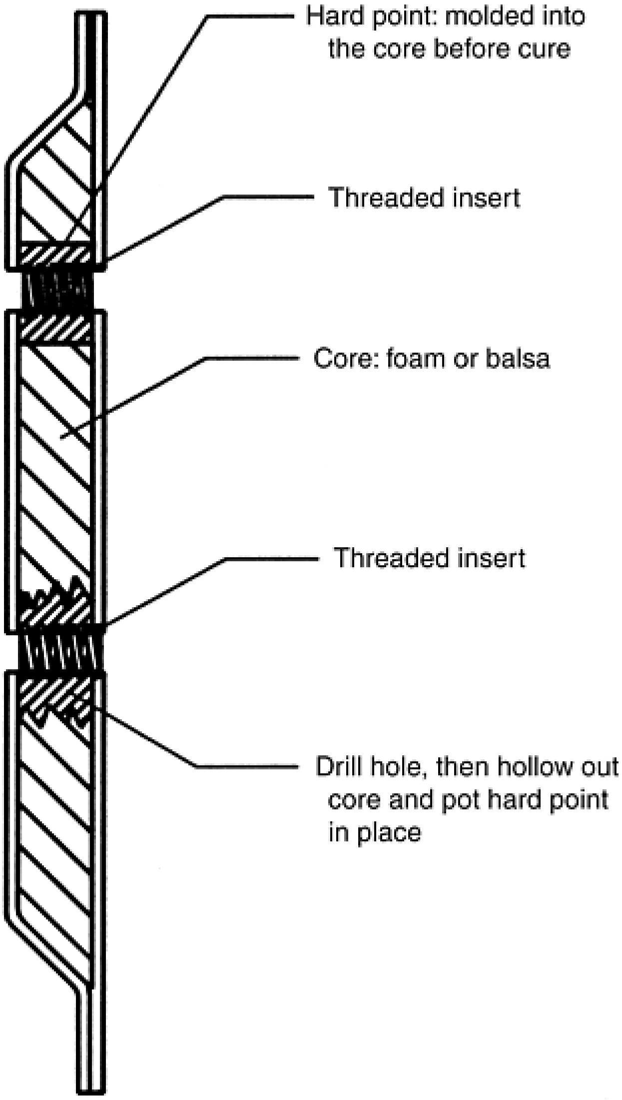

Fig. 11 One method of preparing laminate for threaded insert

If the location of the fastener is not known prior to cure, a hole may be drilled through the laminate, and the core hollowed out and then filled with epoxy or other potting compound. Once this has cured, it is then possible to drill and insert the helical coil inserts or key insert.

Engineering Mechanics and Analysis of Metal-Matrix Composites

Bhaskar S. Majumdar, New Mexico Institute of Mining and Technology

Introduction

METAL-MATRIX COMPOSITES (MMCs) differ from other composite systems primarily with respect to the inelastic deformation mechanisms of the matrix phase. Whereas the inelastic matrix strain in both ceramic-matrix composites (CMCs) and brittle polymer-matrix composites (PMCs) is dominated by the compliance

from multiple matrix cracks, the matrix strain in MMCs arises from plasticity or viscoplasticity (or creep) of the ductile metal matrix. The difference between plasticity and viscoplasticity is that the former mechanism is essentially time-independent, whereas the latter is strongly time-dependent. Their relative magnitudes are governed by the temperature of loading, with viscoplasticity becoming significant at homologous temperatures (T/T_m, where T_m is the melting point), typically above 0.4. In titanium alloys, this temperature is slightly lower, approximately 0.35.

Important reasons for selecting MMCs over other composites in load-bearing applications are their high specific stiffness, strength, wear and environmental resistance, and toughness at temperatures between subzero and 650 °C (1200 °F). The higher temperature limit is based on currently available materials and may increase as new materials and processes become available. On the one hand, PMCs become inoperable above about 250 °C (480 °F), and on the other hand, CMCs have too low a strength without damage in this temperature domain. Thus, there is a range of temperatures where MMCs become strong candidates as the material of choice, and MMCs have indeed been considered enabling for a number of components and systems. The toughness advantage of MMCs derives from the ductility of the matrix. This advantage is reduced when the fiber volume fractions become high (>0.5) or the matrix becomes brittle, such as when the metal is an intermetallic with less than 3% elongation to failure. That is why the fiber volume fraction in most structural applications is typically less than 0.3, although there are a few exceptions. Specifically, higher volume fractions are used in wear, thermal, and electrical applications at the expense of toughness. It is important to bear these properties and the temperature range of application in mind while considering design with MMCs.

The difference between the thermal expansion coefficient of the metal-matrix and the ceramic- fiber or particulate reinforcement is typically large. (See tables in the article “Properties of Metal-Matrix Composites” in this Volume.) Hence, residual stresses from thermal mismatch have a significant effect on the overall deformation and damage response. Thermomechanical loading must be considered an integral aspect of any stress analyses with MMCs.

In addition to thermomechanical loading, it is also important to consider damage in the design of composites. This is because failure theories must realistically be based on the mechanisms of damage. In MMCs, there are essentially three types of damage. Two of the damage mechanisms are fiber-matrix debonding damage and fiber fracture, which are also present in other composite systems. The third form of damage is microvoid nucleation inside the matrix, followed by their growth and coalescence, leading to matrix rupture. The general sequence of damage is as follows:

- Damage initiated as interface crack or fiber crack
- Intense plasticity of the ductile metal matrix adjacent to damage site
- Microvoid nucleation in the matrix
- Microvoids grow and coalesce
- Matrix rupture and composite failure

The discontinuous MMCs are discussed later, but suffice to state that damage in many such composites involve either particle fracture or particle matrix separation followed by intense matrix plasticity and matrix rupture.

Inelastic analyses of MMCs have generally been restricted to interface and fiber damage and matrix plasticity and viscoplasticity. Matrix damage has generally not been considered, except in discontinuous systems whose ductility and toughness are significantly influenced by matrix-failure events. Even here, the analyses have been partial and will need to be expanded greatly to obtain an accurate predictive failure response of MMCs.

Engineering Mechanics and Analysis of Metal-Matrix Composites

Bhaskar S. Majumdar, New Mexico Institute of Mining and Technology

---

Micromechanics of Fiber-Reinforced MMCs

Micromechanics of composites are conducted at the fiber-matrix level to relate the lamina-level properties, such as stress-strain behavior and failure response, to the constituent properties of the reinforcement and matrix. The overall goal is to use the predictive methodology to develop tailored composites and also to make accurate predictions of their performance in service. Indeed, the current rapidly changing and cost-conscious technological environment has made such a predictive formalism essential. Note that this methodology is different from past approaches with PMCs, where the emphasis generally lay on lamina- and laminate-level testing and analyses. Here, a microscopic understanding of stress- strain evolution, damage nucleation, and growth at the fiber-matrix level is emphasized. Even in the case of PMCs, it is now widely recognized that design and development must be micromechanics-based, because testing at lamina and laminate level cannot keep pace with new materials development and the need to insert materials in untested stress-displacement-temperature domains.

The following results, based on the constitutive response of the reinforcement and the matrix, can be derived from micromechanics analyses:

- Overall stress-strain response of the composite under a wide range of load, temperature, time, and cycle conditions
- Stresses and strains at locations corresponding to potential sites of damage and failure

Micromechanics analysis is combined with experimental results at the single-fiber, or single- ply multiple-fiber level, to establish critical conditions for the initiation and propagation of failure. Some of these failure mechanisms are discussed briefly in the next section. However, it is relevant to point out here that damage initiation and failure are gradually being incorporated into micromechanical calculations, although there may be some debate as to whether such calculations fall within the realm of micromechanics or mesomechanics. The insertion of damage into micro- or mesoscale analyses has become possible, because of significant strides in computational power, novel multiscale algorithms, and new experimental insights on damage initiation and growth. Their description, however, is outside the scope of this article.

The following items are discussed subsequently, with reference to a unidirectional fiber- reinforced composite:

- Stiffness in the longitudinal and transverse directions
- Stress-strain response and stress distribution under linear elastic conditions
- Stress-strain response and stress distribution under elastic-plastic or elastic-viscoplastic conditions
- It should be pointed out, especially to those familiar with PMCs, that while MMCs are often fabricated from lamina, the processing is such that there is no discernable interface between the laminae. No concerns about interlaminar shear arise with MMCs, as is the case with PMCs.

Stiffness of MMCs

A rule of mixtures (ROM) formula, derived from a one-dimensional model, is generally adequate for determining the elastic modulus (E_c) of the composite in the fiber (longitudinal) direction:

$$E_c = V_f E_f + V_m E_m \quad \text{(Eq 1)}$$

where V_f is the volume fraction of fibers, V_m is the volume fraction of the matrix ($V_m = 1 - V_f$), and E_f and E_m are the elastic modulus of the fiber and matrix, respectively. The corresponding Poisson's ratio can be determined using the concentric cylinder model (CCM) described later.

The analysis is slightly more complicated for the transverse modulus. In this case, one may consider various self-consistent models (Ref 1) using a composite cylinder assemblage. Alternately, one may use the NDSANDS computer program developed at the Air Force Research Laboratory (Ref 2, 3) and also based on the concentric cylinder analysis. As will be seen later, fiber-matrix debonding is often the critical damage mechanism for transverse loads.

Stress-Strain Response and Stress Distribution Under Linear Elastic Conditions

Longitudinal and Thermal Loading. It is assumed that a stress-free composite is subjected to a temperature change (ΔT), an applied stress (σ_c), or both. The mechanical loading is applied in the fiber direction, and the

temperature is assumed to be uniform throughout. Also, while fibers are generally organized in a rectangular or hexagonal array inside the matrix, major simplification is obtained by considering a concentric cylinder assemblage. The resulting fiber-matrix CCM is illustrated in Fig. 1.

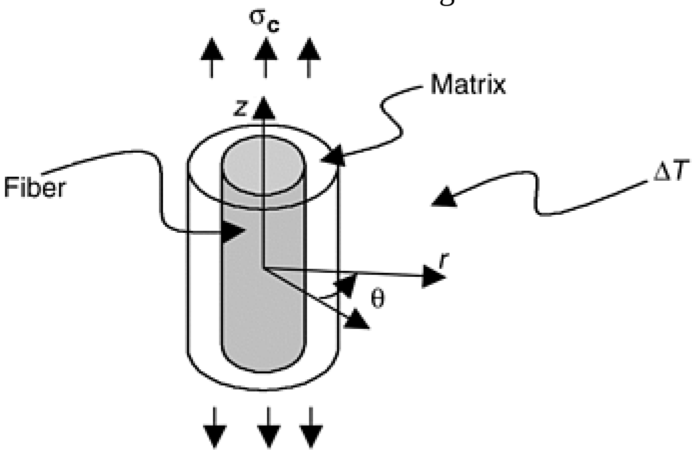

Fig. 1 The concentric cylinder model (CCM) for analyzing metal-matrix composites. The fiber radius is *a*, and the matrix radius is *b*, so the volume fraction of fibers is $V_f = a^2/b^2$. σ_c is the applied far-field stress.

This is an axisymmetric problem, and the equilibrium equations in the *r*-, θ-, *z*-coordinate system reduce to:

$$\frac{d\sigma_r}{dr} + \frac{\sigma_r - \sigma_\theta}{r} = 0 \qquad \text{(Eq 2)}$$

The two independent displacements are *u* and *w* in the *r*- and *z*-directions, respectively. The strains are given by:

$$\varepsilon_r = \frac{du}{dr}, \quad \varepsilon_\theta = \frac{u}{r}, \quad \text{and} \quad \varepsilon_z = \frac{dw}{dz} \qquad \text{(Eq 3)}$$

Note that only ordinary derivatives are used, because *u* cannot be a function of *z* due to the infinitely long cylinders, and because *w* cannot be a function of *r*, otherwise isostrain conditions in the *z*-direction are violated. The displacement field given by Eq 3 can be used to write the compatibility condition for strains. The resultant compatibility condition is:

$$\frac{d\varepsilon_\theta}{dr} + \frac{\varepsilon_\theta - \varepsilon_r}{r} = 0 \qquad \text{(Eq 4)}$$

Equations 2 and 4 form the basis for elastic- plastic-viscoplastic analysis. Under linear elastic conditions, the equilibrium and compatibility requirements are identically satisfied if *u* has the form of Eq 5, where *A* and *B* are constants for each constituent:

$$u = \frac{A}{r} + Br \qquad \text{(Eq 5)}$$

Thus, *A* and *B* may be designated as A_f and B_f for the fiber and A_m and B_m for the matrix. Differentiation of Eq 5 according to Eq 3 provides the strains, and generalized Hooke's law is used to determine the stresses from the strains. When thermal strains are present, they must be subtracted from the total strains derived from Eq 5 and 3, in order to determine the stresses. The stress components then become:

$$\begin{aligned}
\sigma_r &= \lambda(\varepsilon_r + \varepsilon_\theta + \varepsilon_z - 3\alpha\Delta T) + 2G(\varepsilon_r - a\Delta T) \\
\sigma_\theta &= \lambda(\varepsilon_r + \varepsilon_\theta + \varepsilon_z - 3\alpha\Delta T) + 2G(\varepsilon_\theta - a\Delta T) \\
\sigma_z &= \lambda(\varepsilon_r + \varepsilon_\theta + \varepsilon_z - 3\alpha\Delta T) + 2G(\varepsilon_z - a\Delta T)
\end{aligned} \qquad \text{(Eq 6)}$$

where

$$\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)} \quad \text{and } G = \frac{E}{2(1+\nu)}$$

λ is a Lame's constant, and G is the shear modulus. The constants E, λ, G, ν, and α are specific to each material and are designated by subscripts "f" and "m" for the fiber and matrix, respectively. α refers to the thermal expansion, E is the Young's modulus, and ν is the Poisson's ratio of each constituent. The value of α will vary with temperature, so the value appropriate for the temperature range, ΔT, must be used. In Eq 6, the radial and circumferential strains are derived from Eq 5, and $\epsilon_z = k$ is a constant for both the fiber and the matrix for maintaining isostrain conditions. The unknowns of the problem are the constants A_f, B_f, A_m, B_m, and k, requiring five independent boundary conditions. With the fiber radius, a, and matrix radius, b, as shown in Fig. 1, those boundary conditions are as follows:

- The displacement must be finite in the fiber at $r = 0$, hence $A_f = 0$.
- The radial displacements must be continuous across the interface, that is, $u_{fiber} = u_{matrix}$ at $r = a$.
- The radial stresses must be continuous across the interface, that is, $\sigma_r^{fiber} = \sigma_r^{matrix}$ at $r = a$.
- The radial stress must be zero at $r = b$; that is, $\sigma_r^{matrix} = 0$ at $r = b$.
- The sum of the axial stresses, normalized with respect to the respective areas, must be equal to the far-field applied stress in the fiber direction; that is, $V_f\sigma_z^{fiber} + V_m\sigma_z^{matrix} = \sigma_c$.

Once the constants are determined, they can be substituted into Eq 6 to obtain stresses at different locations. The strains can be used to determine the relevant material response, such as the effective elastic modulus and Poisson's ratio, under isothermal axisymmetric mechanical loading. Also, by holding $\sigma_c = 0$, the thermal expansion coefficient of the composite can be determined along both the axial and radial directions.
The set of equations for the remaining unknown constants, B_f, A_m, B_m, and k, can be represented through the following matrix equation:

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{vmatrix} \begin{vmatrix} B_f \\ A_m \\ B_m \\ k \end{vmatrix} = \begin{vmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{vmatrix} \quad \text{(Eq 7)}$$

where the constants a_{ij} and b_i are as follows:

$$
\begin{aligned}
a_{11} &= a \\
a_{12} &= -\frac{1}{a} \\
a_{13} &= -a \\
a_{14} &= 0 \\
b_1 &= 0 \\
a_{21} &= \frac{E_f}{(1+\nu_f)(1-2\nu_f)} \\
a_{22} &= \frac{E_m}{(1+\nu_m)a^2} \\
a_{23} &= -\frac{E_m}{(1+\nu_m)(1-2\nu_m)} \\
a_{24} &= \frac{E_f\nu_f}{(1+\nu_f)(1-2\nu_f)} - \frac{E_m\nu_m}{(1+\nu_m)(1-2\nu_m)} \\
b_2 &= \left[\frac{E_f\alpha_f}{(1-2\nu_f)} - \frac{E_m\alpha_m}{(1-2\nu_m)}\right]\Delta T \\
a_{31} &= 0 \\
a_{32} &= \frac{E_m\nu_f}{(1+\nu_m)a^2} \\
a_{33} &= \frac{E_m}{(1+\nu_m)(1-2\nu_m)} \\
a_{34} &= \frac{E_m\nu_m}{(1+\nu_m)(1-2\nu_m)} \\
b_3 &= \frac{E_m\alpha_m}{(1-2\nu_m)}\Delta T \\
a_{41} &= \frac{2E_f\nu_f V_f}{(1+\nu_f)(1-2\nu_f)} \\
a_{42} &= 0 \\
a_{43} &= \frac{2E_m\nu_m V_m}{(1+\nu_m)(1-2\nu_m)} \\
a_{44} &= \frac{E_f(1-\nu_f)V_f}{(1+\nu_f)(1-2\nu_f)} + \frac{E_m(1-\nu_m)V_m}{(1+\nu_m)(1-2\nu_m)} \\
b_4 &= \sigma_c + \left[\frac{E_f\alpha_f V_f}{(1-2\nu_f)} + \frac{E_m\alpha_m V_m}{(1-2\nu_m)}\Delta T\right]
\end{aligned}
\qquad \text{(Eq 8)}
$$

Equation 7 can be solved, and the radial and circumferential stresses determined through Eq 6:

$$\sigma_r^{\text{fiber}} = \sigma_\theta^{\text{fiber}} = 2(\lambda_f + G_f)B_f + \lambda_f k - (3\lambda_f + 2G_f)\alpha_f \Delta T$$
$$\sigma_r^{\text{matrix}} = -2G_m A_m / r^2 + 2(\lambda_m + G_m)B_m + \lambda_m k - (3\lambda_m + 2G_m)\alpha_m \Delta T$$
$$\sigma_\theta^{\text{matrix}} = 2G_m A_m / r^2 + 2(\lambda_m + G_m)B_m + \lambda_m k - (3\lambda_m + 2G_m)\alpha_m \Delta T \quad \text{(Eq 9)}$$
$$\sigma_z^{\text{fiber}} = 2\lambda_f B_f + (\lambda_f + 2G_f)k - (3\lambda_f + 2G_f)\alpha_f \Delta T$$
$$\sigma_z^{\text{matrix}} = 2\lambda_m B_m + (\lambda_m + 2G_m)k - (3\lambda_m + 2G_m)\alpha_m \Delta T$$

Equation 9 provides accurate solution of the stress and strain fields, as well as the axial strain (k) and radial displacement (u at $r = b$) response of the composite, under any complex combination of thermal and mechanical load under linear elastic conditions. It is important to perform the calculations in Eq 7 with high precision, using double precision numbers so that rounding errors do not significantly affect the stresses and strains. Interface stresses are obtained by substituting $r = a$ in the final solution.

Under purely thermal loading, that is, $\sigma_c = 0$, and when $\nu_f = \nu_m = \nu$, a more concise solution is obtained (Ref 4) for the radial stress at the interface:

$$\sigma_r^{\text{interface}} = -\frac{(\alpha_f - \alpha_m)\Delta T E_m}{2\lambda_1}\left[\frac{V_m}{1-\nu_m}\right]$$
$$\text{where } \lambda_1 = \left(1 - \frac{1}{2}\left\{\frac{1-2\nu}{1-\nu}\right\}\left\{1 - \frac{E_c}{E_f}\right\}\right) \quad \text{(Eq 10)}$$

Here, E_c is the longitudinal modulus of the composite and can be computed using the ROM (Eq 1). Note that when ΔT is negative, such as when cooling from the processing temperature, and $\alpha_m > \alpha_f$, as is often the case, the interface stress is negative; that is, there is a compressive pressure or a clamping stress at the interface. The corresponding axial stresses in the matrix and fiber are:

$$\sigma_z^{\text{matrix}} = (\alpha_f - \alpha_m)\Delta T E_m \left[\frac{\lambda_2}{\lambda_1}\right]\left[\frac{E_f}{E_c}\right]\left[\frac{V_f}{1-\nu_m}\right]$$
$$\sigma_z^{\text{fiber}} = -\frac{V_m}{V_f}\sigma_z^{\text{matrix}} \quad \text{(Eq 11)}$$
$$\text{where } \lambda_2 = \frac{1}{2}\left[1 + \frac{E_c}{E_f}\right]$$

Note that the axial stresses remain independent of r in each of the constituents under elastic conditions. Also, the ratio of the radial stress at the interface to the axial stress in the fiber (both negative quantities) is simply $E_c/(E_f + E_c)$. This ratio is useful for experimentally estimating the radial residual compressive stress at the interface. Thus, the axial residual stress in fibers can be determined relatively easily by chemically dissolving a length of the matrix (Ref 5) and comparing the fiber length before and after removal of the matrix. The radial residual stress at the interface is then the axial residual stress multiplied by a factor derived from the CCM analysis. That factor is simply $E_c/(E_f + E_c)$, when the Poisson's ratios of the constituents are identical. Note that the radial residual stress at the interface is important for the transverse strength of unidirectional composite, as is discussed later. Because of complex viscoplastic deformation, it is often difficult to estimate residual stresses based on thermal processing history of the composite, and so direct measurements using etching, x-ray, or neutron diffraction procedures are necessary. If the bond strength is assumed to be zero, then the radial residual stress can also be estimated from the transverse tension test, from the knee in the stress-strain curve (Ref 6, 7).

Transverse Loading. The deformation is no longer axisymmetric under transverse loading. The finite-element method (FEM) is often employed on a unit cell representation of the structure, as illustrated in Fig. 2. Generalized plane strain is often used in the FEM calculations, and either a constant stress or a constant displacement boundary condition is specified on plane *BC*. The boundary condition on face *AB* is not well

resolved. If the composite is thin, such that plane-stress conditions may be valid, then boundary *AB* is considered to be stress-free. Such analyses show that *AB* is curved and no longer parallel to *DC*. On the other hand, if the cell is embedded well inside a large composite, then face *AB* is considered to move parallel to *CD*, and this usually results in greater tensile stress being generated at the fiber-matrix interface. The type of boundary condition on *AB* has influence on the final local stress-strain fields and needs to be evaluated carefully.

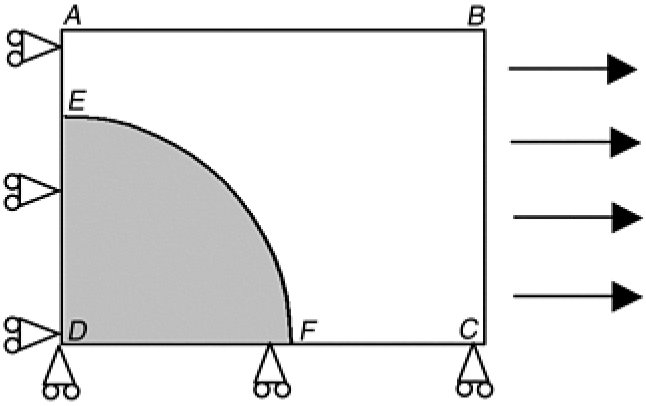

Fig. 2 Unit cell representation of the composite in finite-element calculations. The quarter-fiber is represented by the shaded area.

The FEM procedure is particularly useful for any arbitrary direction of loading and is not restricted to a concentric cylinder geometry. Also, any elastic, plastic, or viscoplastic constitutive response can be built into the calculations. However, the procedure is computer time-sensitive compared with simpler calculations that can be done using calculators or simple computer programs. In particular, the FEM procedure can become fairly time-consuming and expensive if the longitudinal elastic-viscoplastic response has to be analyzed over tens or hundreds of thermomechanical cycles. Under those circumstances, models such as the CCM analysis or Eshelby's method of analysis for particulate composites remain particularly attractive. (The Eshelby method models metal inclusions or reinforcing particles with an ellipsoidal shape.)

A number of analytical techniques have also been developed to determine the stress-strain response and the local stresses under transverse loading. One such formulation is the NDSANDS program (Ref 2, 3). In Ref 8, a three-phase model was formulated for considering both thermal and transverse loading of the composite (Fig. 3). The stress components in cylindrical coordinates are based on the plane-strain formulation in Ref 8 and 9, and are expressed as:

$$\sigma_{rr} = \left[\frac{A}{r^2} + 2B\right] + \left[-2D - 6\frac{F}{r^4} - 4\frac{G}{r^2}\right]\cos 2\theta$$

$$\sigma_{\theta\theta} = \left[-\frac{A}{r^2} + 2B\right] + \left[2D + 12Er^2 + 6\frac{F}{r^4}\right]\cos 2\theta \qquad \text{(Eq 12)}$$

$$\tau_{r\theta} = \left[2D + 6Er^2 - 6\frac{F}{r^4} - 2\frac{G}{r^2}\right]\sin 2\theta$$

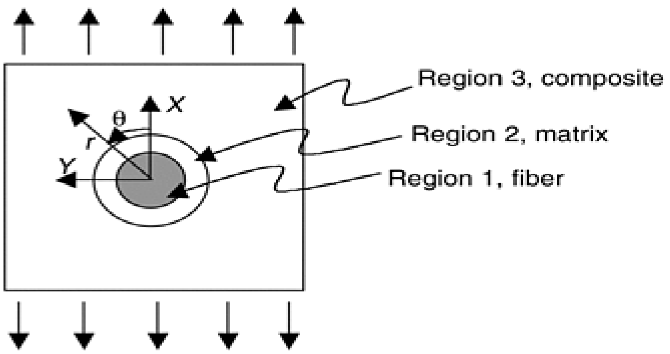

Fig. 3 Three-phase model for analyzing MMCs. Source: Ref 8

Stress boundary conditions are used at each interface, and an initial guess is made for the region 3 composite properties. An iterative scheme is used to determine the constants in Eq 12, and reasonably good correlations were obtained with FEM solution for a MMC under thermal and transverse load.

When the fiber volume fraction is low or when a single-fiber composite is considered, one may consider a single fiber embedded in an infinite matrix. In this case, Eq 13 (Ref 9) may be used to determine the stresses in either the fiber or the matrix:

$$\frac{\sigma_{rr}{}^{m}}{\sigma_{a\theta}} = \frac{1}{2}\left[1 - \frac{\gamma R^2}{r^2} + \left(1 - \frac{2\beta R^2}{r^2} - \frac{3\delta R^4}{r^4}\right)\cos 2\theta\right]$$

$$\frac{\sigma_{\theta}{}^{m}}{\sigma_{a}} = \frac{1}{2}\left[1 + \frac{\gamma R^2}{r^2} - \left(1 - \frac{3\delta R^4}{r^4}\right)\cos 2\theta\right]$$

$$\frac{\tau_{r\theta}{}^{m}}{\sigma_{a}} = -\frac{1}{2}\left[1 + \frac{\beta R^2}{r^2} + \frac{3\delta R^4}{r^4}\right]\sin 2\theta$$

$$\frac{\sigma_{rr}{}^{f}}{\sigma_{a}} = \frac{1}{2}[\beta_o + \delta_o \cos 2\theta]$$

$$\frac{\sigma_{\theta\theta}{}^{f}}{\sigma_{a}} = \frac{1}{2}\left[\beta_o + \left(\frac{6\gamma_o r^2}{R^2} - \delta_o\right)\cos 2\theta\right] \qquad \text{(Eq 13)}$$

$$\frac{\tau_{r\theta}{}^{f}}{\sigma_{a}} = \frac{1}{2}\left[\frac{3\gamma_o r^2}{R^2} - \delta_o\right]\sin 2\theta$$

where

$$\beta = -\frac{2(G_f - G_m)}{G_m + G_f\kappa_m}, \quad \gamma = \frac{G_m(\kappa_f - 1) - G_f(\kappa_m - 1)}{2G_f + G_m(\kappa_f - 1)},$$

$$\delta = \frac{G_f - G_m}{G_m + G_f\kappa_m}$$

$$\beta_o = \frac{G_f(\kappa_m + 1)}{2G_f + G_m(\kappa_f - 1)}, \quad \gamma_o = 0, \quad \delta_o = \frac{G_f(\kappa_m + 1)}{G_m + G_f\kappa_m}$$

and $\kappa_m = 3 - 4\nu_m$, $\kappa_f = 3 - 4\nu_f$

Here, σ_a is the far-field tensile stress perpendicular to the fiber, θ is zero along the direction of loading (Fig. 3), *r* is the radial distance from the center of the fiber, *R* is the radius of the fiber, the superscripts "f" and "m" refer to the fiber and matrix, respectively, G_f and G_m are their shear modulus, and ν_f and ν_m are the corresponding Poisson's ratios. The interface corresponds to the location $r = R$.

In MMCs, the fiber-matrix bond strength is generally kept *low,* because experiments show that the strength and toughness in the longitudinal direction is reduced substantially if the bond is strong. There are essentially two reasons for this behavior. First, a higher interface strength is usually accompanied with some chemical reaction at the interface, which in turn creates minute flaws in the strong fibers (typically > 2 GPa, or 290 ksi). This lowers the fiber strength, thus degrading the fiber-dominated longitudinal strength of the composite. Second, ceramic fibers have a statistical distribution of strengths. When the bond strength is low, premature failure of a weak fiber causes debonding along its sides, and the load in the broken fiber is efficiently distributed among many of its neighbors (global load sharing). In other words, stress concentration on the nearest neighbor is low, and thereby it is protected from immediate failure. On the other hand, when the bond strength is *high*, the load from the broken fiber is transferred mainly to the nearest fiber, causing it to break (local load sharing). This type of localized fracture sequence leads to premature failure of the composite, even though most of the fibers may be of significantly higher strength. There is, however, a penalty for this weak bond. Under transverse stress, a weak bond results in early fiber-matrix debonding. A typical stress- strain curve for a transversely loaded titanium- matrix composite is sketched in Fig. 4, where the knee in the stress-strain curve at *B* is associated with fiber-matrix debonding. Such a mechanism is confirmed by compliance measurements as well as by interpretation of changes in the Poisson's ratio (Ref 6, 7). The strain at *B* is usually low, about 0.3%, and

the associated low strength poses a major limitation to the application of fiber-reinforced MMCs. Attempts are underway to improve this strength with minimal loss of longitudinal properties.

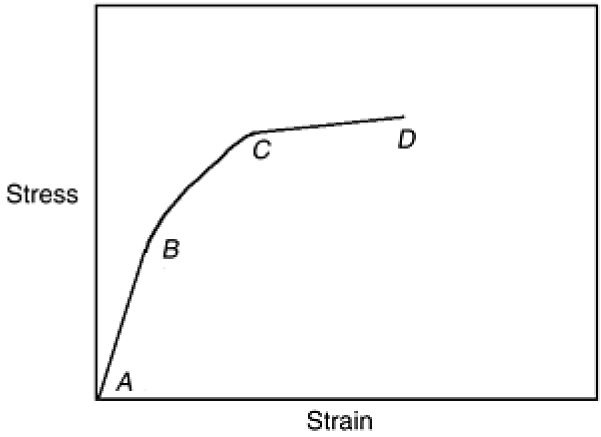

Fig. 4 A typical stress-strain curve under transverse loading when the interface bond strength is weak. Debonding initiates at a fairly low stress at *B*, and is accompanied with small-scale plasticity around the debonded fibers. Large-scale plasticity ensues at *C*, and failure occurs at *D*. Source: Ref 6, 7

The residual radial stress at the interface has a strong influence on the stress corresponding to point *B*, because the local radial stress is simply the sum of the residual clamping stress and the local stress due to far-field transverse loading. Equations have been provided previously for calculating the residual stress as well as the stress due to a transverse applied load. There is also a need to model the postdebonded region, *BC*, when the material is primarily elastic. Reference 9 does provide equations for calculating displacements for a slipping fiber (similar to Eq 13 shown previously), and they may be used to calculate the postdebonded stress-strain behavior in region *BC*.

Stress-Strain Response and Stress Distribution Under Elastic-Plastic and Elastic-Viscoplastic Conditions

Longitudinal and Thermal Loading. Axisymmetric conditions are maintained under longitudinal loading, and the CCM model is particularly advantageous. However, plasticity rules must be invoked. A method for incorporating plasticity and viscoplasticity into the CCM analysis is indicated in Ref 10 and 11. The calculations are based on the successive approximation approach of plasticity (Ref 12), as well as the elastic-plastic calculations performed earlier using a CCM model (Ref 13, 14). The matrix cylinder of Fig. 1 is divided into a series of thin concentric cylinders, and a finite-difference scheme is used to integrate Eq 2 and 4. Any arbitrary strain-hardening behavior can be modeled using the CCM formalism.

A simpler, but less accurate, method is to simply use a one-dimensional isostrain model. Essentially, the composite stress is expressed as:

$$\sigma_c = V_f\sigma_f + V_m\sigma_m \quad \text{(Eq 14)}$$

where σ_f and σ_m are the stresses in the fiber and matrix, respectively. At any given strain, the stresses in the fiber and the matrix can be obtained from the respective stress-strain data, and the results summed according to Eq 14. This approach cannot account for the triaxial stress state around the fiber, but does provide a reasonably good estimate of the stress-strain plot.

A typical stress-strain plot for a longitudinally loaded composite is illustrated in Fig. 5. The onset of nonlinearity of the stress-strain curve is associated with yielding of the matrix, as confirmed by observation of slip bands and using transmission electron microscopy (Ref 6, 15). The yielding of the matrix is influenced by the residual axial stress in the matrix, which is usually tensile, and the yield strength of the matrix. If the stress-strain behavior of the fiber-free "neat" material is known, then the residual axial stress in the matrix can be estimated from the knee, as shown in Ref 6.

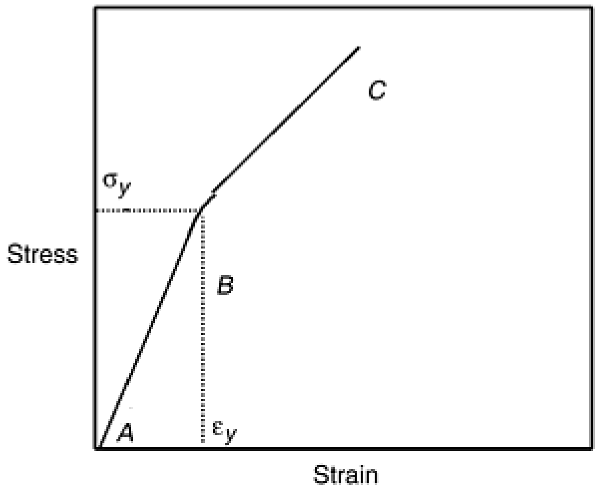

Fig. 5 Typical stress-strain curve for a longitudinally loaded MMC

The postyield domain of the stress-strain plot is matrix-plasticity-dominated. However, toward the end of region *BC* in Fig. 5, fiber cracks start occurring, so that there is combination of plasticity and damage. Here, the statistical fiber-fracture model in Ref 16 and 17 can be used to incorporate the effects of fiber failure. Essentially, the fiber fracture model is used to determine an effective nonlinear stress response of the fiber (see subsequent equations), as indicated in Fig. 6. The effective stress-strain behavior of the damaged fibers can then be used either in the elastic-viscoplastic CCM model, as was done in Ref 18, or in a simple one-dimensional representation of the composite longitudinal response.

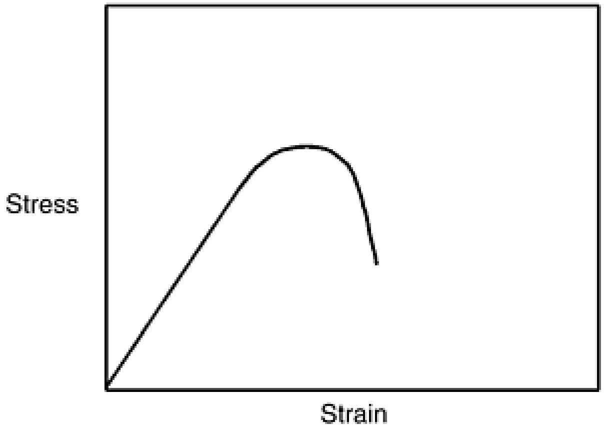

Fig. 6 Schematic of the effective stress-strain response for damaging brittle fibers, based on the statistical model of Ref 16, 17

For time-dependent loading, viscoplastic or creep models have to be used. Among them, Bodner-Partom's viscoplastic model with directional hardening (Ref 19, 20) has been used extensively in the finite difference code for elastic- plastic analysis (FIDEP) computer code (Ref 10, 11) that is based on the CCM model. The model contains 12 unknown constants that are estimated from tension, fatigue, stress relaxation, and creep tests on the matrix-only “neat” material. Values for a number of titanium alloys are provided in Ref 11 and 21.

A number of other models have also been developed to determine the stress-strain response under viscoplastic deformation. These include the vanishing fiber diameter (VFD) model, (Ref 22, 23, and 24), the method of cells (Ref 25), and the generalized method of cells (Ref 26). The computer code VISCOPLY has been developed based on the VFD model and using the viscoplastic model of Ref 27. Results from that code have been compared with experimental data on titanium matrix composites (Ref 28, 29). Comparisons of the different codes with Bodner-Partom's viscoelastic model were conducted in Ref 21 by considering both in-phase and out-of- phase thermomechanical fatigue loading. The models were compared with results from the FEM method.

Transverse Loading. The models referenced in the previous paragraph have been used to determine the stress-strain response under transverse loading. One problem in modeling is that at elevated temperatures, the residual clamping stress at the interface is reduced significantly. Combined with the fact that the transverse strength of

the interface is maintained quite low to obtain damage tolerance in the fiber direction, interface debonding occurs quite early at elevated temperatures. However, because of the ductility of the matrix, debonding does not lead to failure. Consequently, plasticity and viscoplasticity with debonded fibers must be considered during transverse loading of a unidirectional composite.

As indicated earlier, the FEM method may be relied upon, provided the micromechanisms of deformation and damage (such as debonding) are adequately taken into account, and provided the inelastic deformation of the matrix is modeled accurately. However, FEM is not efficient for thermomechanical loading. In recent years, the method of cells has been extended to account for fiber-matrix debonding. Also, the VFD model has been modified to account for a debonded fiber. Details on these issues may be obtained from the references in the previous section.

Simplified equations of the stress-strain behavior under elastic-plastic conditions, based on FEM calculations, have been provided in Ref 30. A Ramberg-Osgood power law model is used to represent the matrix plastic behavior, and it is shown that the effective yield strength of a fully bonded composite is increased over that of the matrix material. Further details are presented in the section on discontinuous composites.

Multiaxial Loading. For loading other than in the 0° or 90° direction, one may refer to the work in Ref 31 and 32, where the plastically deformed composite is treated as an orthotropic elastic-plastic material. The flow rule here allows for volume change under plastic deformation, unlike the case of monolithic alloys. The approach has the advantage of collapsing data from different lamina on a single curve. However, the method is semiempirical and is not based on the constituent elastic-plastic deformation behavior of the matrix.

A more rigorous formulation based on a FEM technique was adopted in Ref 33 and 34. Stand- alone software, called IDAC, is available, such that any multiaxial stress state can be analyzed. Note that off-axis loading is simply a case of multiaxial loading of a unidirectional lamina. The input requirements for the program are the elastic, plastic, and viscoplastic parameters of the matrix and the tensile strength of the fiber- matrix interface. The latter is included because of the propensity for fiber-matrix debonding at low transverse stresses, which strongly influences the post-debond elastic-viscoplastic response of the composite.

Micromechanics of Discontinuously Reinforced MMCs

The stress-strain response of discontinuously reinforced composites (DRCs) is influenced by the morphology of particles, both in the elastic and elastic-plastic domain. Most of the applications of DRCs have been with discontinuously reinforced aluminum alloys (DRAs). The particle shapes of alumina or SiC reinforcements, employed most often in DRAs, are generally blocky and angular, rather than spherical or cylindrical. Whiskers are generally modeled as cylinders with a high aspect ratio, the ratio of height to diameter.

Elastic Deformation. Although the primary effects of particles are their modulus and volume fraction, their shape has influence on the modulus of the composite. The effects of particle shapes are discussed in Ref 35 and 36. Experimental data in Ref 36, 37, 38, and 39 show that the finite- element results of Ref 36 for a unit cylinder with an aspect ratio of unity provide best agreement with experimental data. The Hashin Shtrikman bounds for the elastic moduli (Ref 40) are too wide apart for making an adequate estimate. Rather, Mura's formulation (Ref 41), although developed for spherical particles, appears to match the unit cylinder FEM solution reasonably well up to a fiber volume fraction of 0.25. Beyond that volume fraction the deviation from the FEM result is large, and actual FEM results, such as those in Ref 36 should be used. Note also that the ROM (Eq 1) overestimates the modulus of DRCs and should not be used. The elastic moduli from Mura's analytical solution (Ref 41) are as follows:

$$G = G_m \left[1 + \frac{V_p (G_m - G_r)}{\left(G_m + 2(G_r - G_m) \dfrac{4 - 5\nu_m}{15(1-\nu_m)} \right)} \right]^{-1}$$

$$K = K_m \left[1 + \frac{V_p (K_m - K_r)}{\left(K_m + \dfrac{1}{3}(K_r - K_m) \dfrac{1+\nu_m}{1-\nu_m} \right)} \right]^{-1} \quad \text{(Eq 15)}$$

and E and ν for the composite are obtained from:

$$E = \frac{9KG}{3K + G} \qquad \nu = \frac{3K - 2G}{2(G + 3K)}$$

Here, the subscripts “m” and “r” refer to the matrix and reinforcement, respectively, and G and K are the shear modulus and bulk modulus of the composite, respectively. V_p is the volume fraction of reinforcement.

In addition to the FEM approach, one may use Eshelby's technique to determine elastic modulus for various shapes and volume fractions of reinforcements. Such calculations are nicely illustrated in Ref 35, which provides a computer program at the end of the book. It is also relevant to mention that although particle distribution has negligible effect on elastic modulus at low volume fractions, the effect becomes larger at high volume fractions. The distribution effect is largely experienced through a change in the hydrostatic stress distribution in the matrix, and such a change is anticipated to be larger when the volume fraction of the matrix phase is smaller. However, experimental results are not available that can validate this distribution effect.

Elastic-Plastic Deformation. Analysis of elastic-plastic deformation with rigid, spherical particles has been considered in Ref 42 for an elastic-perfectly plastic (no strain hardening) matrix. The flow stress, σ_c, under dilute conditions ($V_p < 0.25$) may be expressed as:

$$\sigma_c = 1 + \beta V_p \quad \text{(Eq 16)}$$

where β was estimated to be approximately 0.375 for spherical particles.

In Ref 30, FEM analysis was conducted for different-shaped rigid particles. The σ_c for a perfectly plastic matrix reinforced with unit cylinders (loaded perpendicular to the axis of the cylinder) show β to be a function of V_p:

$$\beta = 9V_p - 0.16 \quad \text{(Eq 17)}$$

When matrix strain hardening is considered, the results in Ref 30 can be used. Essentially, the matrix is represented by the Ramberg-Osgood formulation:

$$\varepsilon = \frac{\sigma}{E_m} + \alpha\left(\frac{\sigma}{\sigma_o}\right)^n \quad \text{(Eq 18)}$$

where $\alpha = \frac{3}{7}$, n is the inverse of the work- hardening exponent, N, of the matrix, E_m is the elastic modulus of the matrix, and σ_o is a normalizing parameter approximately equal to the yield strength of the matrix. The corresponding stress-strain response of the particulate-reinforced composite, based on FEM calculations (Ref 30), is estimated to be:

$$\varepsilon_c = \frac{\sigma_c}{E_c} + \alpha\left(\frac{\sigma_o^m}{E_m}\right)\left(\frac{\sigma_c}{\sigma_N}\right)^n \quad \text{(Eq 19)}$$

where the subscript "c" refers to the composite, "m" is the matrix, and σ_N is a reference stress, almost equal to the 0.2% yield stress of the composite. σ_N is a function of the volume fraction, work-hardening rate of the matrix, and the particle shape. It is expressed in Ref 37 as:

$$\frac{\sigma_N}{\sigma_o^m} = \xi\left[(1 + \kappa N)(1 + \beta V_p) - \kappa N\right] \quad \text{(Eq 20)}$$

where V_p is the volume fraction of particles, β can be obtained from Eq 17, and κ is a function of the shape and volume fraction of particles and is plotted in Ref 30. ξ is approximately 0.94 at small plastic strains (less than $3\epsilon_o$, where ϵ_o is the yield strain of the matrix), but ξ becomes unity at large strains. Approximate values of κ are 3.1, 3.5, and 4.25 at V_p of 0.1, 0.15, and 0.2, respectively. All these quantities are valid only for unit cylinder particles, and they are considered here because this shape provides best correlation with the experimentally determined elastic modulus of DRAs. For particles of other shapes, one may refer to Ref 30. In summary, Eq 19 provides the entire stress-strain curve for the composite when the parameters E_m and n (= $\frac{1}{N}$) in Eq 18 are known for the matrix. Results in Ref 37 and 38 for a silicon carbide particle, SiCp, reinforced 7093 aluminum alloy show that the previous estimation formulas provide reasonable correlation with the experimentally determined stress-strain response of the composite.

A few remarks are in order here. The formulas can only provide approximate values, and they were based on rigid particles with infinite elastic modulus. Experiments on composites with the same volume fraction of particles in the same matrix, but with different sizes of particles, show that the strength tends to increase with smaller particle size. This effect is not captured by FEM calculations, where the absolute size of particles do not influence the results. Possible effects of particle size include:

- The reduction of grain size of the matrix and, hence, an increased strength of the matrix
- The punching of dislocations from the particles and the associated strengthening, which would be more effective at small particle sizes
- The limitation of standard FEM solution when the size scales become small
- The matrix alloy may be affected by reaction with the particle.

These issues are not captured by current modeling practice, and hence the predictive equations provided previously should only be used for initial estimation.

The ductility of the composite is an important issue in DRCs, unlike fiber-reinforced systems, where debonding fibers can provide damage tolerance when loaded in the fiber direction. Ductility of DRCs can vary anywhere from 10 to 70% of the matrix, with ductility being affected significantly at volume fractions of 0.25 and higher. Recent discussions on these issues are available in Ref 35, 37, 38, and 39. Important damage mechanisms include particle fracture and particle-matrix debonding (see the article "Fracture and Fatigue of DRA Composites" in *Fatigue and Fracture*, Volume 19 of *ASM Handbook*). Particle fracture is particularly dominant for high-strength matrices, such as peak or underaged 2*xxx* and 7*xxx* aluminum alloys, and is established by

observing mirror halves of the fracture surface. Debonding is observed in lower-strength matrices, such as 6*xxx* aluminum alloys, although it is often difficult to establish whether failure occurred at the interface or whether it initiated in the matrix immediately adjacent to the interface. The latter mode mostly occurs when the bond is strong and the matrix is quite weak, such as aluminum alloys in the overaged condition.

Models of ductility have been proposed in Ref 37 and 39 to obtain initial estimates of ductility. The model in Ref 39 is based primarily on statistical particle fracture according to Weibull statistics and subsequent specimen instability according to the Considere criterion. (See the article “Uniaxial Compression Testing” in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook*, for an introduction to the Considere criterion.) The problem with this approach is that necking is essentially nonexistent in DRCs possessing any appreciable volume fraction of particles. Nevertheless, reasonable agreement was obtained with experiments conducted by the authors. The model in Ref 37 presupposes the existence of particle cracks, and failure is postulated based on rupture of the matrix between cracked particles. Once again, reasonably good agreement is obtained between the predictions of the model and experimental data on DRAs from a wide number of sources. However, the strain prior to particle fracture is neglected. Reference 39 also provides empirical equations for calculating the particle stress in a power-law hardening matrix at different values of imposed plastic strains. These formulas may be used to estimate the extent of damage as a function of applied strain. An alternate simplified methodology is suggested in Ref 37 for calculating particle stress and then determining particle strength based on the fraction of cracked particles. Such analyses suggest a Weibull modulus of approximately 5 and a Weibull strength of 2400 MPa (350 ksi) for 10 μm size SiC particles.

The previously mentioned elastic-plastic models assume a uniform distribution of particles. Although clustering may be considered small in well-processed powder-metallurgy-derived composites of volume fractions less than 0.2, nonuniformity and clustering is the rule rather than the exception. A Voronoi cell FEM approach has been developed in Ref 43 to assess elastic-plastic deformation of a multitude of unevenly distributed particles, rather than the uniform distribution assumed in unit cell FEM calculations. The analyses show that particle fractures occur early in regions of clusters, and this is accompanied with large plastic strains and hydrostatic stresses in damaged regions. These regions then become the locations for microvoid initiation, and because void growth is linearly proportional to the plastic strain and exponentially dependent on the level of hydrostatic tensile stress (Ref 44), the voids can rapidly grow to coalescence. A ductility model based on Voronoi cell computations remains to be established, but should provide a more accurate estimate of damage and failure for a nonuniform microstructure.

Local Failures of Fiber-Reinforced MMCs

Longitudinal Loading. Under monotonic tension loading, failure of the composite is determined by fiber fracture. Generally, fiber strengths follow weak-link Weibull statistics, where the probability of failure (P_f) of a fiber of length L is expressed as:

$$P_f = 1 - \exp\left[-\frac{L}{L_o}\left(\frac{\sigma}{\sigma_o}\right)^m\right] \quad \text{(Eq 21)}$$

where "m" is the Weibull modulus and σ_o is the Weibull (approximately average) strength for a fiber of length L_o.

For a ductile matrix, the matrix is always yielded, so that in a one-dimensional model, the composite ultimate strength, σ_c^U, is simply:

$$\sigma_c^U = V_f\sigma_f^U + (1 - V_f)\sigma_m^{flow} \quad \text{(Eq 22)}$$

where σ_f^U is the effective strength of the fiber at instability of the composite, and σ_m^{flow} is the flow stress in the matrix at that value of composite strain, typically 0.8 to 1%. The value of σ_f^U depends on the mode of failure. If the interface is so weak that failure of a fiber at any location is equivalent to loss of load-carrying capability of the entire fiber, then σ_f^U may be equated to the dry bundle strength (σ_{dbf}) (Ref 45):

$$\sigma_{dbf} = \frac{\sigma_o}{\left(me\frac{L}{L_o}\right)^{1/m}} \quad \text{(Eq 23)}$$

where e is the exponential term approximately equal to 2.718.

A more-realistic situation is the ability of the broken fiber to recarry the load after a sliding distance, δ, from the fiber break. In this case, one must consider the frictional sliding stress, τ, which can be independently determined from pushout or fragmentation tests. The associated effective fiber strength, according to Curtin's global load-sharing model (Ref 16, 17), is:

$$\sigma_{glf} = \sigma_{ch}\left[\frac{2}{m+2}\right]^{\frac{1}{m+1}}\left[\frac{m+1}{m+2}\right] \quad \text{(Eq 24)}$$

where the characteristic fiber strength σ_{ch} is:

$$\sigma_{ch} = \left(\sigma_o^m \tau \frac{L_o}{r}\right)^{\frac{1}{m+1}} \quad \text{(Eq 25)}$$

In Curtin's model (Ref 16, 17), the fragmenting fibers essentially follow the constitutive law:

$$\sigma_f = \varepsilon_f E_f\left[1 - \frac{1}{2}\left\{\frac{\varepsilon_f E_f}{\sigma_{ch}}\right\}^{m+1}\right] \quad \text{(Eq 26)}$$

where the subscript "f" refers to the fragmenting fibers. At instability, this leads to an effective fiber strain (ϵ_f^U):

$$\varepsilon_f^U = \frac{\sigma_{ch}}{E_f}\left(\frac{2}{m+2}\right)^{\frac{1}{m+1}} \quad \text{(Eq 27)}$$

The total strain in the composite at failure (ϵ_c^U) is then simply:

$$\varepsilon_c^{\,U} = \varepsilon_f^{\,U} - \varepsilon_f^{\,Res} \qquad \text{(Eq 28)}$$

where ϵ_f^{Res} is the residual strain in the fiber, being predominantly compressive and negative.

This model has been found to correlate quite well with the strength of a number of fiber-reinforced titanium alloys (Ref 17, 46, and 47). However, local load-sharing has also been observed (Ref 48, 49, and 50), where the density of fiber cracks was found to be far below those predicted by the global load-sharing model. Reference 50 provides a comparison of different models in the context of failure of an orthorhombic titanium alloy reinforced with SiC fibers. The local load- sharing situation is well captured by the second fiber fracture model of Zweben and Rosen (Ref 51), and the pertinent equations are also provided in Ref 50. The local load-sharing model gives effective fiber strengths that are slightly lower than the global load-sharing model. The lowest bound on the effective fiber strength is obtained from the dry bundle model. Although this may be overly conservative during room- temperature deformation, when there is significant clamping stress between the fibers and the matrix, the dry bundle model may provide a reasonable lower bound at high temperatures.

Transverse Loading. Under transverse loading, the onset of nonlinearity is determined by fiber-matrix separation, as discussed earlier. Debonding occurs when the local radial stress is greater than the bond strength of the interface. The local radial stress is simply the far-field stress ($\sigma^{\text{far-field}}$) multiplied by a stress-concentration factor (k) less the residual radial stress ($\sigma_r^{\text{residual}}$) at the interface. Stated mathematically:

$$\sigma_r^{\text{local}} = k\sigma^{\text{far-field}} - \sigma_r^{\text{residual}} \qquad \text{(Eq 29)}$$

Models for determining k and the thermal residual stress have been described earlier, with the single-fiber case being given by the analytical equations (Eq 22). Typical values of k are in the range 1.2 to 1.5.

The ultimate strength is governed by matrix rupture. If the fibers are not debonded, then the models described for discontinuous reinforced particles may be used without much loss of accuracy. Thus, Eq 16 with $\beta = 0.375$ may be used. When the fibers are debonded, then the strength of the composite is less than that of the matrix. In this case, one usually resorts to FEM analysis.

Engineering Mechanics and Analysis of Metal-Matrix Composites

Bhaskar S. Majumdar, New Mexico Institute of Mining and Technology

Macromechanics

Strength of Fiber-Reinforced Composites. The cases of tensile loading in the longitudinal and transverse directions have been described earlier. Figure 7 shows measured and predicted stress-strain plots for 0° SCS6/Ti-15-3 composites, where the sudden increase in the predicted strain response is interpreted as failure of the specimen (Ref 18). Modeling was conducted using the FIDEP code with both elastic-plastic and elastic-viscoplastic matrix using the Bodner-Partom model, which was modified to incorporate fiber fracture according to Eq 26. Figure 7 shows good agreement between the predicted stress- strain curves and strengths with experimental data. This type of correlation also was observed at elevated temperatures, when viscoplastic effects became important.

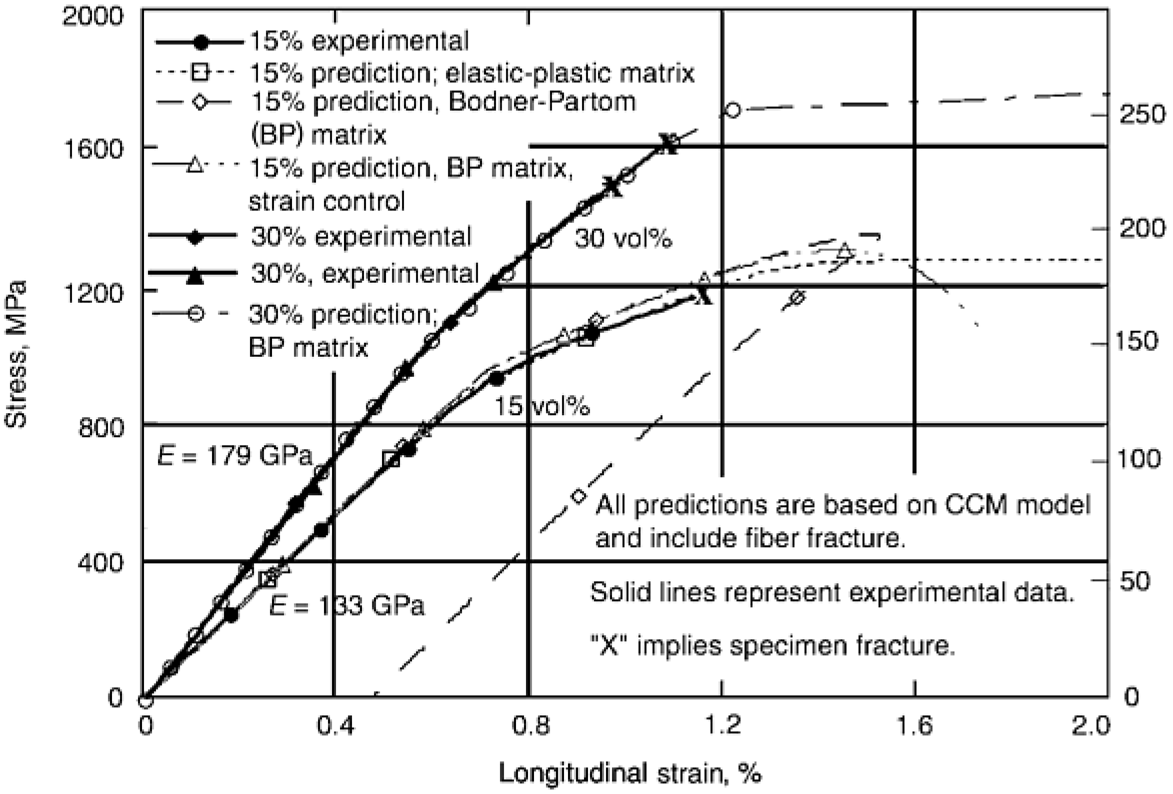

Fig. 7 Comparison of predicted and experimental stress-strain behavior of SCS6/Ti-15-3 composites at room temperature for 15% and 30% fiber volume fractions. Both elastic-plastic and elastic-viscoplastic analysis was conducted, and fiber fractures were incorporated into the model. The sudden increase in strain in the predicted curves signifies specimen failure. Source: Ref 18

For off-axis or multiaxial loading, the IDAC (Ref 33) program may be used to compute the stress-strain response of the composite and the local stresses/strains in the constituents. The onset of failure can then be predicted based on the mechanisms, that is, fiber fracture, transverse failure, or shear failure, depending upon which mechanism can operate at the least value of the far-field load.

Strength of Discontinuous Reinforced Composites. The stress-strain curve has been covered in an earlier section. The ultimate strength is dependent on the elongation to failure, which is generally much less than the matrix. Models of ductility have been presented earlier.

Fatigue of Fiber-Reinforced MMCs. The longitudinal fatigue life of fiber-reinforced MMCs can generally be grouped under three regimes, in a plot of stress or strain range versus the cycles to failure (N_f). They are illustrated in Fig. 8, which was first postulated for polymer- matrix composites (Ref 52). The regimes have also been confirmed in MMCs and exhibit distinct differences in failure mechanisms (Ref 53, 54).

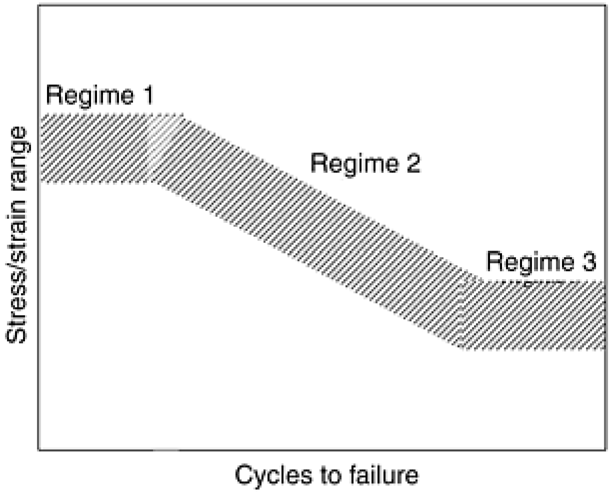

Fig. 8 Schematic showing the three regimes of fatigue of fiber-reinforced MMCs

Regime 1, with N_f typically between 1 and 1000 cycles, is dominated by fiber fractures without any matrix cracks. At elevated temperatures under isothermal fatigue conditions, fiber fractures appear to be precipitated by ***progressive ratcheting*** of the matrix under viscoplastic conditions. Essentially, matrix viscoplasticity results in the gradual transformation of the matrix strain range from tension-tension to fully reversed- loading tension-compression, where $R = -1$, although the composite may be subjected to only tension-tension loading at an R-ratio (minimum to maximum stress ratio on the composite) of 0.1, for example. The offloading of the matrix results in progressively increased loading being experienced by the fibers, as required by Eq 14, causing them to fail with an increased number of cycles. In this scenario, if the final fiber stress is insufficient to cause any significant breakage of fibers (well below the rounded region of Fig. 6), progressive fiber failure should be avoidable. Indeed, this maximum stress approximately delineates the boundary between regimes 1 and 2 under isothermal conditions.

The frequency of loading becomes an important factor in regime 1, because matrix creep can lower the maximum matrix stress attainable in both the tension and compression part of the cycle at low frequencies (<0.01 Hz). The result is an even greater load being carried by the fibers and a consequent poorer fatigue performance with lower frequency. The increased matrix creep and associated transfer of load to the fiber is manifested in the strain-ratcheting behavior of the composite, which shows increased ratcheting with reduced frequency at elevated temperatures. Thus, life prediction in regime 1 requires both a modeling of the composite response based on a good viscoplastic characterization of the matrix and adequate incorporation of fiber fracture using Weibull statistics. The CCM model for analysis has already been discussed, and reference has been made to the Bodner-Partom model for viscoplastic characterization of the matrix (Ref 10, 11, and 21). The matrix responses have been integrated into the available FIDEP and IDAC codes.

Under in-phase thermomechanical fatigue (IP- TMF), the extent of matrix ratcheting and fiber damage is observed to be larger (Ref 18, 55, and 56), and simultaneously the IP-TMF life is observed to be shorter than under isothermal conditions. One problem found with various investigations was that often the frequency of loading was smaller under IP-TMF than under isothermal conditions. In the extreme case, creep of the matrix may relax its value to zero at the end of the tension cycle. The result is that the entire applied load would then be carried only by the fibers, causing their stress to be significantly higher than under faster isothermal conditions. If all these factors are appropriately taken into account, then results under different test conditions (isothermal and IP-TMF) in regime 1 can be rationalized in terms of the maximum fiber stress (Ref 57). However, this does not clarify the entire picture, because the CCM model with Bodner-Partom constants accurately predicts the isothermal ratcheting response at the highest temperature, but significantly underpredicts the ratcheting response for IP-TMF at the same frequency (Ref 18). Thus, other factors may be present as well, and fiber damage due to molybdenum weaves was suggested for a SCS6/Ti-15- 3 system (Ref 18, 55). However, this explanation may only be valid for panels with molybdenum weaves. Overall, a complete understanding of IP-TMF has yet to emerge, although current predictions are much closer to experiments.

At room temperature, when viscoplastic conditions are negligible, the previous explanation is inadequate to explain why fibers should fail after the first cycle. In Ref 53, an alternate mechanism was proposed for the

initiation of fiber cracks. Microstructural observations suggested damage in the coating and in the reaction zone, leading to cracking of fibers.

Regime 2 is matrix-crack dominated, similar to monolithic alloys, but fiber stress also plays an important role. In this regime, the fatigue life can either be plotted as the stress range ($\Delta\sigma$) versus N_f, or as the strain range ($\Delta\epsilon$) versus N_f. A plot of $\Delta\sigma$ versus N_f shows that fatigue life increases with fiber volume fraction and is mainly an effect associated with load transfer from the matrix to the higher-strength elastic fibers. Such a plot also shows that composites have fatigue performance superior to the matrix alloy. This behavior is also observed with discontinuous reinforcements. However, if the fatigue life is plotted as $\Delta\epsilon$ versus N_f, as is most often done with monolithic alloys, then the MMC is generally found to have slightly poorer performance than the monolithic alloy. Fatigue tests with ***R***-ratio of –1 show better performance than with an ***R***- ratio of 0.1, at the same strain range (Ref 58). Microstructures show a greater density of matrix cracks, but the stress in the fibers are only half of what would occur under tension-tension loading. Because composite failure requires the breakage of fibers, life is improved under negative ***R***-ratio compression conditioning. Models have been proposed to include both the composite strain range and the fiber stress for predicting fatigue life in regime 2 (Ref 53, 57, 58, and 59).

In regime 2, matrix cracks can initiate anywhere between 10 and 30% of life, depending on the preparation of samples. In other words, the majority of life is spent in the fatigue crack growth (FCG) domain. A number of investigators have addressed FCG (Ref 60, 61, 62, and 63), and the common feature of their models is the reduction of the stress-intensity factor (shielding) at the matrix crack tip by the bridging fibers:

$$\Delta K_{\text{local}} = \Delta K_{\text{applied}} - \Delta K_{\text{bridging}} \quad \text{(Eq 30)}$$

The primary difference between the models is the way in which the shear lag analysis is conducted. Canonical equations are provided in Ref 64 to simplify calculations of fatigue crack growth. However, a factor that has not been considered in these models is the shielding of the crack due to higher-modulus fibers ahead of the crack tip. The effect of this shielding is analyzed in Ref 65, and it is observed that the interface tensile strength can have a substantial effect on the retardation of matrix crack growth in the low ΔK regime. The interface tensile strength then constitutes a microstructural variable, in addition to the friction shear stress parameter (τ), that could be used to control the crack growth kinetics.

Regime 3 represents the fatigue limit, which is the stress level below which the material can be cycled infinitely without damage. The matrix behavior is elastic in this region.

Engineering Mechanics and Analysis of Metal-Matrix Composites

Bhaskar S. Majumdar, New Mexico Institute of Mining and Technology

---

Fracture Toughness

Fiber-Reinforced Composites. In ductile matrix systems, a number of different behaviors have been observed, depending on the strength of the matrix, the fiber-matrix bond strength, and the volume fraction of fibers.

When the matrix strength is low, matrix-dominated shear deformation occurs prior to any fiber fracture. Indeed, in boron-fiber-reinforced aluminum composites, a shear deformation mode parallel to the fibers is observed (Ref 66, 67, and 68). Here, an intense slip zone develops over a plastic zone of length L perpendicular to the crack plane. At a critical load, when L is on the order of 3 to 17 times the crack length, the damage zone stops propagating and is replaced by failure of fibers at the crack tip. This in turn leads to catastrophic fracture of the composite along the original notch plane. Most notable is the fact that an H-shaped shear zone is created prior to crack extension, which is absent during propagation of the crack. The crack extension is not self-similar. A similar type of damage zone and crack extension has also been observed in glass- fiber-reinforced epoxy composites (Ref 69).

In the previous type of deformation mode, the effective toughening is extremely high, because the blunted, deflected crack tip attenuates the stress ahead of the crack tip over a distance of the order of the crack tip opening displacement. For crack lengths of a few millimeters or longer, toughness values of 100 MPa $\sqrt{m}$(91 ksi $\sqrt{in.}$) have been realized for the boron aluminum system. The effect is reduced for a smaller crack length and approaches approximately 30 MPa $\sqrt{m}$(27 ksi $\sqrt{in.}$) at a crack length less than 0.5 mm (0.02 in.). Thus, fracture toughness may not be the appropriate parameter for predicting failure in these systems, which do not obey self-similar crack growth. In Ref 66, an attempt was made to estimate the onset of fracture with H-shaped cracks, based on the attainment of a critical strain in the fiber direction a distance of over two fiber diameter (2*a*) ahead of the crack tip. It was found that the local strain in the representative volume element for specimens

with different notch lengths all fell in the error band for the failure strain of unnotched composites. The following set of equations may be used to estimate the failure load, P_{ult}, for a center-cracked panel of width W and crack length $2a$ (Ref 70) and possessing an unnotched strength, $\sigma_{unnotched}$:

$$\frac{P_{ult}}{\left(1-\frac{2a}{W}\right)}+2\frac{\tau^*}{\pi(a_2-a_1)}\left[-a_1^2 Ln\left(\frac{1+\sqrt{1+a_2^2\beta^2}}{a_1\beta}\right)+a_2^2 Ln\left(\frac{1+\sqrt{1+a_2^2\beta^2}}{a_2\beta}\right)\right]=\sigma_{unnotched} \quad \text{(Eq 31)}$$

where

$$a_{1,2}^2=\frac{E_1}{2G_{12}}-\nu_{12}\pm\sqrt{\left(\frac{E_1}{2G_{12}}-\nu_{12}\right)^2-\frac{E_1}{E_2}} \quad \text{(Eq 32)}$$

and where + is for a_1^2 and – is for a_2^2, and

$$b\approx d\left(\frac{2\pi}{3\sqrt{3}\ c}\right)^{1/2} \qquad \beta=\frac{aP_{ult}}{b\tau^*}$$

Here, d is the fiber diameter, c is the volume fraction of fibers, τ^* is the in-plane shear strength of the unidirectional composite in the fiber direction, E_1 is the modulus in the fiber direction, E_2 in the transverse direction, G_{12} is the shear modulus, ν_{12} is the Poisson's ratio, and b is of the order of distance between two adjacent fibers.

When the matrix strength or the fiber volume fraction is high, the dominant damage mode is fiber fragmentation in the zone of intense matrix plastic deformation near the crack tip and ultimately, composite fracture. In order to predict the fracture toughness, some estimate of the flow stress and the critical displacement is needed. This was modeled in Ref 71 and 72 by considering that the periphery of fractured fiber tips acts as the nucleation center from which intense matrix plasticity develops. This is a form of macroscopic void growth, at a length scale that is significantly larger than the distance between intermetallic particles, which act as the void nucleation site for fracture of monolithic metallic alloys. The following estimated toughness (J_{Ic} is obtained (Ref 71):

$$J_{Ic}\approx\frac{1}{\sqrt{3}}\ (1-V_f)\sigma_Y L_D \quad \text{(Eq 33)}$$

where

$$L_D\approx\beta_n d\frac{(1-\sqrt{V_f})}{\sqrt{V_f}} \quad \text{(Eq 34)}$$

and β_n is approximately 2. Here d is the diameter of the fiber, V_f is the volume fraction of fibers, and σ_Y is the yield stress of the matrix.

Very few experiments have been conducted on the fracture toughness of titanium-matrix composites. In Ref 73, a toughness of approximately 71 kJ/m^2 (4900 ft · lbf/ft^2) was reported for a SiC-Ti alloy, which may be compared with a typical toughness of 40 kJ/m^2 (2700 ft · lbf/ft^2), based on K_{Ic} = 70 MPa $\sqrt{m}$(64 ksi $\sqrt{in.}$) for monolithic Ti-6Al-4V alloy. Using Eq 33 with σ_Y = 1040 MPa (150 ksi), V_f= 0.32, and d = 100 μm, a toughness value of 63 kJ/m^2 (4.3 ft · lbf/ft^2) is estimated, which compares reasonably well with the experimental data.

It is useful to note that J_{Ic} predicted by Eq 33 and 34 is quite strongly dependent on the volume fraction of fibers. Thus, $(1 - V_f) \cdot (1 - \sqrt{V_f})/\sqrt{V_f}$ decreases from approximately 0.59 to 0.12 on increasing V_f from 0.3 to 0.6. High-volume-fraction alumina/aluminum composites are currently being developed for a variety of applications, such as high-tension electrical cables and piston rods. Because of the lower strength of the alloy and the high volume fraction of alumina fibers, toughness values significantly less than titanium-matrix composites are anticipated.

A final note is in order regarding the role of the fiber-matrix interface. Equation 33 shows that the toughness is an increasing function of L_D. Weak interfaces would permit greater fiber- matrix sliding, thereby increasing the fracture toughness. This effect was elegantly used in Ref 74 to toughen aluminum-based composites while maintaining acceptable transverse strengths. In SiC-reinforced titanium-matrix composites pullout lengths are typically less than one fiber diameter, even for weak carbon-based interfaces. This is largely because of the high radial compressive stress that is generated at the fiber-matrix interface at the tip of a cracked fiber. For strong interfaces, such as those formed without a carbon layer on the SiC monofilaments, the pullout length will be even shorter. However, the effect of a smaller L_D may be balanced by a higher flow stress associated with constrained yielding of the matrix in the fragmentation zone. Tensile tests on unnotched SiC-Ti-matrix composites with different interfaces indicate correlated fiber fractures, independent of the type of interface. Slip band observations and ultrasonic images of fiber breaks confirm that correlated fractures are a result of slip band interactions. A slip band impinging on a fiber localizes sufficient strain to fracture that fiber (Ref 49). Similar experiments have to be conducted with notched composites to provide an assessment of the role of interface strength on the toughness of composites with high matrix strength.

Discontinuously Reinforced Composites. Hahn and Rosenfield's ductile fracture model (Ref 75) is by far the most commonly used model for particulate MMCs. Assuming that crack growth will occur if the extent of heavily deformed zone ahead of crack tip becomes comparable to the width of the unbroken ligaments separating cracked particles, the fracture toughness can be expressed as:

$$K_{\mathrm{Ic}} = \left[2\sigma_y E \left(\frac{\pi}{6} \right)^{1/3} d \right]^{1/2} V_p^{-1/6} \quad \text{(Eq 35)}$$

where K_{Ic} is the critical value of the stress-intensity factor, V_p is the volume fraction of particulates, d is the particle diameter, E is the composite modulus, and σ_y is the yield strength of the composite. A key validation point for the model was the $V_p^{-1/6}$ dependence observed in a number of monolithic aluminum alloys. A slight modification of the model was made in Ref 76 to account for the observed effect of specimen thickness on the fracture toughness of the material.

The main problem with Eq 35 is that it shows an increasing toughness with yield strength, σ_y, whereas the reverse is normally observed. A summary of toughness data with comparisons to models can be found in Ref 77. From a microstructural perspective, a higher strength is usually accompanied by concentrated and localized slip bands, which accelerates the initiation of microvoids in those bands. Mechanically, a higher strength is accompanied with a reduction in the work-hardening exponent, *N*. This effect was accounted for in the model of Garrett and Knott (Ref 78), which was essentially based on an earlier paper of Hahn and Rosenfield (Ref 79). The following equation was obtained in Ref 78:

$$K_{\mathrm{Ic}} = N \sqrt{\frac{2EC\varepsilon_c^{*}\sigma_y}{(1-\nu^2)}} \quad \text{(Eq 36)}$$

Typical values of the parameters were C = 0.025 m and ϵ_c^{*}= 0.1.

This form does indeed show the correct inverse dependence of toughness on strength, because *N* generally decreases sharply with increasing strength. However, the problem with the analysis is that the results of Ref 80 illustrate that local strains along any orientation θ (measured with respect to crack plane) are extremely insensitive to the material parameters, rather than the strong *N* dependence that was assumed in Ref 78 and 79. A recent discussion on these models, in the context of the micromechanisms of fracture, is provided in Ref 37. This reference also presents an alternate model, based on localized slip, to explain the large decrease in toughness in the peak-aged condition of DRAs. Although reasonably good agreement was found with limited experimental data, further validation of the model is necessary.

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

Introduction

ONE OF THE KEY ATTRIBUTES of continuous fiber-reinforced ceramic composites (CFCCs) is their ability to undergo inelastic straining upon mechanical loading (Ref 1). The mechanisms for these strains involve matrix cracking and debonding and sliding along the fiber–matrix interfaces. The inelastic strains impart a high toughness to CFCCs in essentially the same manner that dislocation plasticity imparts high toughness to metallic alloys. That is, the inelasticity reduces the local levels of stress around strain-concentrating features, such as cracks and notches, and hence increases the level of applied stress necessary to initiate fiber fracture at the crack tip. This phenomenon is referred to as *plastic shielding*. An additional attribute of CFCCs is the stochastic nature of fiber fracture within the composite. A consequence is that fiber failure occurs over a range of locations relative to the macroscopic crack plane. The subsequent *pullout* of broken fibers leads to additional shielding of the crack tip.

From a macroscopic viewpoint, the fracture properties of CFCCs differ from those of metals in three important respects, as listed in Table 1. These differences provide the impetus and the directions for modifying existing methodologies for damage-tolerant failure prediction (currently used for metallic components) such that they can be applied to CFCC components.

Table 1 Macroscopic differences in fracture properties of CFCCs and metals

Characteristic	**CFCC**	**Metal**	Consequence
Failure strains	The magnitude of the total straining capacity of CFCCs is limited to values of ≈1%.	In metallic alloys, failure strains in the range of 10–50% are common.	**These differences have implications in the efficacy of plastic shielding in the two classes of materials.**
Nonlinear behavior	Because the mechanism of inelasticity in CFCCs involves cracking, the process is driven	Plasticity in metals is driven by the deviatoric component [(a)] of the stress state and is	**The constitutive laws for the mechanical response of metals and CFCCs in the**

	largely by normal (tensile) stresses.	essentially independent of the hydrostatic stress.	**nonlinear regime are fundamentally different from one another. A related feature is the mechanical anisotropy of CFCCs with most common (two dimensional) fiber architectures.**
Fracture resistance	**The increase in fracture resistance due to fiber pullout is typically much greater than the intrinsic composite toughness (in the absence of bridging). Additionally, the amount of crack growth needed to attain a steady-state resistance is typically of the same order as the dimensions of CFCC coupons or components of interest.**	**Fracture resistance is dictated largely by the behavior of an enclave of heavily deformed material at the crack tip. In most cases of practical interest, this enclave is very small in relation to other structural dimensions, and thus a *small-scale yielding* (SSY) treatment is adequate. The problem of *large-scale yielding* (LSY) arises in very tough metals, especially under plane-stress conditions.**	**A *large-scale bridging* (LSB) mechanics is needed to describe the structural response in CFCCs, including the conditions associated with crack stability.**

(a) The stress component that is related to the difference in the stress and the mean stress. The hydrostatic stress is the mean stress. This terminology is used in modeling the observation that plastic deformation is a shear phenomena and not dependent on hydrostatic stress.

Some trends in the degree of damage tolerance, as manifested in the notch sensitivity of strength, are highlighted in Fig. 1, based on Ref 2, 3, 4, and 5. Results are presented for the net-section tensile strength, σ_N, of open-hole specimens for typical metals, CFCCs, and polymer-matrix composites (PMCs), all with the same normalized hole radius, a/w = 0.2. The metals listed exhibit no notch sensitivity for hole diameters approaching 10 mm (0.4 in.). This behavior is attributable to the extensive plasticity that occurs across the entire net section prior to fracture and the effects of this plasticity on reducing the stress concentration at the hole edge. At the other extreme, PMCs exhibit severe notch sensitivity. The strength diminishes rapidly with increasing hole diameter and eventually approaches the value predicted from the elastic stress concentration factor, k_σ. This notch sensitivity is largely a consequence of the absence of inelastic straining mechanisms in these composites. Continuous fiber-reinforced ceramic composites with high toughness exhibit intermediate behavior in the sense that their strength diminishes gradually with hole diameter and appears to saturate at a relatively high value, typically 70% of the unnotched strength.

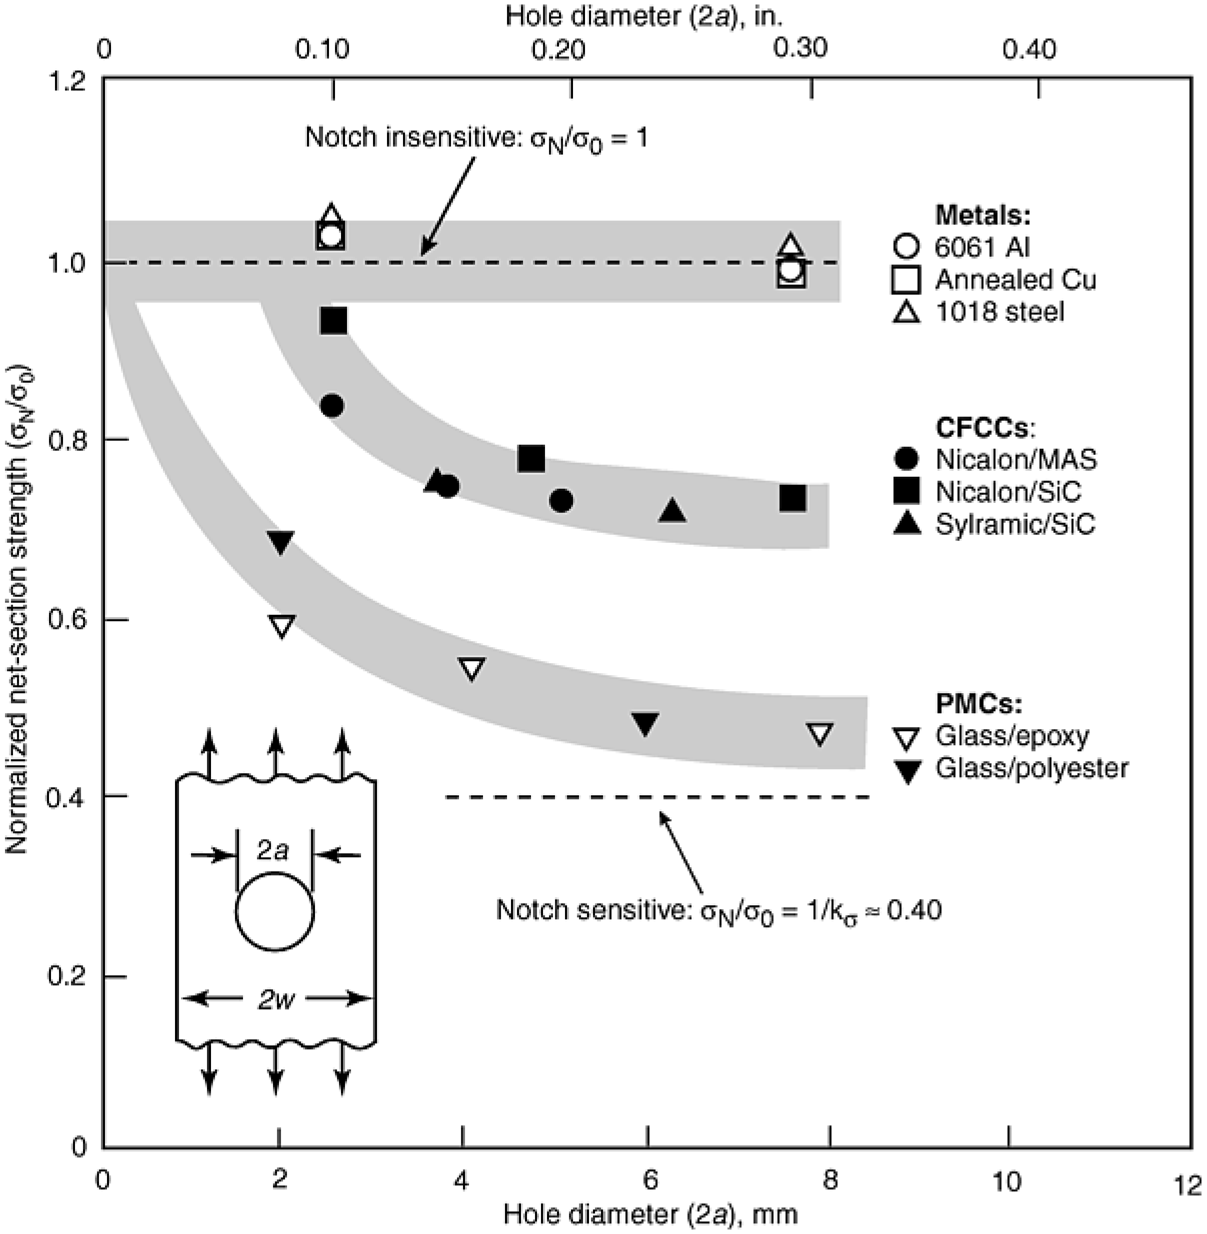

Fig. 1 Notch sensitivity. Effects of hole diameter on the tensile strength of metals, CFCCs (Ref 2, 3), and polymer-matrix composites (PMCs) (Ref 4, 5). The data are presented on the basis of the net-section strength, σ_N, normalized by the respective unnotched tensile strength, σ_0. The composites have two-dimensional (2D) fiber architectures (either laminated or woven), and the loads are applied parallel to one of the fiber axes. In all cases, the normalized hole diameter is a/w = 0.2. The lower limit on the notched strength is given by $1/k_\sigma$, where k_σ is the elastic stress concentration factor. Data on metals courtesy of J.C. McNulty, University of California, Santa Barbara

The objective of this article is to review the mechanics of inelastic deformation and fracture of CFCCs, as needed for the development of damage-tolerant failure prediction methodologies for use in engineering design. An underlying theme pertains to the anisotropy in their mechanical properties and its effect on notch sensitivity of strength. The scope of the article is restricted to CFCCs with balanced 0°/90° fiber architectures, because of the emphasis on these architectures within the CFCC community.

Many of the concepts and models described here have been adapted from analogous problems in monolithic materials. Notable examples include: models of stress redistribution around strain concentrations due to inelastic straining; fracture resistance curves and the conditions associated with crack stability; cohesive or bridging zone concepts; and effects of material and structural size scales, leading to large scale bridging (LSB) or large scale yielding (LSY). Such connections are noted where appropriate.

The coverage in this article is organized as follows:

- A general framework for damage-tolerant design with structural materials is outlined. The framework identifies two broad classes of phenomena that are obtained in such materials: *crack-tip inelasticity* prior to the onset of fracture initiation, and *crack bridging* during crack propagation.
- The common classes of fracture behavior of CFCCs are described. The classification system provides a rationale for selecting the pertinent features and mechanisms into the failure prediction methodology.
- The constitutive laws needed to describe crack-tip inelasticity are presented.
- The stress distribution section demonstrates the effects of inelasticity on crack-tip stress fields.
- Models for crack initiation are discussed.
- Crack propagation models are derived.
- Environmental degradation effects on damage tolerance are addressed.

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

General Framework for Fracture Analysis

It is instructive to begin by outlining a general framework for the description of fracture in structural materials in the presence of notches and cracks. There are two broad categories of phenomena (Fig. 2). The first involves *local inelastic straining* in the material surrounding the crack tip, which reduces the intensity of the stress singularity. Inelastic straining can occur by one of numerous mechanisms, including dislocation glide in metallic alloys, distributed microcracking in two-phase ceramics with large internal stresses, stress-induced phase transformations in stabilized zirconia alloys, and matrix cracking and interface sliding in CFCCs. The magnitude of the shielding effect can be computed using standard finite-element methods, provided suitable constitutive laws for the inelasticity are available.

The second category of phenomena pertains to the *fracture process zone* (FPZ). The FPZ represents the region directly ahead of the crack within which the strains become highly localized and lead to the initiation and propagation of a macroscopic crack. Generally, fracture initiation is stochastic when it involves fracture of brittle constituents. Indeed, stochastic behavior is obtained in CFCCs as well as in fiber-reinforced polymer-matrix composites. Following fracture initiation, the mechanical response of the material in the crack wake is characterized by a bridging traction law, as shown schematically in Fig. 2. Of the two steps in the fracture process, fracture initiation and crack propagation, the one requiring the higher stress dictates the notched strength.

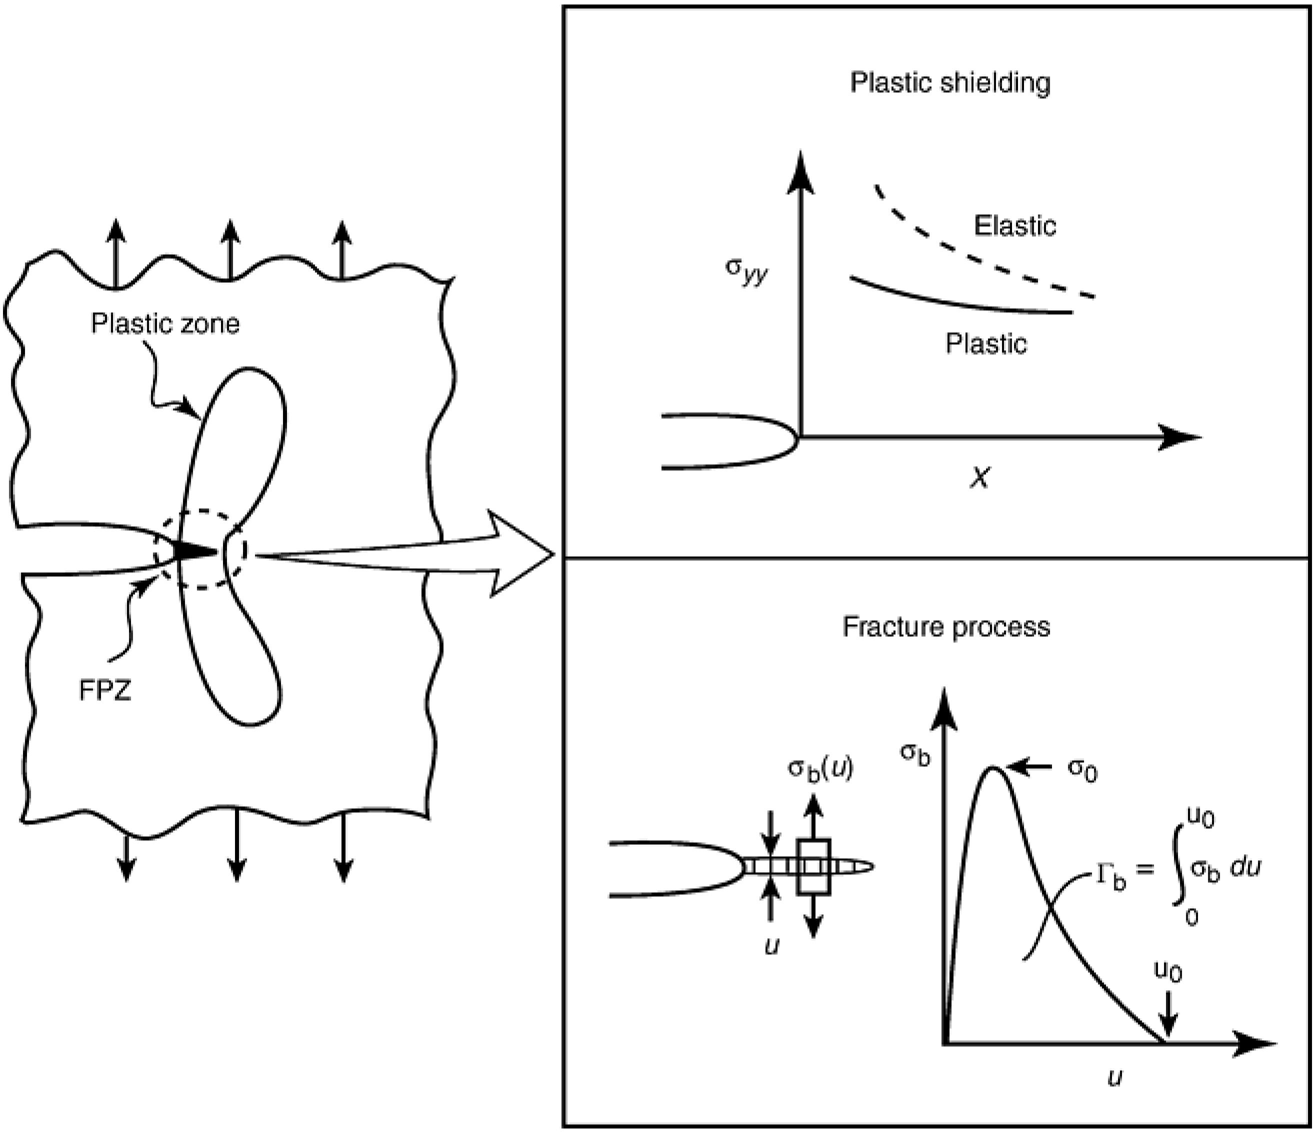

Fig. 2 The effects of inelasticity on the crack-tip stresses and the characterization of the fracture process zone (FPZ) through a bridging traction law. Here Γ_b is the steady-state toughness of the FPZ, independent of plastic shielding.

This framework for fracture analysis has been used successfully in the context of numerous fracture mechanisms, including ductile rupture of metals, cleavage of inhomogeneous alloys, such as steels (Ref 6), and fracture along bimaterial interfaces (Ref 7). It is anticipated that the framework will be implemented by the CFCC design community once an understanding of the features specific to CFCCs reaches a suitably mature level. The remainder of this chapter focuses on the features needed for this implementation.

Classes of Material Behavior

Continuous fiber-reinforced ceramic composites exhibit one of three broad classes of deformation and fracture behaviors, designated class I, II, and III (Ref 8). The key features associated with each are shown schematically in Fig. 3. In CFCCs with 0°/90° fiber architectures, these behaviors are elicited by performing tension tests both with and without notches in two orientations: with the loading direction parallel to one of the two fiber axes, denoted the 0°/90° orientation; and with the loading direction oriented at ± 45° to the fiber axes.

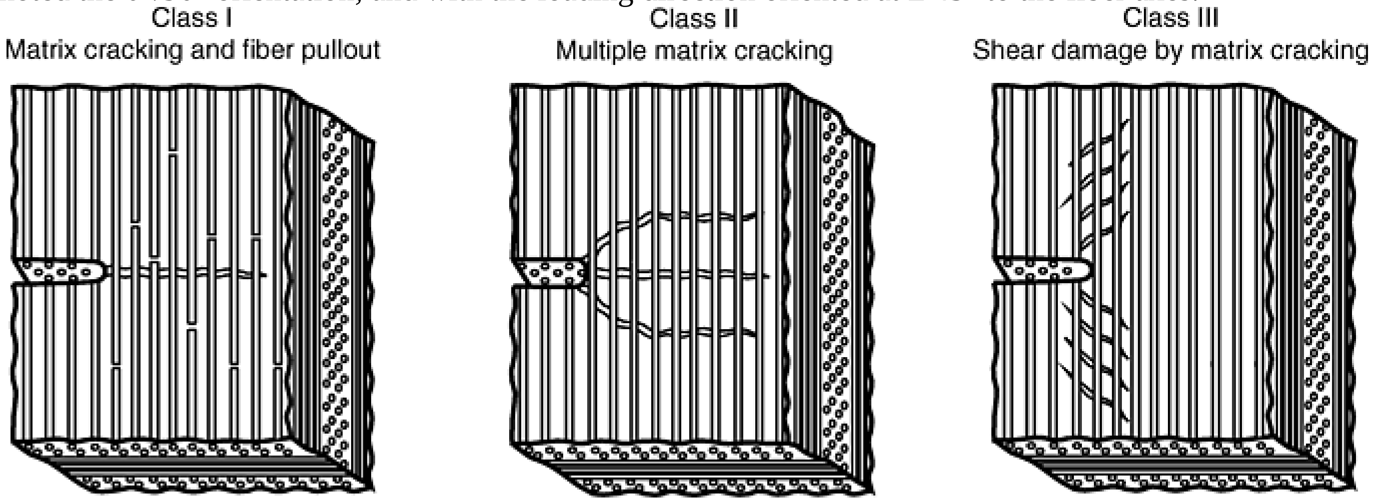

Fig. 3 The three common classes of fracture behavior in CFCCs. Source: Adapted from Ref 8

Class I behavior is characterized by the propagation of a dominant matrix crack, accompanied by fiber pullout, but with otherwise negligible inelastic deformation. This behavior is obtained in materials with unusually high interfacial toughness and/or sliding resistance (as a consequence of oxidation of the fiber–matrix interfaces, for example) and yields relatively damage-intolerant behavior. Fiber pullout is manifested in the form of a *rising fracture resistance curve* (so-called *R*-curve). The fracture resistance starts at a value comparable to the fracture toughness of the matrix and increases with crack growth as the bridging zone develops. Once the broken fibers at the point furthest from the crack tip completely disengage from their respective matrix sockets, a steady-state fracture resistance is obtained. Because of the large length scales associated with the bridging, the extent of crack growth needed to attain steady state is rather large, typically approximately 10 to 100 mm (0.4 to 4 in.). An implication is that extremely large test specimens, on the order of 1 m (40 in.), are needed to obtain *small-scale bridging* (SSB) conditions and hence extract in a direct manner the intrinsic fracture resistance curve. In smaller test specimens and structures, the fracture resistance curve is influenced by structural dimensions. The connections between the macroscopic structural response and the fundamental parameters dictating the pullout process are made through a LSB mechanics (Ref 9). Some typical experimental results for the fracture resistance behavior of a class I material are shown in Fig. 4. For comparison, predictions based on both LSB and SSB models, described subsequently, are shown also.

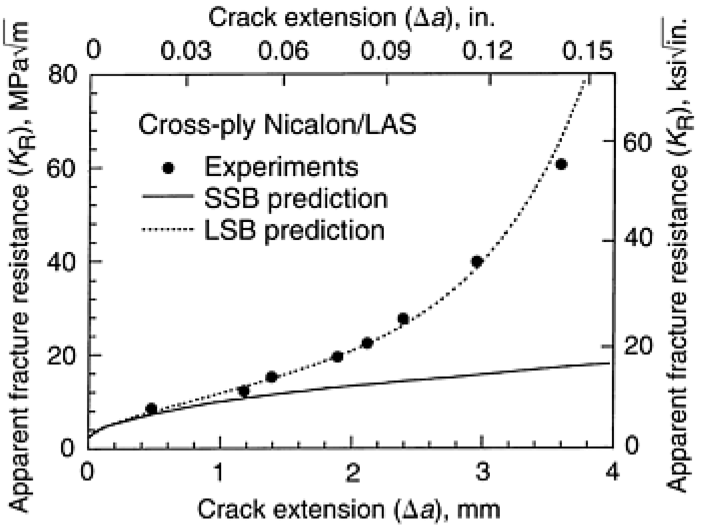

Fig. 4 Fracture resistance curve for a Nicalon/LAS (Li_2O-Al_2O_3-SiO_2) composite that had been subjected to an embrittling heat treatment in air of 16 h at 800 °C (1470 °F). Upon heat treatment, the carbon coating on the fibers is replaced with an oxide layer that inhibits interfacial debonding and sliding. The solid line shows a LSB prediction, based on a linear softening traction law (Eq 4). The bridging parameters are: τ = 270 MPa (39 ksi), E = 150 GPa (22 × 10^6 psi), ν = 0.25, h = 11 μm (4.33 × 10^{-6} in.), f_0 = 0.22, and R = 7 μm (2.75 × 10^{-6} in.); the initiation toughness is K_0 = 2 MPa $\sqrt{\mathrm{m}}(1.8\ \mathrm{ksi}\sqrt{\mathrm{in.}})$. The dashed line shows the corresponding SSB prediction for the same bridging parameters. Source: Adapted from Ref 10

Class II behavior is characterized by the formation of *multiple* matrix cracks in both 0°/90° and ±45° orientations, initially with negligible fiber fracture. The cracks are manifested macroscopically as inelastic strain. Some results for a Nicalon/SiC composite are shown in Fig. 5(a). The inelasticity serves to redistribute the stresses in notched specimens, such that the peak stress concentration is reduced from its initial (elastic) value. Once fiber fracture begins, the subsequent pullout leads to *R*-curve behavior in essentially the same manner as in class I materials; the main difference is that the extent of pullout in class II materials is greater than it is in class I materials, because the interfaces are weaker and hence the lengths over which debonding and sliding occur are greater. The combined effects of plastic shielding and fiber pullout lead to highly damage-tolerant and notch-insensitive fracture behavior. Large-scale bridging models can be used to simulate the fracture resistance behavior, although complications exist with regard to the coupled effects of the bridging and the inelastic straining.

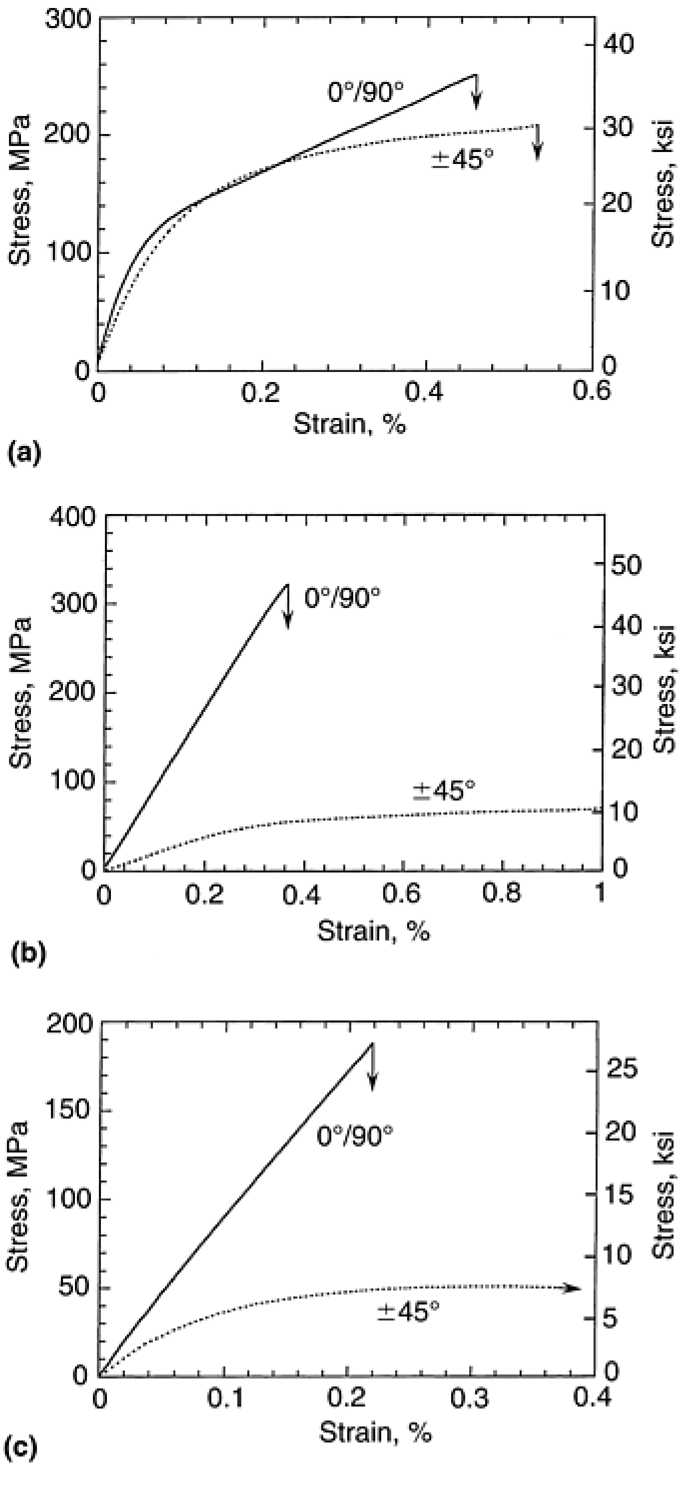

Fig. 5 Stress–strain behaviors of 2-D woven composites in 0°/90° and ±45° orientations (a) Nicalon/SiC (plain weave fabric). Source: Ref 11. (b) Carbon-carbon (plain weave). Source: Ref 13. (c) Al_2O_3/mullite (eight-harness satin weave). Source: Ref 14

Class III behavior materials exhibit essentially linear behavior up to fracture in the 0°/90° orientation, but significant inelasticity in the ±45° orientation. This behavior is obtained in CFCCs in which the matrix modulus is much lower than that of the fibers. In 0°/90° orientations, the contribution of the matrix to the initial elastic modulus of the composite is small, and hence any subsequent matrix damage has little effect on the composite response. In some cases, the low matrix modulus arises from the presence of a high level of matrix porosity, introduced intentionally to impart high damage tolerance in the absence of weak fiber coatings (Ref 12). In others, it is a consequence of the high density of matrix cracks and fine-scale porosity resulting from the constrained pyrolysis and densification of the matrix precursor material (Ref 13). In the ±45° orientation, the matrix modulus plays a more significant role in the initial elastic response, and hence the matrix damage that occurs as a consequence of loading is manifested in significant inelasticity. An example of this anisotropic

behavior in a carbon-carbon (C-C) and an all-oxide CFCC are shown in Fig. 5(b) and (c). In notched geometries in the 0°/90° orientation, the inelasticity occurs in the form of long, slender shear bands aligned parallel to the loading direction. This deformation can reduce the stress concentration by a modest amount in some cases, although the efficacy of this deformation is considerably lower than that in class II materials, as demonstrated in the section "Stress Distributions in Notched Specimens" in this article. In other cases, the deformation has the effect of increasing the stress concentration (Ref 15). Fiber pullout and the associated *R*-curve are again obtained during fracture.

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

Constitutive Laws for Inelastic Straining

The micromechanics of matrix cracking, interface debonding and sliding, and their roles in the macroscopic stress–strain response are very well understood. Indeed, there exists a vast scientific literature dealing with this class of problems (see, for example, Ref 16, 17, and 18). Despite their large collective volume, most papers are restricted to unidirectionally-reinforced composites, subject to uniaxial loadings parallel to the fibers. Some have dealt with 2-D cross-ply and woven architectures, but again, subject to uniaxial loading along one of the fiber axes. Although these studies have yielded important insights into the mechanisms and mechanics of failure in CFCCs, they have not lead directly to the development of tools that are amenable for use in structural analysis, especially when off- axis and/or multitiaxial stresses are present.

With this recognition, two independent groups recently have developed engineering approaches to describe the inelasticity of CFCCs, specifically for use in structural analysis. The key papers were published almost simultaneously in 1997 (Ref 15, 19). Although the details of the two approaches differ considerably, both contain three key features:

- They faithfully (albeit approximately) represent the material behavior under *multiaxial* stress states.
- They can be implemented readily into finite- element codes that are used commonly in engineering design.
- They can be calibrated using a small number of standard mechanical tests.

Both approaches are based on a homogenized representation of the composite without an explicit dependence on the fiber architecture or the size scale of the microstructure, except insofar as these features influence the macroscopic properties obtained from the mechanical tests used for calibration and the macroscopic material symmetry. Preliminary assessments of their capabilities and use in engineering design have been encouraging. Selection of one over the other will be based ultimately on trade-offs between the level of complexity and the level of effort required for their calibration and implementation. The extent to which they explicitly incorporate the damage mechanisms and associated micromechanics also may have some bearing on the selection process, although the criticality of this feature in engineering design has yet to be established.

BHL Approach. The first approach, developed by Burr, Hild, and Leckie (Ref 19) and subsequently referred to as BHL, is couched in terms of continuum damage mechanics. To begin, the physical internal variables that characterize the damage state are identified. For 2-D laminates or weaves under biaxial stressing, ten internal variables are needed to fully characterize the extent of matrix cracking, interfacial sliding, and fiber damage in the two-ply types. State potentials are then derived in terms of the state variables. The derivations of these potentials are guided closely by micromechanical models of matrix cracking and interface sliding. The potentials are then used in a framework of irreversible thermodynamics to obtain the forces driving each of the damage mechanisms. The growth laws for each of the state variables are calibrated by performing uniaxial tension tests in both the 0°/90° and ±45° orientations along with periodic unloading-reloading excursions to measure hysteresis. The behavior of the composite in other loading directions or under multiaxial loading is obtained through an interpolation procedure. The behavior upon unloading also can be obtained. Once calibrated, the constitutive law can be implemented into a finite element code as a user material subroutine.

GH Approach. The second approach, developed by Genin and Hutchinson (Ref 15) and subsequently referred to as GH, is based on a purely phenomenological representation of the stress- strain response of a CFCC along the directions that coincide with the material symmetry: 0°/90° and ±45° for balanced 2-D laminates and weaves. It begins by partitioning the two in- plane strains for principal stressing in the 0°/90° orientation into two functions, with each function being dependent on only one of the two principal stresses. Similar partitioning is invoked for principal stressing in the ±45° orientation, yielding two additional strain functions. Because the principal axes are indeterminate for equibiaxial loading, the strain functions obtained from principal stressing in the 0°/90° must match those obtained for principal stressing in the ±45° orientation. The latter requirement reduces the number of independent functions to three. The nonlinearity in these functions is couched in terms of "stress deficits," defined as the difference between the elastic stress that would exist at a prescribed strain and the one actually obtained. For other stress states, where the principal stress directions are at an arbitrary angle to the fiber axes, the stress deficits are obtained using an interpolation procedure. A summary of this procedure is given in the Appendix of this chapter. The constitutive law is calibrated through monotonic tension tests in the 0°/90° and ±45° orientations; no unload-reload excursions are required. The calibrated constitutive law is implemented into a finite-element code as a user material subroutine, similar to that of the BHL constitutive law. The GH law has the advantage of being somewhat easier to calibrate and implement; for balanced 2-D laminates, it requires only three independent strain functions, whereas the BHL law requires calibration of ten state functions.

Validation of the BHL and GH constitutive laws has been accomplished by performing tests other than those used for their calibrations and comparing the measured responses with the predicted ones. Two test types have been used. The first is the Iosipescu test, which is used to measure the response in pure shear parallel to the fibers. Comparisons between the BHL law and measurements made on a woven Nicalon/SiC composite are shown in Fig. 6. The agreement between theory and experiment is good (within about 5%). Similarly good agreement has been obtained between the predictions of the GH law and pure shear measurements made on a 0°/90° Nicalon/CAS ($CaO-Al_2O_3-SiO_2$) laminate (Ref 15). The second test geometry is an open-hole tensile specimen. Strains are measured at select points around the hole using small, 0.7 mm (0.025 in.), strain gages. Comparisons between these types of measurements on a 0°/90° Nicalon/MAS ($MgO-Al_2O_3-SiO_2$) laminate and those predicted by the GH law are presented in Fig. 7. Again, the agreement is very good, thereby providing additional confidence in the predictive capability of the constitutive law. A related feature that emerges from the latter experiments is that the local strain at the hole edge (in the region of maximum stress concentration) can attain values that are considerably larger than the unnotched tensile failure strain. This difference highlights the importance of size scale and stress gradient effects in the onset of failure. This issue is addressed further in the section “Fracture Initiation” in this article.

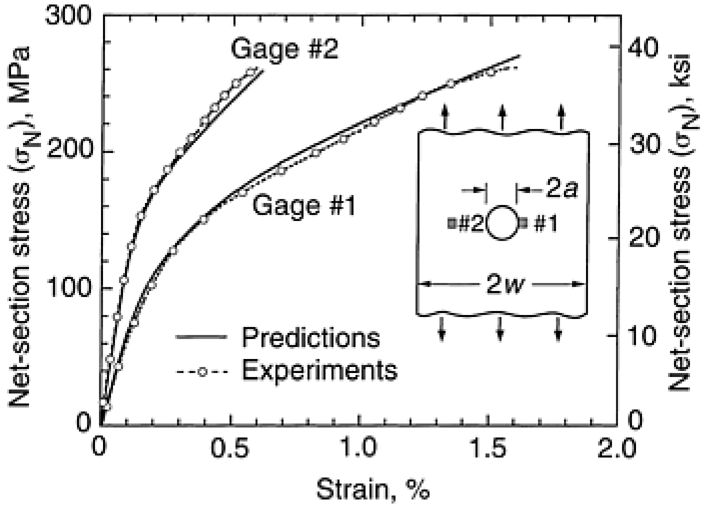

Fig. 7 Comparisons of measured and predicted strains at two locations in an open-hole tensile specimen of a $[0°/90°]_{3s}$ Nicalon/MAS CFCC. The predictions are based on finite-element calculations using the GH constitutive law. Source: Adapted from Ref 2

Binary Model. One of the deficiencies of both the BHL and GH constitutive laws is the absence of an explicit dependence on the fiber architecture and the nonuniformity of the damage at the scale of the fibers and the fiber tows. This deficiency is expected to be important in cases where the stress gradients exist over distances that are comparable to or smaller than the length scales associated with the microstructure. An alternate modeling approach that provides a more rigorous numerical representation of the behavior of the fibers and/or the fiber tows and the intervening matrix is the so-called binary model (Ref 20, 21). The model can be implemented in two ways. In the first, one-dimensional spring elements are used to represent the individual fibers within a tow, and the surrounding matrix is represented by effective medium elements with the appropriate nonlinear behavior. In this implementation, the model is capable of simulating the interactions between fiber fracture events at the *microscale*, thereby providing a critical theoretical link between the properties of the individual fibers and the properties of the fiber *tows*. In the second implementation, spring elements are used to represent the fiber *tows* (rather than the individual fibers) and the surrounding matrix and transverse fiber tows by effective medium elements. In this implementation, the model represents the material behavior at the *mesoscale*, with information from the microscale computations integrated accordingly. The tow properties may encompass nonlinear deformation caused by fiber failure, matrix cracking, and interface sliding within the tow.
The binary model has numerous attractive features:

- It does not rely on periodicity in the fiber architecture.
- It can readily deal with large spatial variations in the stress.

- It can incorporate any arbitrary nonlinear response in the fibers and the matrix as well as statistical strength distributions.
- It can compute stress and strain distributions in the matrix and fiber elements.

It is ideal for capturing the interactions between stress concentration sites, fiber weave patterns, and multiaxial three-dimensional stress states. Generally, however, the model is more computationally intensive than the homogeneous model and does not lend itself to the simulation of full-scale subelements or components. Its role in structural analysis is expected to be limited to the representation and simulation of those material elements within a component that are most critically stressed and are likely to be the sites of component failure. In this context, the binary model would be combined with an appropriate homogenized constitutive law (such as the one of GH or BHL) to perform global/ local analyses, closely analogous to those for textile polymer-matrix composites. (For global/ local approaches to polymer composite structures, see, for example, papers by J.D. Whitcomb, A. Tabiei, and their coworkers). The implementation of this approach awaits further developments in the numerical codes and an assessment of the use of the codes in damage and failure prediction.

Stress Distributions in Notched Specimens

The homogeneous nonlinear constitutive laws can be used to calculate the spatial extent of inelastic straining around notches and holes and to assess the role of this inelasticity in mitigating stress concentrations. The results of some finite- element calculations of the crack-tip stresses and the inelastic zones under SSY conditions are plotted in Fig. 8 and 9. The examples are selected to be representative of the behaviors of class II and class III materials. All calculations are based on the GH model. For the purpose of these calculations, the

in-plane properties of the class II material are assumed to be isotropic. The tensile stress–strain response is taken to bilinear, with the initial moduli $E_0 = E_{45}$. The change in slope occurs at a critical cracking stress, σ_c, and the tangent moduli beyond cracking are $E_0' = E_{45}' = 0.2E_0$. Similar properties are assumed for the class III material, with the exception that the response in the fiber direction is taken to be linear for all stress levels. Two pertinent features emerge:

- The shape of the inelastic zone for the class III material is distinctly elongated along the loading direction, because of the strong anisotropy of the inelasticity. The length of this zone is $\approx 0.1(K/\sigma_c)^2$. Furthermore, there is essentially no inelasticity directly ahead of the crack tip along the incipient fracture plane. By contrast, the inelastic zone in the class II material is essentially equiaxed and of a size $\approx 0.1(K/\sigma_c)^2$.
- The tensile stresses ahead of the crack in the class II material are reduced considerably to about half of the elastic values, over distances that are comparable to the inelastic zone size. Only small reductions in stresses are obtained in the class III material, largely because of the absence of inelasticity ahead of the crack tip. Clearly, the efficacy of the inelasticity in stress redistribution is superior in class II materials.

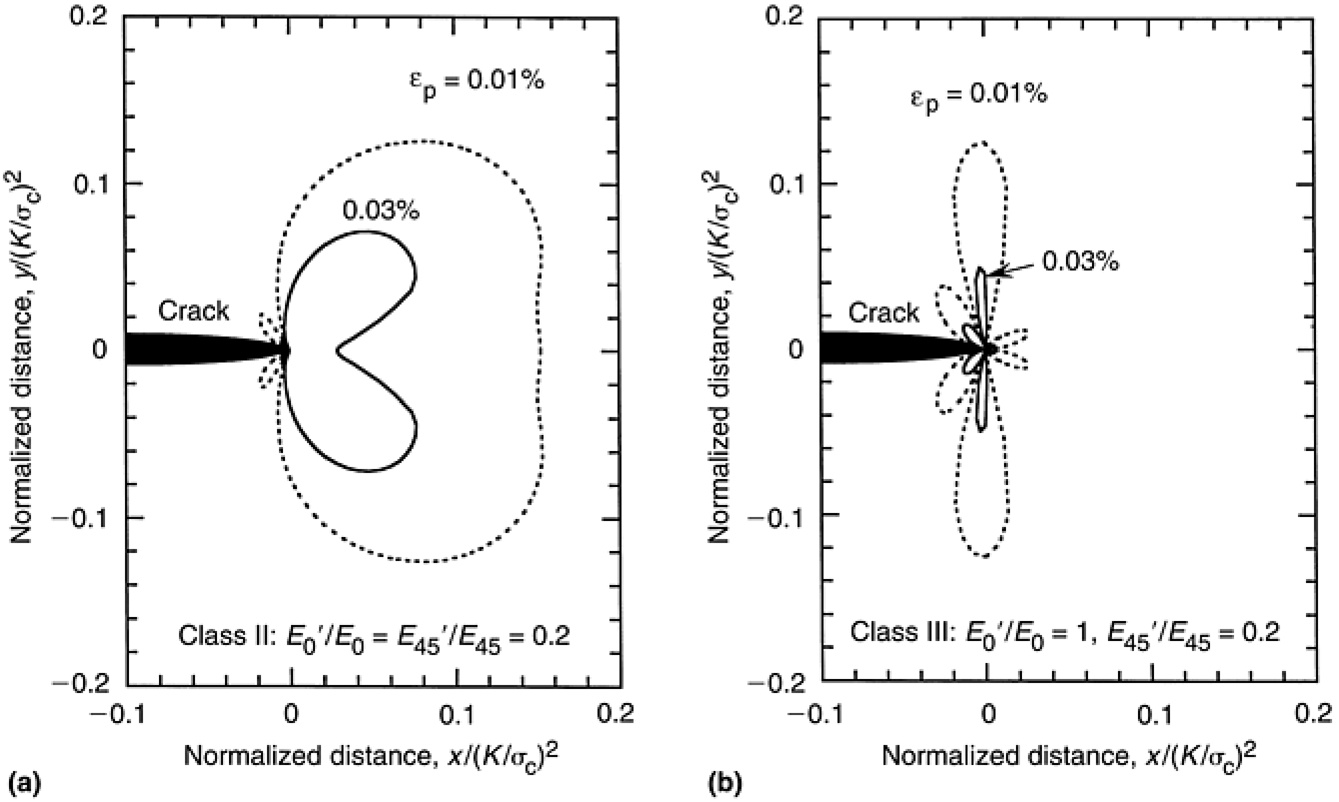

Fig. 8 Inelastic zones around a crack tip under SSY yielding conditions for (a) class II and (b) class III materials. The coordinates *x* and *y* are measured horizontally and vertically, respectively, from the crack tip, and the stresses are applied remotely along the *y*-direction. The effective plastic strain is denoted ϵ_p. The normalizing distance is $(K/\sigma_c)^2$, where *K* is the applied mode I stress-intensity factor and σ_c is the matrix cracking stress. Courtesy M.Y. He, University of California at Santa Barbara

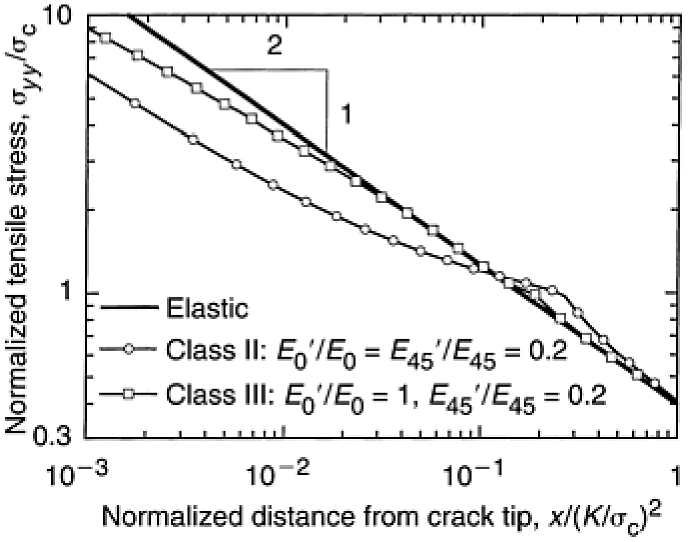

Fig. 9 Stress distribution along the incipient fracture plane, for class II and class III materials as well as in an elastic, isotropic material. The stresses are normalized by the matrix cracking stress, σ_c. The corresponding inelastic zones are plotted in Fig. 8. Courtesy M.Y. He, University of California at Santa Barbara

The reduction in the peak stress concentration due to inelasticity in notched specimens can be determined in an approximate way using the method developed by Neuber (Ref 22). Neuber's rule states that the *stress* and *strain concentration factors*, k_σ and k_ϵ, following the onset of local nonlinear straining are related to the *elastic stress concentration factor*, k_e, through the relation $k_\sigma k_\epsilon = k_e^2$. Neuber demonstrated this relation to be strictly valid for metals subject to antiplane shear loading (Ref 22). Subsequently, the law has been used extensively in predicting stress concentrations in metals for a variety of notch and loading configurations (Ref 23). A graphical representation of Neuber's rule is shown in Fig. 10. From an operational viewpoint, the law is implemented by finding the intersection point between the tensile stress-strain curve and a hyperbola described by $\sigma\epsilon = k_e^2 \sigma_A \epsilon_A$, where σ and ϵ are the local (maximum) stress and strain, and σ_A and ϵ_A are the corresponding applied values. The stress concentration factor, k_σ, is then the ratio of the stress at the intersection point to the applied stress. In applying Neuber's rule to CFCCs subject to remote loading in the 0°/90° orientation, the relevant stress-strain curve is taken to be the one measured in that same orientation.

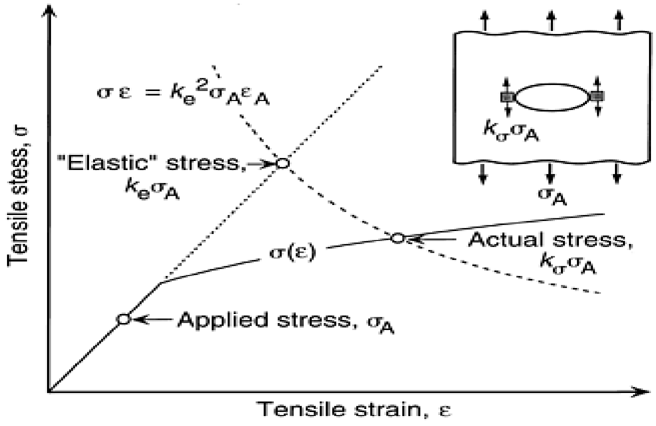

Fig. 10 The procedure used to implement the Neuber law in calculating the stress concentration factor in an elastic-plastic material

Figure 11 shows the stress concentration factors obtained from finite-element calculations for a class II material and those from Neuber's rule for some typical notched geometries. The comparisons indicate that Neuber's rule provides an accurate description of k_σ over a wide range of applied stress and notch shape. The results can be used to estimate the notched strength by combining the stress concentration factor with the measured unnotched tensile strength, assuming the failure criterion to be deterministic. However, as demonstrated in the subsequent section, this approach yields overly conservative estimates of the notched strength and fails to predict size-scale effects. (Similarly conservative estimates are obtained when the stress concentration factors obtained through Neuber's rule are used to predict fatigue lives in notched metal components; empirical methods have been developed to account for these size-scale effects and have found use in fatigue lifing [Ref 23]). Nevertheless, when a conservative design is necessarily required, or as a first step in the design process, this approach is expected to provide some useful guidance.

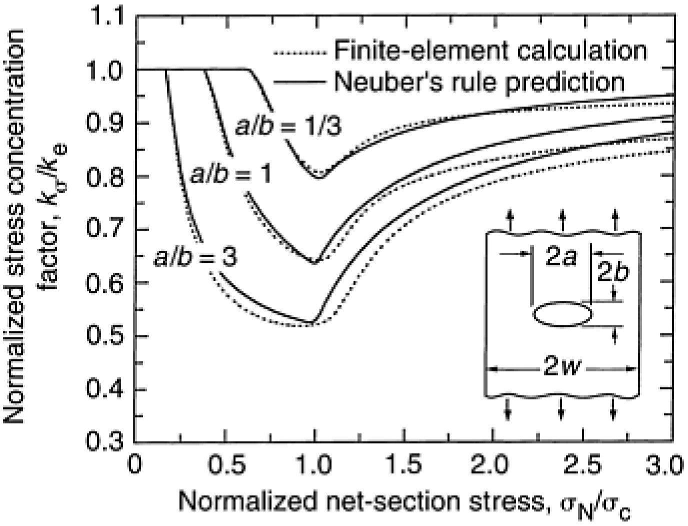

Fig. 11 Effects of inelasticity and notch shape on the stress concentration factors in a class II CFCC. The finite-element results are based on the GH constitutive law, assuming bilinear stress–strain behavior with the parameters shown in the inset of Fig. 8(a). Also shown for comparison are the predictions of the Neuber law. Courtesy X.-Y. Gong, University of California at Santa Barbara

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

Fracture Initiation

Fracture initiation occurs essentially when the peak tensile stress exceeds the fiber bundle strength and the inelastic strains become highly localized in the region of extensive fiber fracture. Experiments on several CFCCs indicate that the conditions for fracture initiation depend on the volume of highly stressed material. Direct evidence of these size effects has come from comparisons of the maximum strains that are attained in test specimens with varying stress gradients. For instance, in the $[0°/90°]_{3s}$ Nicalon/MAS composite, the unnotched tensile failure strain is 1.0%, the tensile failure strain in four-point flexure is ≈1.4%, and the failure strain at the edge of the hole in one a center-hole tensile specimen is ≈1.6% (Ref 2, 24). These measurements are consistent with the expectation that the failure strain increases with decreasing volume of material in the most heavily stressed region of a structure.

The volume-dependence of the fracture initiation condition has been modeled using two approaches. The first is based on the *point-stress failure* criterion. Here, fracture is postulated to initiate when a critical stress (taken to be the unnotched tensile strength) is attained over a characteristic length, *d*, ahead of the notch. This approach is analogous to that used to describe cleavage fracture in ferrous alloys containing carbide particles; in the latter case, the characteristic distance correlates with the particle spacing, and the critical stress is dictated by the particle strength (Ref 6). The procedures for its implementation and assessment include:

- Performing nonlinear finite-element calculations of the stresses around the notches
- Calculating the notched tensile strength using several assumed values of the characteristic distance, *d*
- Making comparisons between the predictions and the experimental data in order to infer the characteristic distance and to check on the consistency in the trends with various structural dimensions and geometric features

Figure 12 shows examples for the Nicalon/ SiC system (Ref 2). The effects of hole diameter, 2*a*, at a constant value of *a/w* (Fig. 12a) and of specimen width at a constant value of hole diameter (Fig. 12b) are captured remarkably well using this approach, when the characteristic distance is selected to be *d* = 0.75 mm (0.030 in.) Furthermore, in situ observations indicate that strain localization does not occur prior to the ultimate strength, confirming that fracture coincides with the initiation event. Similarly good correlations have been obtained for other CFCCs, including Nicalon/MAS (Ref 2), Sylramic/SiC (Ref 3), and Al_2O_3/mullite (Ref 14). Interestingly, the inferred characteristic distances for these CFCCs lie in the rather narrow range of ≈0.50 to 0.75 mm (0.020 to 0.030 in.). This correlation suggests a commonalty in the size- dependence of fiber bundle failure and strain localization; however, quantitative connections between *d* and the size scales in fiber bundle failure have yet to be established. Nevertheless, the narrowness of the inferred range of *d* suggests that the approach is quite robust and probably applicable to other CFCCs of interest. From an engineering viewpoint, it has the further advantage of being relatively easy to implement and use. Its main deficiency is in the lack of a sound physical basis.

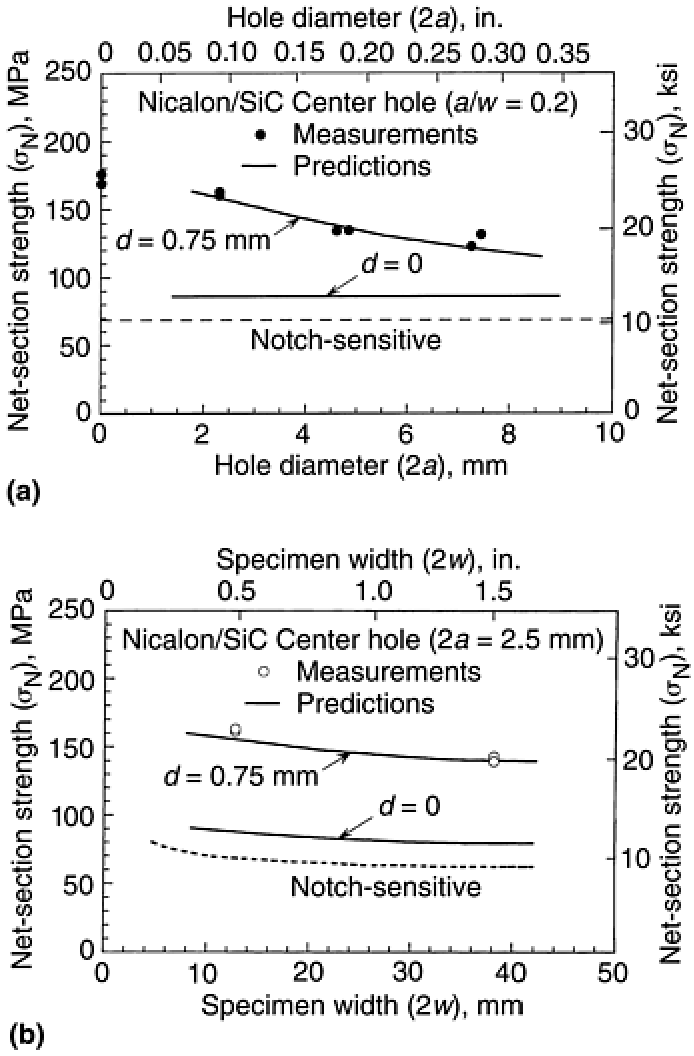

Fig. 12 Comparisons of measured strengths with predictions based on the point-stress failure criterion. The dashed lines show predictions based on the elastic stress concentration factor and the unnotched tensile strength. Hole is centered. *d* is the characteristic distance. (a) Hole-to-width ratio is constant. (b) Hole diameter is constant, 2*a*= 2.5 mm (0.098 in.), as width varies. Source: Adapted from Ref 2

To further illustrate the size effect, Fig. 12 also shows notched strength predictions stemming from a deterministic (size-independent) failure criterion (labeled $d = 0$). This prediction is based on the assumption that failure occurs when the maximum tensile stress (at the hole edge) reaches the unnotched tensile strength. These predictions strongly underestimate the measured notched strengths and fail to correctly predict the size-scale effects that are found experimentally.

An alternate approach to modeling fracture initiation is based on the premise that the composite strength is probabilistic and follows *weakest-link fracture statistics*. Figure 13 shows the results of a preliminary attempt to assess the probabilistic approach in failure prediction of a Nicalon/SiC CFCC. The predictions are based on finite-element calculations of the stresses in the notched specimens using the GH constitutive law and assuming that the composite strength distribution follows the Weibull function. The comparisons suggest that the composite Weibull modulus is $m = 15\pm5$, which is significantly higher than that of the fibers alone ($m\approx 3$–5). This approach is expected to be more robust than the point-stress failure criterion, because it has a stronger mechanistic basis, but is more cumbersome to implement. Furthermore, issues pertaining to the nature and the size of strength-limiting flaws in CFCCs and the broad applicability of weakest-link scaling approaches have yet to be addressed. For instance, the critical “flaw” that leads to fracture in CFCCs is not preexisting (as it is in monolithic ceramics), but rather “evolves” during the straining process and comprises clusters of numerous broken fibers. The size of these clusters dictates the minimum volume that can be used when applying weakest-link scaling laws at the macroscopic level (Ref 25). The binary model, which is described in the section

"Constitutive Laws for Inelastic Straining" in this article, is expected to be well suited to addressing these issues.

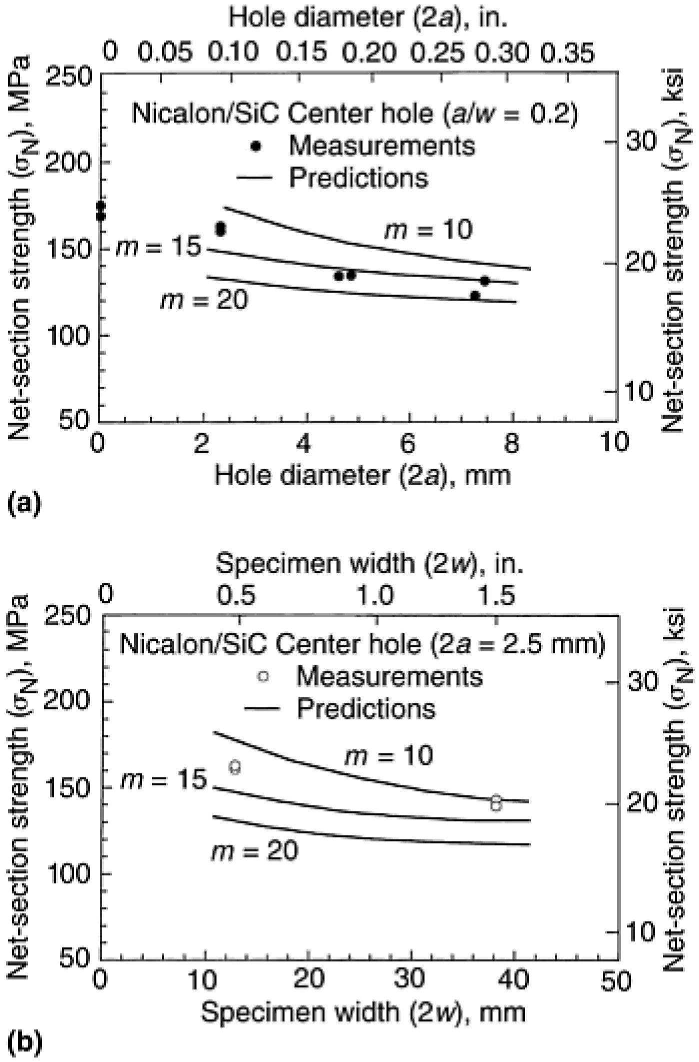

Fig. 13 Comparisons of measured strengths with predictions based on the probabilistic failure model. Hole is centered. (a) Hole-to-width ratio is constant. (b) Hole diameter is constant 2*a* = 2.5 mm (0.98 in.), as width varies. Source: Adapted from Ref 2

Crack Propagation

The effects of fiber pullout on crack propagation can be modeled using well-established bridging or cohesive zone concepts. The general approach to this class of problem is to establish the integral equations that describe the crack-tip stress-intensity factor and the crack-opening displacement profile for the specimen geometry and loading configuration of interest, following standard procedures in the stress analysis of cracks. Solutions to these equations (normally obtained through numerical methods) yield results in the form of stress versus crack length. In this context, the key material properties are: the bridging law, which describes the relationship between the crack surface tractions, σ_b, and the crack- opening displacement, u; and the intrinsic crack- tip toughness, K_0.

Closely analogous problems associated with crack bridging in other materials systems have been studied extensively; the materials include ductile particle-reinforced ceramics, short fiber- reinforced cementitious materials, and monolithic ceramics, such as Al_2O_3 and Si_3N_4. (For details on the latter materials and a good treatment of the pertinent mechanics, see the book by B. Lawn, Ref 26, and the references therein.)

A useful pedagogical tool for representing the instability conditions for the propagation of a bridged crack is the tangent construction plot, shown in Fig. 14. (This construction has been used in the context of metals that exhibit *R*-curve behavior; see, for example, the books by D. Broek, Ref 27, and Kanninen and Popelar, Ref 28.) The plot contains two types of curves: the fracture resistance, K_R, plotted against the crack extension, Δa (beyond the initial notch length); and the stress-intensity factor, K_I, due to the applied load, plotted against the ***total*** crack length, $\Delta a + a_0$. In this context, the right side of the abscissa is interpreted as Δa and the left side as a_0. The fracture resistance curve initiates at the intrinsic fracture toughness, K_o, (at $\Delta a = 0$) and subsequently increases with crack extension as the bridging zone develops. Under SSB conditions, once the bridging elements furthest from the crack tip disengage, both the bridging zone length and the fracture resistance reach steady- state values, independent of additional crack growth. Using the *J*-integral, the steady-state resistance, K_{ss}, is given by:

$$\frac{K_{ss}}{K_0} = \sqrt{1 + \frac{\bar{E}\Gamma_b}{K_0^2}} \qquad \text{(Eq 1)}$$

where $\bar{E}$ is the plane-strain composite modulus and Γ_b is the bridging toughness:

$$\Gamma_b = \int_0^{u_0} \sigma_b(u)du \qquad \text{(Eq 2)}$$

The amount of crack extension, Δa_{ss}, needed to achieve the steady state under SSB conditions is dependent somewhat on the shape of the traction law, but scales with the quantity $u_0\bar{E}/\sigma_0$. For typical values of these parameters ($u_0 \approx 10$ to 100 μm, $\bar{E} \approx$ 100 GPa, and $\sigma_0 \approx 100$ MPa), this bridging length is in the range of ≈10 to100 mm. The conditions for instability are:

$$K_I = K_R \quad \text{and} \quad \frac{dK_I}{da} \; \frac{dK_R}{da} \qquad \text{(Eq 3)}$$

These conditions are satisfied when the curve K_I ($\Delta a + a_0$) is tangent to the curve K_R (Δa). The curves shown in Fig. 14 illustrate that when the initial flaw is small in relation to Δa_{ss}, the instability occurs when the crack has grown only a small amount. In this case, the bridging plays a negligible role in the strength. By contrast, when the flaws are comparable or larger than Δa_{ss}, the instability occurs when the crack has extended by $\approx \Delta a_{ss}$. In this case, the steady-state toughness is almost fully used in the composite strength.

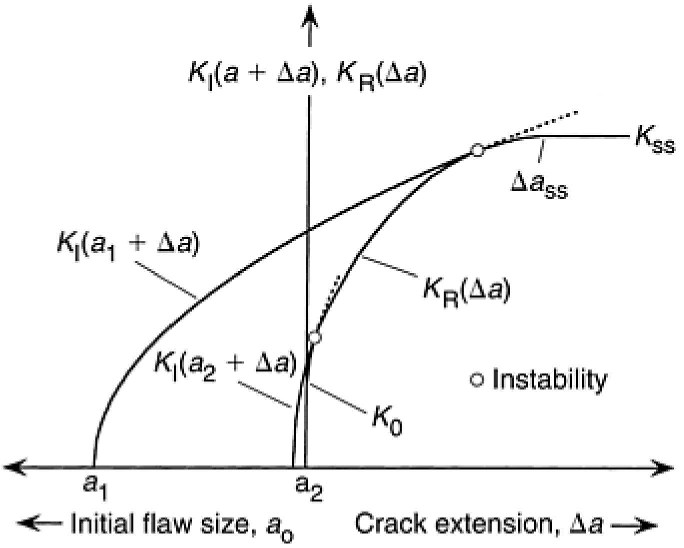

Fig. 14 Tangent construction plot used to represent the stability of bridged cracks. Fracture resistance (K_R) is plotted against crack extension (Δa). Stress-intensity factor, K_I, is plotted against total crack length.

Rather comprehensive solutions exist for the crack propagation stress in uniaxial tension for a variety of traction law shapes, including rectilinear, linear hardening, linear softening, and parabolic (Ref 29, 30, 31, and 32). All are based on the assumption that the adjacent composite material remains *elastic*; the coupled effects of inelastic deformation and fiber pullout have yet to be explored. Representative results are plotted in Fig. 15 for center-cracked specimens of infinite width ($a/w \approx 0$) for the linear softening traction law (Ref 32). The latter traction law is selected here because it is consistent with the prediction from a shear lag analysis of a single bridging fiber. The result of this analysis is:

$$\sigma_b(u) = \frac{2\tau f_0 h}{R}\left[1 - \frac{u}{h}\right] = \sigma_0\left[1 - \frac{u}{h}\right] \quad \text{(Eq 4)}$$

where τ is the interfacial sliding stress, f_0 is the volume fraction of fibers that are aligned parallel to the loading direction, h is the fiber pullout length, and R is the fiber diameter. The results are presented in terms of the propagation stress, σ_p, normalized by the peak stress, σ_0, in the traction law and plotted against a nondimensional crack length, α, defined by (Ref 29, 32):

$$\alpha \equiv \frac{a_0 \sigma_0}{u_0 \bar{E}} \quad \text{(Eq 5)}$$

where $2a_0$ is the initial crack length and u_0 is the critical crack-opening displacement upon complete disengagement of the bridging elements (equivalent to h in the shear lag result in Eq 4). The normalizing crack length, $u_0\bar{E}/\sigma_0$, is the characteristic bridging-length scale that dictates Δa_{ss}. The effects of the intrinsic toughness are incorporated into a normalized toughness parameter, λ, defined by (Ref 32):

$$\lambda \equiv \frac{\Gamma_0}{\sigma_0 u_0} = \frac{K_0^2}{\sigma_0 u_0 \bar{E}} \quad \text{(Eq 6)}$$

where Γ_0 is the intrinsic fracture energy (related to the intrinsic fracture toughness, K_0, through the Irwin relation, $\Gamma_0 = K_0^2/\bar{E}$), and the normalizing fracture energy, $\sigma_0 u_0$, is proportional to the bridging toughness. The results show three main regimes of behavior, governed mainly by the value of α. When the initial crack length is very small ($\alpha \leq 0.01$), the propagation stress is dictated by the intrinsic toughness, K_0, in accordance with the Griffith relation (written in non- dimensional form):

$$\frac{\sigma_p}{\sigma_0} = \left[\frac{\lambda}{\pi\alpha}\right]^{1/2} \quad \text{(Eq 7)}$$

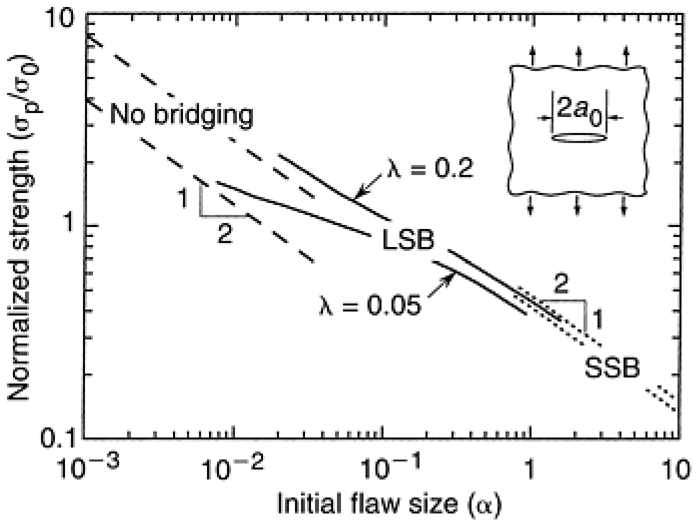

Fig. 15 Normalized strength vs. nondimensional crack length (α). Effects of flaw size (α) and the toughness (λ) on the crack propagation stress (σ_p) for *a/w* << 1. The bridging law is assumed to be linear softening, with a peak stress, σ_0. The dotted lines on the right are the SSB predictions and are applicable when α > 1. The dashed lines on the left side represent the behavior in the absence of crack bridging and are applicable when α < 0.01. Source: Adapted from Ref 32

The predictions of Eq 7 are plotted as a series of dashed lines on the left side of Fig. 15. In this regime, crack bridging has negligible effect on the crack stability, as illustrated by the tangent construction plot in Fig. 14. At the other extreme, where the initial crack length is very large (α >1), the propagation stress again follows the Griffith relation, except now the pertinent toughness is the steady-state composite toughness; this defines the SSB regime. In this regime, the relation between the strength and the initial crack length can be expressed as:

$$\frac{\sigma_p}{\sigma_0} = \left[\frac{\lambda + \frac{1}{2}}{\pi\alpha}\right]^{1/2} \qquad \text{(Eq 8)}$$

These predictions are shown by the dotted lines on the right side of Fig. 15. Between these extremes, the strength is predicted by a LSB model. The predictions of the LSB model converge with the nonbridging prediction and the SSB prediction when the initial flaw size approaches the respective limiting value, as required. Furthermore, because the flaws of interest are generally smaller than the characteristic bridging-length scale, u_0E/σ_0, SSB conditions are rarely achieved, and hence the LSB model is needed to describe the notch sensitivity of the propagation stress.

The bridging law parameters can be determined in one of several ways. The first is based on micromechanical models, such as the shear lag model that leads to the result in Eq 4, coupled with independent measurement of the pertinent material parameters, including the sliding stress and the pullout length. The accuracy of the resulting bridging law depends on the accuracy of these measurements, recognizing that some are difficult to make in a manner that accurately reflects the fracture process. For instance, the sliding stress that is obtained by common measurement techniques, such as by fiber push-in (Ref 33) or push-through tests (Ref 34), is usually higher than the value that is representative of the pullout process. The discrepancy is the result of the difference in the sign of the Poisson strain; in some cases, it may also be associated with a dependence of the sliding stress on the extent of interface sliding (because of wear, for example, Ref 35). The accuracy of the bridging law depends also on the fidelity of the micromechanical model upon which the law is based. Notwithstanding these complications, micromechanical models are attractive and popular, because they form a critical link between the physics of the pullout process and the associated macroscopic mechanical response.

The second approach involves either direct or semidirect mechanical measurements. The most direct method is to perform a tensile test on a deeply notched specimen and measure the variation in the load with the crack-opening displacement in the regime beyond the load maximum (Ref 35, 36). Although direct, this type of test is prone to instabilities near the load maximum, a consequence of the elastic unloading of the material away from the crack plane when the load falls from its peak value. Indeed, in cases where the values of the bridging

stresses and the pullout lengths are small, catastrophic fracture occurs *at* the load maximum, leading to complete separation of the two crack faces and the loss of all information about the bridging parameters. An example of a pullout test on a $[0°/90°]_{3s}$ Nicalon/MAS CFCC is shown in Fig. 16. Most of the information about the bridging is extracted, with the exception of the portion immediately following the load maximum (shown by the dashed line). In this case, the bridging law in the pullout regime is well described by an exponential softening function, given by (Ref 35, 36):

$$\sigma_b = \sigma_* \exp(-u/u_*) \quad \text{(Eq 9)}$$

where σ_* is the peak pullout stress and u_* is a characteristic displacement. The inferred values of the bridging parameters are $\sigma_* \approx 100$ MPa and $u_* \approx 300$ μm. In addition to its use in fitting experimental data of this type, the use of the exponential function can be further justified on the basis of a micromechanical model of fiber *bundle* pullout through a shear lag analysis. The analysis is essentially identical to that used for pullout of a single fiber, but incorporates the distribution in pullout lengths. When this distribution is exponential, the analysis yields an exponential bridging law, essentially identical to Eq 9, with the characteristic displacement, u_*, being equivalent to the average pullout length, $\bar{h}$, and the bridging stress, σ_*, related to the other parameters by (Ref 35):

$$\sigma_* = \frac{2\tau f_0 \bar{h}}{R} \quad \text{(Eq 10)}$$

This direct approach is preferred for determining the bridging parameters.

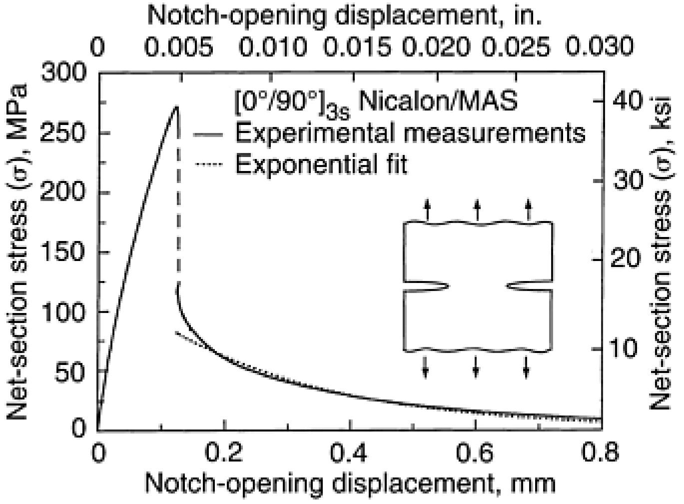

Fig. 16 Measurement of the pullout response of a $[0°/90°]_{3s}$ Nicalon/MAS CFCC and the fitting of the exponential function in the regime following complete fiber fracture (Eq 9). Source: Adapted from Ref 35

In instances where the bridging parameters cannot be measured directly through notched tension tests, the parameters can be obtained through a semidirect method, using test geometries that promote stable crack growth and yield data that are amenable to analysis. One such method is based on edge-notched flexure tests. Measurements are made of the load–deflection response as well as the crack length. The bridging parameters are then inferred by fitting the data (in the form of an *R*-curve, for example) with the predictions of a bridging model, using an assumed form for the bridging law. One example is shown in Fig. 4 (Ref 10). In general, the uniqueness of such a fit may be questionable, because of the assumptions about the form of the traction law and the intrinsic toughness, and is therefore inferior to the more direct approach described previously. A related indirect method for deducing the traction law is through a combination of high-resolution crack-opening displacement measurements ahead of a notch and numerical simulations (Ref 37).

A variation on this semi-direct method involves measurement of either the load versus displacement response or the load versus *crack mouth-opening displacement* (CMOD) response of an edge-notched three-point flexure specimen once the matrix crack has propagated across the *entire* cross section (Ref 38). In this regime, the response is dictated entirely by fiber pullout, independent of the intrinsic toughness, K_0. This loading geometry can be analyzed fairly accurately using beam theory. For this purpose, the two halves of the broken composite are treated as rigid blocks; the bridged crack is assumed to be an infinitesimal plastic hinge, and the crack-

opening profile is assumed to be linear across the cross section. If the traction law follows an exponential form (Eq 9), the predicted load-CMOD response in this regime is given by (Ref 38):

$$P = \frac{4B\sigma_* W^2 u_*^2}{S\delta^2} \times \left[1 - \left(1 + \frac{\delta(W - a_0)}{W u_*}\right)\exp\left(-\frac{\delta(W - a_0)}{W u_*}\right)\right] \quad \text{(Eq 11)}$$

where *P* is the applied load, *B* is the specimen thickness, *W* is the specimen width, a_0 is the notch depth, *S* is the loading span, and δ is the notch mouth-opening displacement. An analogous result can be derived for the load-displacement response. The fit of Eq 11 to the measured *P*-δ curve for a [0°/90°] Si_3N_4/BN composite is shown in Fig. 17.

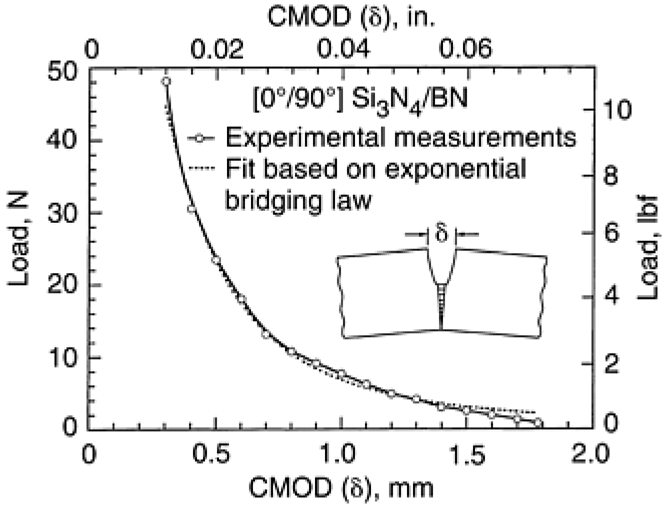

Fig. 17 Load vs. crack mouth-opening displacement (CMOD). Measurement of the traction law from the load-CMOD response following complete cracking in an edge-notched flexure specimen of a [0°/90°] Si_3N_4/BN composite. Source: Adapted from Ref 38

The fracture stress is the larger of the critical stress needed for fracture initiation, σ_i, and that needed for propagation, σ_p. Comparisons of σ_i and σ_p for a $[0°/90°]_{3s}$ Nicalon/MAS CFCC are shown in Fig. 18. The traction law for this material is shown in Fig. 16, and the initiation condition is calculated using the point-stress failure criterion, as described previously. When the notches are short, the strength is dominated by the initiation event. A transition to propagation- controlled fracture occurs at a critical value of notch length, dependent on the value of the characteristic length in the point-stress criterion. Using a value, *d*= 0.5 mm (0.02 in.), that is consistent with the experimental data in the short notch regime, the transition is predicted to occur at a ≈80 mm (3 in.). The transition shifts rapidly to larger values of crack length as the characteristic length increases. It also shifts in this direction when the notches are more blunt, for example, circular holes (Ref 2). These results suggest that fiber pullout (following fiber fracture) contributes negligibly to the notched strength of this particular CFCC, except in cases where the initial crack length is very large and probably outside the range that is relevant to most CFCC components. Given the rather large values of bridging stress and pullout lengths obtained in this composite, it is surmised that the pullout process is likely to be comparatively unimportant in the notched tensile strength of other class II CFCCs. However, it may play an important role in preventing catastrophic fracture under displacement-controlled modes of loading. Additional work is needed to confirm this hypothesis and to assess the importance of bridging in the fracture properties of other classes of CFCCs.

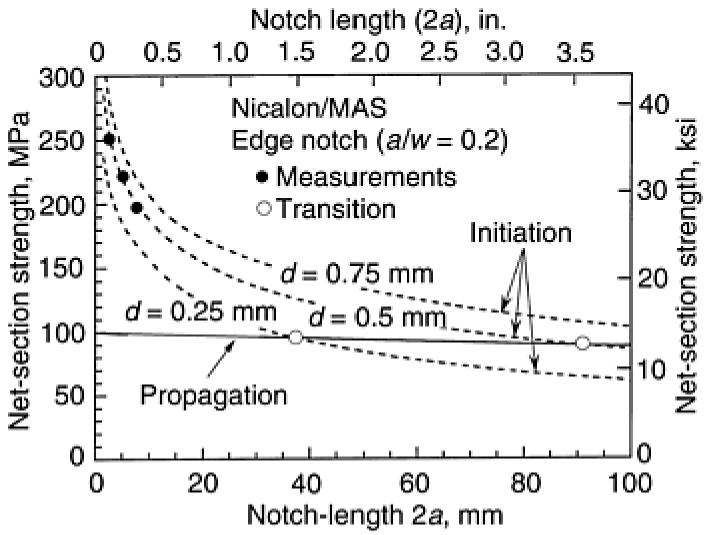

Fig. 18 Stresses required for fracture initiation and crack propagation in double-edge-notched tensile specimens of a Nicalon/MAS CFCC. The transition from initiation-controlled to propagation-controlled fracture occurs at the intersection points of the curves, indicated by the open symbols. Source: Adapted from Ref 2

Environmental Degradation

One of the most significant problems hindering the widespread use of SiC-based CFCCs is their susceptibility to oxidation in the targeted service environments. A particularly insidious form of oxidation occurs internally within these CFCCs, without significant gain or loss of material. The process occurs by oxygen ingress through matrix cracks, followed by reaction of the oxygen with the fibers and the fiber coatings (Ref 3, 39, 40 41, and 42). Commonly, the reactions result in the elimination of the fiber coatings (carbon or boron-nitrogen) and the formation of silicate glasses that bond the fibers to the matrix. Once bonding has occurred, the damage tolerance associated with sliding interfaces is lost. The problem is particularly severe at intermediate temperatures, 600 to 900 °C (1100 to 1650 °F) and is thus known as a "pesting" phenomenon. At lower temperatures, the reaction kinetics are too slow to have a substantial impact, and at higher temperatures, a protective oxide layer forms on the composite surface, which seals the surface and inhibits oxygen ingress. The embrittlement phenomenon can be overlooked during routine mechanical property characterization studies, which normally focus on ambient temperature and high-temperature properties, 1100 to 1300 °C (2000 to 2400 °F), with the tacit assumption that the properties vary monotonically with temperature. It can be identified experimentally by performing stress-rupture tests on tensile specimens subject to a temperature gradient along the specimen length that spans the embrittlement range, from less than 600 °C (1100 °F) to greater than 900 °C (1650 °F). The temperature at the location of failure corresponds with the most severe embrittlement at the prescribed stress level (Ref 39). Corroborating evidence of the embrittlement can be obtained from fracture surface examinations. Because oxygen ingress occurs along matrix cracks, the embrittlement problem is prevalent at stresses above the matrix-cracking limit and is exacerbated by conditions that accelerate the rate of oxygen ingress or compromise the integrity of the protective oxide layer. Such conditions are obtained during thermal and/or mechanical cycling.

The loss in damage tolerance associated with cyclic mechanical loading in notched specimens in the intermediate-temperature regime is demonstrated in Fig. 19. The material is comprised of Sylramic SiC fibers in a plain weave architecture and a SiC matrix. The unnotched *low cycle fatigue* (LCF) threshold at 815 °C (1500 °F) is dictated by the matrix-cracking stress, 150 to 160 MPa (22 to 23 ksi). Above the cracking stress, fracture occurs rapidly, typically in <100 hours. Moreover, the LCF curve for stresses slightly above the threshold is extremely shallow, indicating a very strong sensitivity of fracture time to applied stress. The matrix-cracking stress similarly dictates the LCF threshold for open-hole tensile specimens. That is, once the cracking stress is exceeded locally, even over a very small distance ahead of the hole, fracture ensues. Consequently, a reasonably accurate prediction of the threshold stress is obtained through the *elastic* stress concentration factor in combination with the matrix-cracking stress. This highly notch-sensitive behavior suggests the need for an extremely conservative design approach for CFCC structures containing holes when this embrittlement mechanism is operative. Furthermore, it precludes the exploitation of the inelastic straining mechanisms that operate in these materials and impart good damage tolerance in nonoxidizing environments.

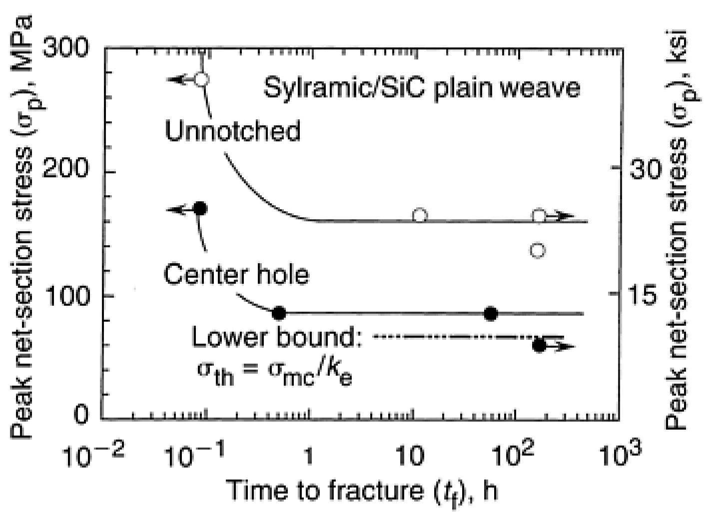

Fig. 19 Low cycle fatigue (LCF) behavior of a SiC- based CFCC at a temperature of 815 °C (1500 °F). Arrows pointing to the right indicate runout; arrows pointing to the left indicate test results obtained from uniaxial tension tests. The loading spectrum comprised relatively rapid loading and unloading (each taking about 1 min) and a hold time of 2 h at the peak stress. σ_{th} is the threshold stress in the open-hole specimen, and σ_{mc} is the matrix-cracking stress. Source: Adapted from Ref 3

The pathway for achieving significant improvements in the long-term durability of this class of composite remains ill-defined. One approach that has received renewed interest in recent years involves the use of environmental barrier coatings. The robustness of such coatings and their effectiveness in improving durability of the underlying CFCC have yet to be demonstrated.

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

Conclusions

Many of the features needed for damage-tolerant design of CFCC components are available for use by the engineering community. The general framework is consistent with that used for other structural materials, most notably metals. The important features that have been developed specifically for CFCCs include: nonlinear constitutive laws for inelasticity at the macroscopic scale; rudimentary models of fracture initiation at a crack or notch tip, including the effects of size scales; and bridging models to describe the effects of fiber pullout on crack propagation. The models can be calibrated through the use of relatively straightforward test procedures. Ongoing activities in the development of numerical models to simulate the response of CFCCs at the microscopic and mesoscopic scales are expected to significantly enhance the predictive capability of the deformation and fracture models. The mechanics of other material phenomena, including oxidative embrittlement, creep, and fatigue, are expected also to emerge once CFCCs are used more extensively in thermostructural components.

Other characteristics of CFCCs are discussed in "Properties and Performance of Ceramic-Matrix and Carbon-Carbon Composites" in this Volume.

Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites

F.W. Zok, University of California at Santa Barbara

Appendix: The Genin-Hutchinson Constitutive Law

The Genin-Hutchinson constitutive law is valid for proportional in-plane loading of fiber composites with balanced fiber architectures. The following summary applies specifically to 2-D orthogonal architectures.

When the principal axes of loading (denoted I and II) are aligned with the two fiber axes, the principal strains, ϵ_I and ϵ_{II}, are assumed to be related to the principal stresses, σ_I and σ_{II}, through the functions, f_0 and f_{0T}, via:

$$\varepsilon_I = f_0(\sigma_I) + f_{0t}(\sigma_{II}) \quad \text{(Eq 12a)}$$

$$\varepsilon_{II} = f_0(\sigma_{II}) + f_{0T}(\sigma_I) \quad \text{(Eq 12b)}$$

The two functions represent the stress-strain measurements in a 0°/90° tension test, with f_0 obtained from the axial strains (parallel to the loading direction) and f_{0T} obtained from the transverse strains. Similarly, when the principal straining axes are at 45° to the two fiber directions, the principal strains and stresses are assumed to be related by:

$$\varepsilon_I = f_{45}(\sigma_I) + f_{45T}(\sigma_{II}) \quad \text{(Eq 13a)}$$

$$\varepsilon_{II} = f_{45}(\sigma_{II}) + f_{45T}(\sigma_I) \quad \text{(Eq 13b)}$$

where f_{45} and f_{45T} are obtained from a tension test performed in the ±45° orientation. Consideration of the special case of equibiaxial tensile loading ($\sigma_I = \sigma_{II} = \sigma$) requires that the four functions be related through:

$$f_{45T}(\sigma) = f_0(\sigma) + f_{0T}(\sigma) - f_{45}(\sigma) \quad \text{(Eq 14)}$$

Hence, only three of the stress-strain curves are independent functions.

For the purpose of implementing the constitutive model into a finite-element program, Eq 12a and 13a are inverted such that:

$$\sigma_I = \Sigma_0\ (\varepsilon_I, \varepsilon_{II}) \quad \text{(Eq 15a)}$$

$$\sigma_{II} = \Sigma_0(\varepsilon_{II}, \varepsilon_I) \quad \text{(Eq 15b)}$$

for the 0°/90° orientation, and

$$\sigma_I = \Sigma_{45}\ (\varepsilon_I, \varepsilon_{II}) \quad \text{(Eq 16a)}$$

$$\sigma_{II} = \Sigma_{45}(\varepsilon_{II}, \varepsilon_I) \quad \text{(Eq 16b)}$$

for the ± 45° orientation. The reductions in the stresses due to matrix cracking (the so-called “stress deficits”) are:

$$\Delta\sigma_I^0 = \frac{E_0}{(1-\nu_0^2)}(\varepsilon_I + \nu_0\varepsilon_{II}) - \Sigma_0(\varepsilon_I, \varepsilon_{II}) \quad \text{(Eq 17a)}$$

$$\Delta\sigma_{II}^0 = \frac{E_0}{(1-\nu_0^2)}(\varepsilon_{II} + \nu_0\varepsilon_I) - \Sigma_0(\varepsilon_{II}, \varepsilon_I) \quad \text{(Eq 17b)}$$

for the 0°/90° orientation, where E_0 and ν_0 are the Young's modulus and Poisson's ratio, respectively. Similarly, in the ±45° orientation, the stress deficits are:

$$\Delta\sigma_I^{45} = \frac{E_{45}}{(1-\nu_{45}^2)}(\varepsilon_I + \nu_{45}\varepsilon_{II}) - \Sigma_{45}(\varepsilon_I, \varepsilon_{II}) \quad \text{(Eq 18a)}$$

$$\Delta\sigma_{II}^{45} = \frac{E_{45}}{(1-\nu_{45}^2)}(\varepsilon_{II} + \nu_{45}\varepsilon_I) - \Sigma_{45}(\varepsilon_{II}, \varepsilon_I) \quad \text{(Eq 18b)}$$

where E_{45} and ν_{45} are the corresponding Young's modulus and Poisson's ratio in the ±45° orientation.

When the axes of the principal strains are oriented at an arbitrary angle, θ, to the fiber directions, the stress deficits along the principal strain axes are obtained through an interpolation between the stress deficits in the 0°/90° and ±45° orientations in accordance with:

$$\Delta\sigma_I = \Delta\sigma_I^0 \cos^2 2\theta + \Delta\sigma_I^{45} \sin^2 2\theta \quad \text{(Eq 19a)}$$

$$\Delta\sigma_{II} = \Delta\sigma_{II}^0 \cos^2 2\theta + \Delta\sigma_{II}^{45} \sin^2 2\theta \quad \text{(Eq 19b)}$$

Upon transforming these stress deficits back to the fiber axes (denoted 1 and 2), the full in-plane stress-strain relations are obtained:

$$\sigma_1 = \frac{E_0}{1-\nu_0^2}(\varepsilon_1 + \nu_0\varepsilon_2) - \Delta\sigma_I \cos^2\theta - \Delta\sigma_{II} \sin^2\theta \quad \text{(Eq 20a)}$$

$$\sigma_2 = \frac{E_0}{1-\nu_0^2}(\varepsilon_2 + \nu_0\varepsilon_1) - \Delta\sigma_I \sin^2\theta - \Delta\sigma_{II} \cos^2\theta \quad \text{(Eq 20b)}$$

$$\tau_{12} = \frac{E_{45}}{2(1+\nu_{45})}\gamma_{12} - (\Delta\sigma_I - \Delta\sigma_{II})\sin\theta\cos\theta \quad \text{(Eq 20c)}$$

Introduction to Manufacturing of Polymer-Matrix Composites

B. Tomas Åström, IFP SICOMP AB, Sweden

Introduction

WHEN FABRICATING components and structures from traditional construction materials, manufacturing is usually a matter of machining, molding, or joining material that is already solid and in such forms as block, rod, plank, or sheet. With fiber-reinforced composites, the situation is different in that both the material and component are manufactured simultaneously. (There are some exceptions with both metals (e.g., casting, sintering, and extrusion) and composites (e.g., prepregs, molding compounds, and, in some cases, thermoplastic composites). Most often, the aim in composites manufacturing is to realize near-net-shape or, ideally, net-shape manufacturing, meaning that little or no post-manufacturing machining and trimming is needed, which improves both process economy and individual component properties.

When material and component are simultaneously manufactured, both designer and manufacturer should have a good understanding of how manufacturing conditions influence material properties, since there is often a notable processing–property dependency. In addition to working with an anisotropic material, the designer must also have a good understanding of the processing requirements of candidate raw materials and the specifics of potential manufacturing techniques to be able to estimate the final properties of the component. Obviously, a candidate manufacturing technique must be capable of producing a part with the required geometry, but it is also important to note that the technique selected influences surface finish, allowable reinforcement configurations, available resins and their properties as matrices, as well as a host of other properties, including cost. Table 1 illustrates some of the challenges facing the composite designer when selecting the raw materials and manufacturing technique for a particular design.

Table 1 Manufacturing-related issues to consider in design

Requirements due to component performance specifications
Reinforcement
Type
Continuous or discontinuous
Random or oriented
Sizing, coupling agent, and surface treatment
Volume fraction
Weave style
Filament count
Yarn characteristics
Matrix
Thermoset or thermoplastic
Temperature tolerance
Environmental tolerance
Compatibility with reinforcement
Additives and fillers
Void fraction
Surface finish
Dimensional tolerance
Damage tolerance
Holes, undercuts, bosses, and ribs

Inserts, fasteners, and potting compounds
Repairability
Requirements on manufacturing technique imposed by raw material
Reinforcement
Continuous or discontinuous
Random or oriented
Volume fraction
Matrix
Viscosity
Temperature, pressure, and time requirements
Toxicity
Requirements on manufacturing technique imposed by geometry
Overall size
Thickness
Hollow or solid
Constant or varying cross-sectional shape
Single or compound curvature
Requirements on manufacturing technique imposed by economy
Production rate and total series length
Degree of automation
Post-molding machining, trimming, surface preparation, painting, and finishing
Cost of
Capital equipment
Mold
Raw material
Labor
Energy

Metals are essentially isotropic and homogenous and have predictable properties; material selection and component design for metals normally precede manufacturing considerations. Using the same methodology with composites (which, unfortunately, is not uncommon), will often produce an unsatisfactory end product. This is one reason why composite parts are rarely successful as direct replacements for metal parts; to be successful, composite components must be designed with composites in mind from the onset of the design process. For this reason, the designer must have a good understanding of the candidate materials and must be well versed in the manufacturing techniques that may be employed. The basics of polymer chemistry and physics, as well as available material types and forms, are covered in the Section “Constituent Materials” in this Volume. The bulk of this Section aims to provide reasonably detailed insight into the commercially most relevant techniques to manufacture composites, as well as fabrication of molds for these techniques. The Section focuses on structurally capable (meaning continuous- or at least long fiber-reinforced) polymer composites. The intention of the articles is to explain the key features of each technique and provide the reader with sufficient insight to allow selection of a technically and economically feasible manufacturing technique for a composite design. With product development times constantly decreasing, the need for predictive capabilities and process robustness increases; the article “Process Modeling” provides an introduction to the topic.

Once the appropriate manufacturing technique and raw material type and form have been selected and a mold fabricated, success in composites manufacturing requires close control of temperature and pressure throughout the molding process and throughout the component. During molding, the key is to employ sufficient pressure to maintain the liquid reinforcement-matrix mass in the desired shape at a specified temperature until it becomes dimensionally stable. If the reinforcement needs to be impregnated as part of the process, a pressure gradient is required to force the matrix through the fiber bed. For thermoset matrices, the time interval from (preimpregnated) molding compound to demoldable part is on the order of a few minutes; however, when the raw material is prepreg or separate fibers and matrix, the time interval may be hours or even days. For thermoplastic matrices in the form of preimpregnated reinforcement or molding compound, the time to

demolding (excluding the preheating stage) may be less than a minute to a few minutes, since the part only needs to be cooled to achieve dimensional stability.
When trying to grasp the essentials of a composite manufacturing technique, consider the following questions:

- What is used as the mold to give the composite its shape?
- How is the raw material made to conform to the mold?
- How is the impregnation pressure gradient applied (if applicable)?
- How is the consolidation pressure applied?
- How is the temperature controlled?

The emphasis of this Section is on widely accepted and emerging techniques to manufacture polymer composites. However, any technique which maintains the liquid reinforcement-matrix mass in the desired shape, typically at elevated temperature, until it becomes a solid will produce a composite. Whether the composite properties are acceptable and whether the technique is cost-effective are entirely different issues. There is no reason why different manufacturing techniques cannot be combined to create a new technique, underscoring the fact that, with composites, the only limitation is the imagination. Not surprisingly, this imagination also applies to the terminology used in manufacturing, and there is rarely a universally accepted name or acronym for a given technique.

Outlook

When trying to envisage future developments in composites manufacturing, it is instructive to take a look at the previous edition of this Handbook (*Engineered Materials Handbook,* Volume 1, ASM International, 1987). While most techniques covered in the present edition also were described in the 1987 edition, some techniques now covered are new (vacuum infusion and several thermoplastic techniques), and a couple that previously were reported as representing recent developments are now well established (fiber placement and tape laying). This observation indicates that the field of composite manufacturing is developing, albeit not at breakneck speed. What may not be immediately obvious are more subtle developments, some of which are discussed here.

- Traditional open-mold techniques, such as wet hand lay-up and spray-up, are gradually being replaced with closed-mold techniques, such as resin transfer molding (RTM), structural reaction injection molding (SRIM), and vacuum infusion. The primary driver in this transition is reduction in volatile emissions to improve work environment and reduce factory emissions (or, alternatively, reduce air treatment costs); these techniques also provide improved and more consistent component properties and reduced matrix use.
- In manufacturing of competition yachts, the materials and manufacturing techniques used increasingly resemble those traditionally used in aerospace applications. More specifically, preimpregnated reinforcement is used, together with high-performance polymer foam and honeycomb cores, and the composite matrix is crosslinked under vacuum and at elevated temperature, sometimes even in an autoclave. In this case, the main driver is performance enhancements.

- In aerospace applications, hand lay-up of preimpregnated reinforcement is still the industry norm, but automated lay-up techniques and RTM are gaining ground in the drive to reduce cost and enhance repeatability.
- The trial-and-error approach has long been the way to optimize a technique, and to a significant extent, this is still the case. However, process modeling, which has been an active research field in academia for a couple of decades, is now maturing to the extent that it is gradually becoming commonplace in industry. The overall driver is cost reduction, which is made possible through automation and enhancements in cycle time, process robustness, and component properties.
- For expensive components with high requirements (e.g., aircraft components) it may be financially beneficial to embed, within the component, sensors that monitor factors like degree of mold filling or crosslinking; this allows processing conditions to be tailored in order to optimize properties. Such tailoring depends on real-time process modeling to interpret sensory output and determine the most appropriate course of action. Also, in this case, the driver is cost reduction through improvements in process robustness and component properties.

To some extent, all techniques to manufacture polymer composites are seeing gradual improvements to enhance their competitiveness. In addition to the improvements already mentioned, there are gains to be made in terms of more intricate geometries, more complex reinforcement orientations, reduced void content, improved surface finish, etc., all of which ultimately lead to cost reductions. Such gradual refinements may very well be more important to the overall competitiveness of composites than invention of entirely new techniques.
A comprehensive treatment of materials, manufacturing, and post-manufacturing issues relevant to polymer composites is provided in Ref 1.

Introduction

POLYMER COMPOSITES have been in use for a considerable part of the twentieth century. Their advantages over other materials for high- performance, lightweight applications have increased their use in many aerospace, automobile, infrastructure, sports, and marine applications. The path to design and manufacturing of composite structures was pursued in evolutionary as well as revolutionary ways. They ranged from using hand

lay-up with labor- and cost-intensive autoclave processing to the use of automated processes such as injection molding and extrusion, which traditionally have been employed by the polymer processing industry (Ref 1, 2, and 3).

In order for composites to be widely used, especially for consumer goods such as in the automotive and recreational industries, two major goals had to be achieved. First of all, the cost of raw materials had to be competitive. Secondly, manufacturing methods had to be developed to achieve high-volume production. The methods needed to be based on the fundamental understanding of the physics of the process, rather than on the accepted trial and error practice ingrained on the shop floor of manufacturing sites (Ref 1, 4). Since the 1980s, composites research has led to the development and improvement of manufacturing methods.

The objective of this article is to categorize various composite manufacturing processes based on similar transport processes and to briefly outline the modeling philosophy and approach that is useful in describing composite manufacturing processes.

Classification Based on Dominant Flow Process

Transport processes encompass the physics of mass, momentum, and energy transfer on all scales. Because the composites are heterogeneous materials, there are simultaneous transfers of heat, mass, and momentum at micro-, meso-, and macroscales. This often occurs with chemical reactions in a multiphase system with time-dependent material properties and boundary conditions.

Composites manufacturing processes can be grouped into three categories:

- Short-fiber suspension methods
- Squeeze flow methods
- Porous media methods

Figure 1 shows the types of flow expected in these processing methods.

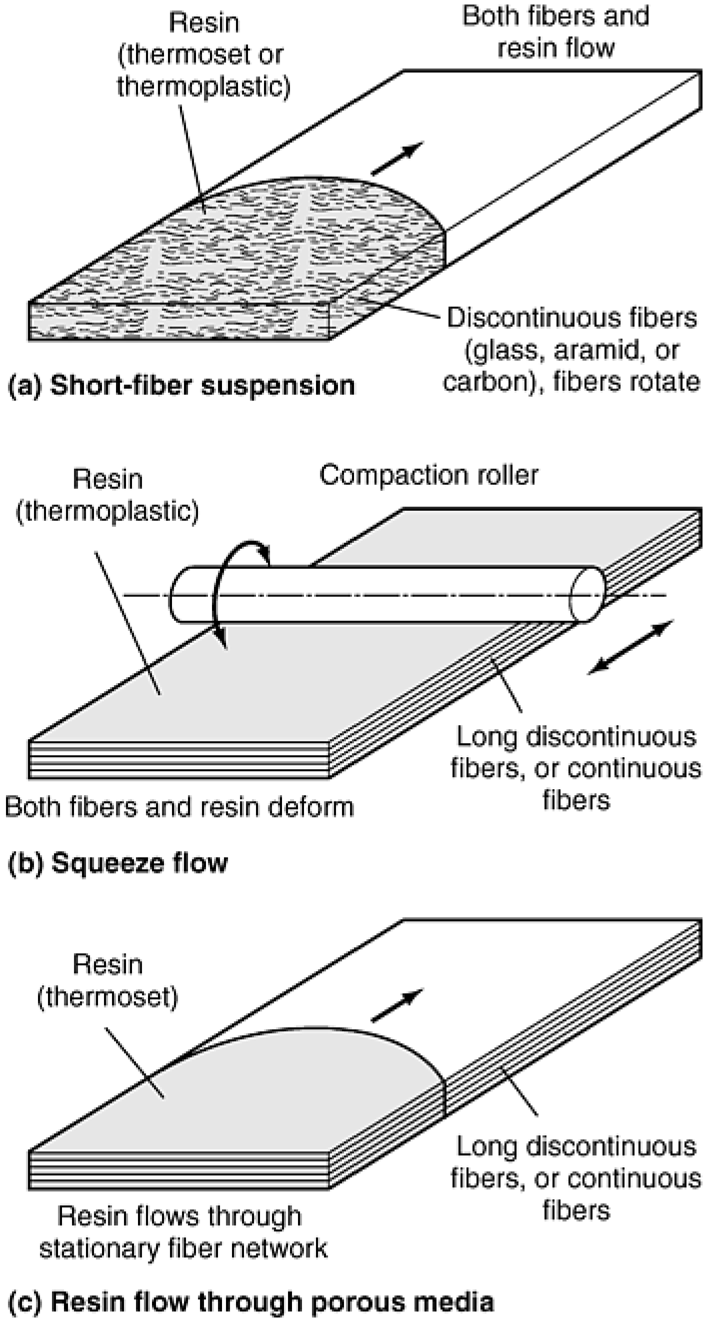

Fig. 1 Schematic of types of flows expected in composites processing. (a) Short-fiber suspension manufacturing methods: flow of resin-fiber suspension in a mold or through a die. Examples are injection molding, compression molding, and extrusion. (b) Squeeze flow manufacturing methods (advanced thermoplastic composites manufacturing methods): compaction roller deforms both thermoplastic resin and preimpregnated fiber network. Examples are thermoplastic sheet forming, thermoplastic pultrusion, and tape laying. (c) Porous media manufacturing methods (advanced thermoset manufacturing methods): resin flows through stationary fiber network. Examples are liquid composite molding, thermoset pultrusion, filament winding, and autoclave.

Short-fiber suspension manufacturing methods consist of manufacturing processes that involve the transport of fibers and resin as a suspension into a mold or through a die to form the composite. In such processes, the fibers in the molten deforming resin can travel large distances and are usually free to rotate and undergo breakage. The microstructure of the final product is linked with the processing method and the flow of the suspension in the mold. Injection molding, compression molding, and extrusion processes fall under this category. The reinforcements are usually discontinuous glass, aramid, or carbon fibers, and the resin may be either thermoset or thermoplastic.

Squeeze flow manufacturing methods, or advanced thermoplastic composites manufacturing methods, usually involve continuous or long, aligned, discontinuous fibers either partially or fully preimpregnated with

thermoplastic resin. In these processes, the fibers and the resin deform together, like a dough containing strands of continuous wires or wire screens under applied stress to form the composite shape. The presence of fibers creates anisotropic resistance to the applied load, and usually the viscosity can be over a million times that of water. This prevents large bulk movements of the composite. Thermoplastic sheet forming, thermoplastic pultrusion, and fiber tape-laying methods can be described by this physics (Ref 6, 7). The precursor materials can be in various forms. One such form is thermoplastic tapes impregnated with aligned and continuous or long discontinuous fibers (Ref 8, 9, and 10). The other popular form is a preform weave of the polymer fibers commingled with glass or carbon fibers. Under applied heat and pressure, the polymer fibers melt and occupy the space between the reinforcing fibers (Ref 11). The polymer may also be in powder form attached to the fibers during the initial stages. Heat will melt and the pressure will help fuse and consolidate the fiber assembly (Ref 12, 13, and 14). Thermoplastic resins cannot travel and infiltrate large distances due to their very high viscosity. Thus, the precursor material form has to accommodate a distributed resin percolation among the fiber architectural network.

Porous media manufacturing methods, or advanced thermoset composite manufacturing methods, involve usually continuous and nearly stationary fiber networks into which the resin will impregnate and displace the air, forming the composite in an open or a closed mold (Ref 1, 4, 15, and 16). The resin in such processes is almost always a thermoset, due to its low viscosity. One does need to account for the complex chemical reactions that are prevalent in these methods. Liquid composite molding, thermoset pultrusion, filament winding, and autoclave processing are included in this category (Ref 7, 17, 18, 19, and 20). The materials can take various forms: partially impregnated prepregs, fibers with the liquid thermoset resin applied on the fly, or a stationary network of fibers impregnated with resin. The low viscosity of thermoset resin allows for this versatility. However, the disadvantage is introduction of complex chemical reaction and the gelling and curing phenomena.

Usefulness of Process Models

A model is an idealized mathematical representation of the physical process or the system. Manufacturing of composites has relied on intuition based on experience and trial and error methods when designing, developing, and producing new products. However, this approach has proven to be expensive in time and money when developing new prototype geometries. The risks involved have hindered the use of composite materials in many potential industrial applications. Use of process models can accelerate the path from conception to prototype development, thus making these materials and their processing operations cost-competitive with metals and other materials (Ref 5). The fundamentals in building process models for polymer-composite manufacturing methods, such as injection molding, pultrusion, and resin transfer molding are outlined in this section.

Composites processing models are built on the foundation of physical laws, appropriate assumptions, and boundary conditions based on an understanding of the physical phenomena and constitutive laws derived from experimental data. Once the model is well posed in mathematical equations, the behavior of the model in response to changes in the process and materials variables can be examined. This information can prove to be very useful in mold or die design, or in altering the manufacturing process to create a successful part. In order to investigate the behavior of a composite manufacturing process in a routine manner with minimum effort, the process model can be incorporated in a computer simulation. A computer simulation or a virtual processing scenario is a combination of:

- An idealized process model expressed in mathematical equations
- Numerical method to solve the equations
- Computer software to carry out the solution
- Software to display the results graphically, mimicking the physical behavior of the process

Such virtual composite processing scenarios can provide valuable and detailed information about the process and improve the understanding of the effects of process variables.

Example 1: Filling a Simple Mold. An L- shaped mold needs to be filled in minimum time without any "dry spots." There are three choices for injections, as shown in Fig. 2. Which one will provide the best results?

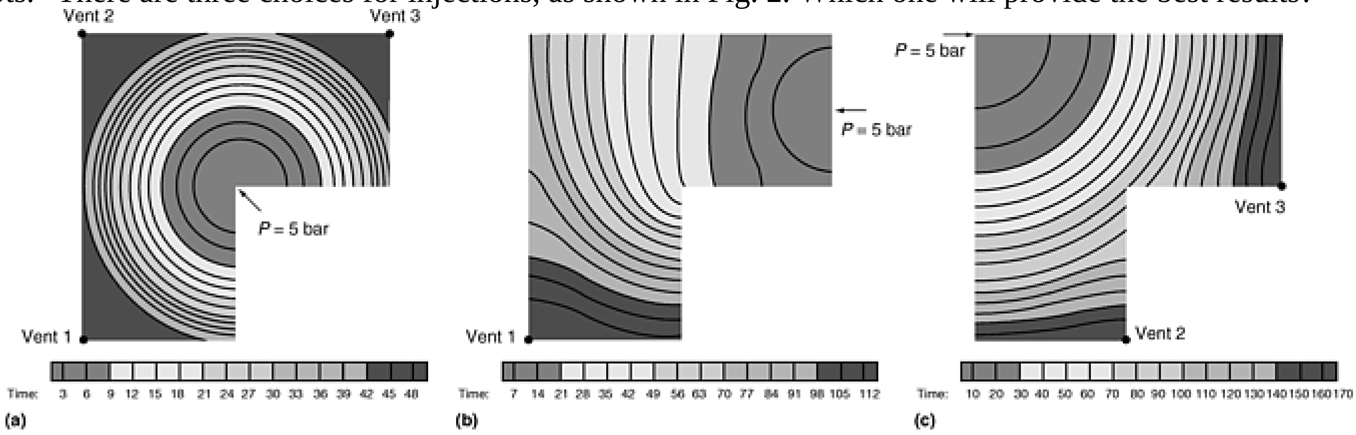

Fig. 2 Different scenarios in the mold-filling simulation code. Three different gate locations (arrows) are tried to find the minimum mold-filling time. The filling times are (a) 51 s, (b) 118 s, and (c) 169 s.

Different gate locations and conditions can be investigated to achieve the mold-filling goals. In the L-shaped mold shown in Fig. 2, three different gate locations under the same injection pressure are analyzed to find which location results in the minimum filling time, assuming that vent(s) will be placed at the last point(s) to be filled. In all three cases, the molds are filled through porous media under vacuum. The complete filling times are 51, 118, and 169 seconds in (a), (b), and (c), respectively. Actual trial and error tests would be expensive and take considerable design time. Incomplete filling can be avoided by choosing the gate location appropriately, and placing the vent(s) at the last points to be filled. One can conclude that 3, 1, and 2 vents are needed in (a), (b), and (c), respectively. During the design stage, engineers must analyze not only the injection time, but also the cost of gates, vents, and injection pressure. In each case, one gate and an injection pressure of 5×10^5 Pa (5 bar or 72.5 psi) were assumed. One can conclude that case (b) is a better choice than (c), because it takes less filling time and also requires fewer vents. By knowing the relative importance of filling time and vent cost, a design engineer could choose either (a) or (b).

Experimentation. Models are useful in understanding and codifying the manufacturing operation. Models provide detailed information about a process, such as flow front location, resin pressure, temperature, and flow rate. A model is like a scientific hypothesis that should be validated with experiments. If experiments conflict the hypothesis, the model continues to be revised until it agrees with the experiments. A scientist is more interested in understanding the physical world by using models, whereas a process engineer is usually interested in manipulating the model. A reliable mathematical model will reduce the scope of experiments by combining the effects of different variables and testing unproven design ideas. Finally, models can possibly provide more detailed information than an experiment. Models can provide information about variables that cannot be directly measured. Models do not replace experiments, but the combination of experiments, mathematical theory, physical laws, and models gives engineers and scientists insight to the process so it can be manipulated and tailored to meet their requirements (Ref 5).

Resin transfer molding (RTM) provides an excellent example of the uses of process models (Ref 4, 15, 17, and 18). In just the filling and curing of a RTM part, many physical phenomena transpire. A viscous polymer flows through a network of channels created between the fiber preforms to fill the mold cavity. Heat may enter the cavity by conduction from the mold walls. The resin molecules may start to react and form a cross-linked network, increasing the viscosity of the resin and also releasing heat, which needs to be dissipated. All these factors determine if the cavity will be completely filled, how long the part should be left in the mold, whether the part will wrap due to residual thermal stresses, and the final properties of the manufactured part.

As one cannot see inside a closed mold, it is difficult to know if the resin occupied all the empty spaces between the fibers, and if the part had cured sufficiently to retain its shape when it is demolded. A process model can let the engineer or the scientist "see" the filling pattern (as shown in Fig. 2) and the curing rate, thus quantifying the knowledge of the filling process. While learning more about the filling from the process model, an engineer does not need to run many experiments to find the best location for injection. The model can

provide a few possible locations, which reduces the scope of experiments. Thus, a reliable model can reveal the performance and outcome of different mold designs, without the added expense and time of fabricating molds and testing every design.

Resin transfer molding simulations provide further benefits, such as characterization of preform and resin. From experiments, one can monitor the resin pressure, flow rate, and temperature by placing sensors at desired locations. A process model provides detailed information about the pressure field, flow-front shapes, temperature distribution, cure profiles, and velocity fields. These usually can be graphically displayed and easily interpreted to improve the understanding of the process and to identify the problem issues. However, computer simulations must be validated and verified if they are to represent the physical world. Also, one needs to conduct experiments to characterize permeability and cure kinetics that are used as inputs into the model. Thus, experiments are a necessary component in the construction of a process model.

---

Ingredients of a Process Model

A process model is constructed and verified from six main ingredients (Ref 1):

- Model or system boundary that identifies the system being studied
- Physical laws that ensure conservation of mass, momentum, and energy
- Constitutive laws to describe the materials and their phenomenological behavior. These are needed because we cannot completely describe, from first principles, some of the transport phenomena, such as the nonlinear material behavior of resin, the resin and fiber interactions, and resin cure kinetics at the macro scale.
- Boundary conditions to tailor the model to a specific composite manufacturing process
- Assumptions to simplify the process
- Experimental validation

These six ingredients are discussed in the following subsections.

Model or System Boundary

This is the region in which one should consider physical and constitutive laws. For example, if one wanted to model the material flow inside the screw of an extruder or injection molding machine, as shown in Fig. 3, one would identify the channel inside the screw as the system of interest. The external influences on the system, such as the rotation of the barrel and heat supply by the heaters, will be expressed as boundary conditions.

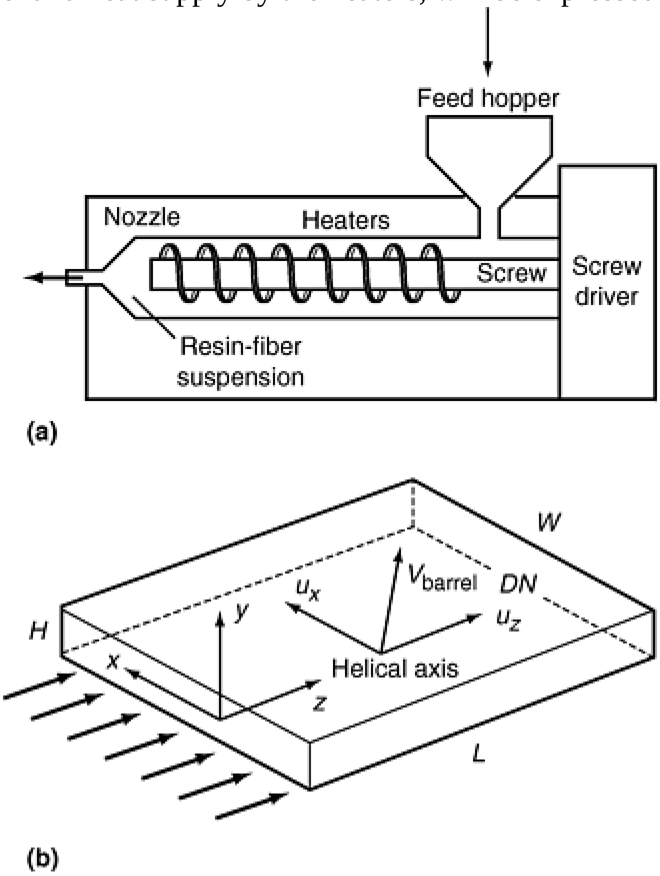

Fig. 3 Model of injection molding machine. (a) Flow of material inside the screw of an injection molding machine. (b) Model boundary and coordinate system. Instead of choosing a spiral coordinate system, which leads to complex mathematics, the screw is considered fixed, and the barrel is rotated in the opposite direction. The coordinate system is then fixed on the unwrapped channel of the screw. V_{barrel} is the velocity of the upper plate. u_x and u_z are components of this velocity in *x* and *z* directions respectively. $V_{barrel} = \pi DN$, where *D* is the diameter of the screw and *N* is the speed in revolutions per second.

Physical Laws

Once the system is identified, one would express conservation of mass, momentum, and energy within the system boundaries (Ref 21, 22). The conservation equations are developed by choosing a small control volume within the system, such that the control volume is much smaller than the system being considered, but is much larger than the molecular volume so that the variables such as pressure, velocity, and temperature can be considered on a continuum scale.

The mass conservation equation is formulated by equating the difference between the rate at which the mass of the material is entering and leaving the system, to the rate at which the mass is increasing within the control volume:

$$\begin{pmatrix}\text{Rate of}\\ \text{mass increase}\end{pmatrix} = \begin{pmatrix}\text{Rate of}\\ \text{mass inflow}\end{pmatrix} - \begin{pmatrix}\text{Rate of}\\ \text{mass outflow}\end{pmatrix} - \begin{pmatrix}\text{Rate of mass lost}\\ \text{due to a sink}\end{pmatrix} \quad \text{(Eq 1)}$$

The momentum conservation is based on Newton's law that rate of change of momentum is equal to the forces acting on the control volume. The forces acting on the control volume are the shear stresses due to the viscous action of the deforming material, normal stresses due to the material deformation, the pressure within the material, and body forces due to any noncontact forces such as gravity or electromagnetism. This generates the equation of motion for the material in the system being considered. The equation of motion relates the velocity field of the material to the stresses and pressure acting on the system:

$$\rho \frac{DU}{Dt}(\text{Inertia force}) = -\nabla P(\text{Hydrodynamic force})$$

$$+\nabla \cdot \tau(\text{Force due to stresses}) + \mathbf{F_B}(\text{Body force}) \qquad \text{(Eq 2)}$$

where ρ is material density, U is the velocity vector, *P* is static pressure, τ is the viscous stress tensor, F_B is the body force vector, and *t* is time. However, one does need a relationship between stresses and the deformation of the fluid before one can solve for either pressure or velocities experienced by the fluid. The equations that describe this relationship are called constitutive equations.

For thermoset materials, where the viscosity is low, one can usually impregnate the resin within a stationary fiber preform bed and thus use the flow through porous media theory to describe the motion. Hence for such materials, the momentum conservation is not described by a physical law but by an empirical relationship between the velocity and the pressure gradient within the material.

Energy conservation allows one to determine the temperature field by considering the energy balance for a control volume within the system:

$$\begin{pmatrix}\text{Rate of increase}\\ \text{of internal and}\\ \text{kinetic energy}\end{pmatrix} = \begin{pmatrix}\text{Inflow flux}\\ \text{of internal and}\\ \text{kinetic energy}\end{pmatrix} + \begin{pmatrix}\text{Inflow flux}\\ \text{of heat}\end{pmatrix} + \begin{pmatrix}\text{Rate of energy}\\ \text{increase due to}\\ \text{total stress, } \sigma\end{pmatrix} + \begin{pmatrix}\text{Rate of energy}\\ \text{increase due to}\\ \text{body forces } \mathbf{F_B}\end{pmatrix} + \begin{pmatrix}\text{Rate of energy}\\ \text{generation due}\\ \text{to a source}\end{pmatrix} \qquad \text{(Eq 3)}$$

where σ is the total stress tensor given by $\sigma_{ij} = \tau_{ij} - P\mathbf{I}_{ij}$. Here $\mathbf{I}_{ij} = 1$ when $i = j$ and $\mathbf{I}_{ij} = 0$ when $i \neq j$.

The energy produced within the system may be due to crystallization kinetics or to reaction kinetics. In the latter case, the energy generation term will be a function of the temperature, and the equation is nonlinear. For thermoplastics, due to their high viscosity, much of the heating of the material is caused by viscous dissipation. For example, in injection molding, although the heaters supply the heat to initially melt the polymer, a substantial amount of heat is generated as the material deforms through the narrow channels, generating heat due to viscous dissipation. Hence, this should be accounted for in the energy balance. Because composites consist of resin and fibers, laws of mixture are usually applied to calculate thermophysical properties, such as heat capacities and thermal conductivities.

Constitutive Laws

Constitutive equations are empirical relations between parameters of interest. They usually do not incorporate the physics, studied and analyzed at the micron and molecular level, into the equation at the macroscale (Ref 23).

These equations must be such that the relationships and the results do not change with the coordinate frame. Almost all constitutive equations require the researchers to characterize constants needed in the equation that are specific to the material and its state. For example, for a fluid subjected to a stress, if the stress is always directly proportional to the strain rate the fluid undergoes, the empirical constant of proportionality is called viscosity. This constitutive relation is known as Newtonian law, and the fluids that exhibit this behavior are

called Newtonian fluids. Constitutive equations should also be stable in the processing regime to be consistent with the physics, as exhibited by the experiments.

Constitutive equations are necessary to describe the processing of composite materials due to their heterogeneous nature, the complex chemistry of the resin and its interaction with fibers and fillers, and simultaneous transport of mass and energy at the micro-, meso-, and macrolevels. Issues that are analyzed at the microscale, such as growth rate of a micron-size spherulite, can be represented at the macroscale level, for this case, in terms of crystallization kinetics, by use of appropriate constitutive equations. Constitutive equations describe the global picture of the process and the process parameters, which is of interest to the process engineer, instead of getting entangled in the details at the micron level (Ref 1). Constitutive equations invariably require the researchers to determine constants that are functions of the material and process conditions. Thus, independent characterization and cataloging of material constants for constitutive equations can become a daunting task, which slows down and undermines the modeling of such processes.

Some examples of constitutive equations in composites manufacturing processes are tabulated in Table 1.

Table 1 Examples of constitutive equations in some composites manufacturing processes: empirical relations between parameters of interest

The change in fiber orientation tensor, a_{ij}, due to flow (Ref 25):

$$\frac{Da_{ij}}{Dt} = -\frac{1}{2}(\omega_{ik}a_{kj} - a_{ik}\omega_{kj}) + \frac{1}{2}\lambda(\dot{\gamma}_{ik}a_{kj} + a_{ik}\dot{\gamma}_{kj} - 2\dot{\gamma}_{kl}a_{ijkl}) + 2C_I\dot{\gamma}(\delta_{ij} - 3a_{ij})$$

where $\omega_{kj} = (\partial u_j/\partial x_k)-(\partial u_k/\partial x_j)$ (the vorticity tensor)

$$\dot{\gamma} = \sqrt{\frac{1}{2}\dot{\gamma}_{ij}\dot{\gamma}_{ji}}$$

(magnitude of the rate of strain tensor)

C_I= interaction coefficient

λ = aspect ratio of the fiber

Approximation of a_{ijkl} in terms of a_{ij} (Ref 24):

$$a_{ijkl} = \frac{1-f}{35}(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) + \frac{1-f}{7}(a_{ij}\delta_{kl} + a_{ik}\delta_{jl} + a_{il}\delta_{jk} + a_{kl}\delta_{ij} + a_{jl}\delta_{ik} + a_{jk}\delta_{il})$$

here δ_{ij} is the Dirac delta function and f is the degree of alignment

Specific energy generated during cure of a resin system; is

$=R_\alpha E_\alpha$

where E_α = the heat of reaction

$$R_\alpha = (A_1 e^{E_1/RT} + A_2 e^{E_2/RT}\alpha^m)(1-\alpha)^n$$

***α* = degree of cure**

***R* = universal gas constant**

***m*, *n*, A_1, A_2, E_1, and E_2 are empirical constants**

Temperature-dependent resin viscosity (Arrhenius equation):

$$\mu = \mu_0 e^{-c(T-T_0)}$$

where T_0 is the reference temperature at which $\mu = \mu_0$.

Temperature and degree of cure-dependent resin viscosity (Ref 16, 25):

$$\mu = a_0 e^{-b_0 \alpha_c (a + b\alpha)/RT}$$

where *a*, *b*, a_0, and b_0 are to be determined experimentally.

Permeability of a porous medium, *K*, by a capillary model (Ref 26, 27):

$$K = C \frac{\phi^3}{(1-\phi)^2} = \frac{1}{DS^2} \frac{\phi^3}{(1-\phi)^2}$$

where *S* = the specific wetted surface area

$\varphi = 1 - V_f$ = the porosity of porous medium and V_f is the fiber volume fraction

$D = k_0(L_e/L)$ = the dimensionless shape factor (an experimental parameter)

The constitutive equations that are used to describe the material behavior along with the mass, momentum, and energy conservation equations form a system of eleven equations with eleven primary variables. These variables are pressure, three components of velocity, temperature, and six independent components of stresses. To solve this system of equations, one would need to prescribe boundary conditions.

Boundary Conditions

The external influences that affect the system or process are expressed by formulating boundary conditions for the variables. In general, there are two types of boundary conditions: kinematic, which deal with velocity, and dynamic, which deal with stress fields.

Considering the physical contact of the fluid at the boundary, boundary conditions can be further divided into five groups (Ref 28):

- Liquid-solid interface (contact at solid surface)
- Liquid-liquid interface
- Liquid-vapor interface
- Free surface
- Specified inlet and exit boundary conditions

Liquid-Solid Interface. At the liquid-solid interfaces, the relative velocity of a viscous fluid with respect to the solid boundary is assumed to be zero. That is, $\mathbf{U} = \mathbf{U}_{Solid}$. This is known as no-slip condition. Although this assumption is not always correct, that is, fluid may slip on the solid surface, the idea of no-slip approximation is supported by many experiments in the literature.

Some examples of fluid-flow problems with liquid-solid-interface-type boundary conditions are shown in Fig. 4. In all four cases, it was assumed that the fluid domains in *z*-direction (out of paper) are large so that there is no variation in *z*-direction. In Fig. 4 (a) and (b), a fluid is bounded by two parallel, infinitely long plates. The lower plate is stationary, but the upper one moves horizontally in *x*-direction. Due to the disturbance from the moving upper plate, there will be fluid flow. The upper plate is pulled with a constant speed, *V*, in Fig. 4(a). In Fig. 4(b), the pulling force is specified instead of the speed.

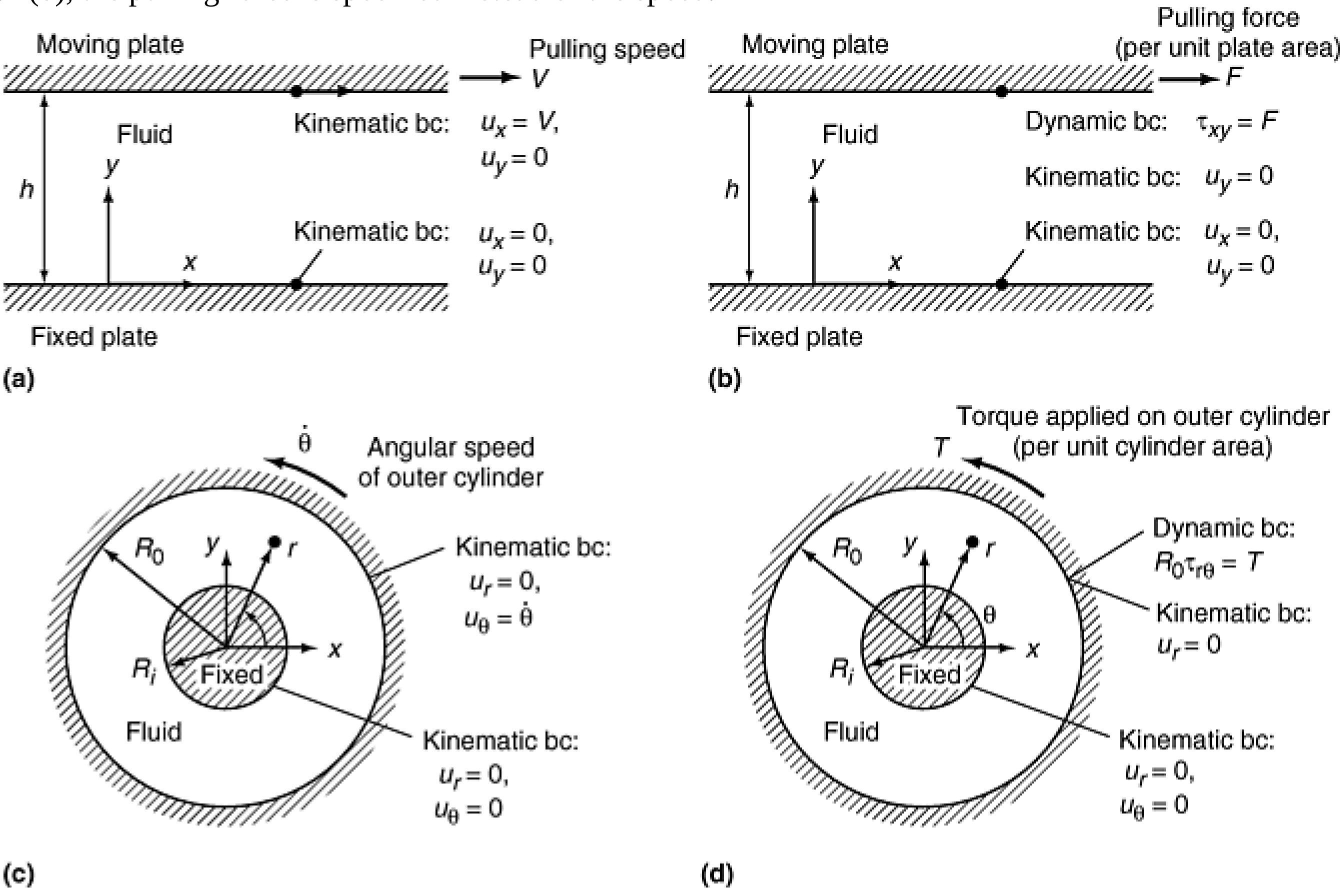

Fig. 4 Four example situations for different boundary conditions (bc). (a) Kinematic bc at the upper and lower boundaries of fluid flow within a rectangular channel. (b) The same as in (a), except that the pulling force, *F*, on the plate is specified instead of the speed. So, this bc on the upper boundary of (b) is dynamic. (c) Kinematic bc on the outer- and inner-cylinder boundaries of fluid flow within a concentric domain (R_o and R_i are the radii of the outer and inner cylinders, respectively, and *u* is the velocity). (d) The same as in (c), except that the torque, *T*, applied to the outer cylinder is specified instead of the angular speed. So, this bc on the outer boundary of (d) is dynamic.

The no-slip condition can be directly applied in Fig. 4(a). If the plates are impermeable (nonporous), there is no fluid flow in the normal directions on the plates, which can be written as $\mathbf{U}\cdot\mathbf{n} = u_y = 0$ at $y = 0$ and $y = h$, where $\mathbf{U}$ is the fluid velocity vector, and $\mathbf{n}$ is the normal vector on the plate. The tangential velocity component, $u_x = V$ at $y=h$, and $u_x = 0$ at $y = 0$, considering the no-slip condition. These are kinematic boundary conditions because they only involve the velocity field.

The boundary condition on the upper plate of Fig. 4(b) is a dynamic condition. The pulling force applied on the plate is specified. The pulling force per unit area, *F*, can be calculated as $\left(\int \tau_{xy}\middle| dx\,dz\right)$/(total plate area). In fact, this problem is a one-dimensional problem, because the velocity vector and stress tensor are functions of only *y*, not *x*. Hence, τ_{xy} is constant at $y = h$. The dynamic boundary condition is then $\tau_{xy} = F$.

In Fig. 4(c) and (d), the fluid domain is a concentric gap between a fixed inner cylinder and a rotating outer cylinder. Because the inner cylinder is fixed (it has a zero velocity vector), and the fluid will also have the same

zero velocity vector on that cylinder, according to the no-slip condition. In Fig. 4(c), the angular velocity of the outer cylinder is specified as $\dot{\theta}$. The fluid will also have the same angular velocity, or equivalently the same tangential velocity component, $u_\theta = \dot{\theta}R_0$.

In Fig. 4(d), the external torque is applied to the outer cylinder. The torque per unit area, T, is calculated as $\left(\int r\tau_{r\theta}|rd\theta\right)$/(total cylinder area) on the outer-cylinder surface where $r = R_0$. Here θ changes from 0 to 2π, and the total area is $2\pi R_0 L$, where L is the length of the cylinders in z-direction. This problem is only one-dimensional; the velocity and stress fields are functions of r only, hence $\tau_{r\theta}$ is constant at $r=R_0$. The corresponding dynamic boundary condition is then $R_0\tau_{r\theta} = T$.

Liquid-Liquid Interface. Consider the two immiscible fluids A and B within a rectangular channel, as shown in Fig. 5. The kinematic boundary conditions on the upper and lower plates are $u_{xB} = V$ at $y = h_A + h_B$, and $u_{xA} = 0$ at $y = 0$, respectively. Two more boundary conditions are needed at the liquid-liquid interface in order to uniquely solve this problem. For viscous fluids, the velocities are assumed to be continuous at their interface. $\mathbf{U}_A = \mathbf{U}_B$ in vectorial form, or $u_{xA} = u_{xB}$ and $u_{yA} = u_{yB}$ in scalar form at $y = h_A$. Considering the dynamic interactions of adjacent control volumes of fluids A and B, the viscous shear stress τ_{xy} must be continuous across the interface. Hence, $\tau_{xyA} = \tau_{xyB}$, which can also be written as $\mu_A\partial u_{xA}/\partial x = \mu_B\partial u_{xB}/\partial x$ at $y = h_A$ for Newtonian fluids.

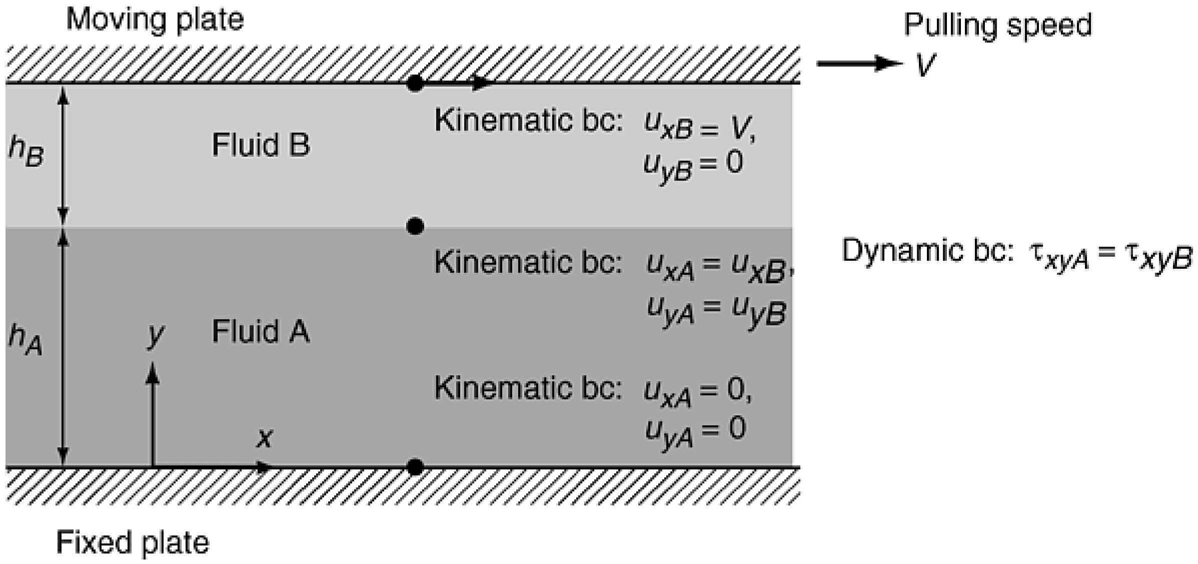

Fig. 5 Boundary condition (bc) at a liquid-liquid interface

The boundary conditions of mold filling during the resin transfer molding process are illustrated in Fig. 6. No leakage of resin along the wall is assumed, considering an impermeable mold wall. That corresponds to the normal component of velocity being zero:

$$\bar{u}_n = -\frac{1}{\mu}\left(K_{nn}\frac{\partial P}{\partial n} + K_{nt}\frac{\partial P}{\partial t}\right) = 0$$

where n and t denote the directions normal and tangent to the mold wall, respectively. However, the tangential velocity component is nonzero, allowing a slip on the wall. Pressure of resin is equal to the vent pressure, if it is directly connected to the vent. At the injection gate, either the pressure or the flow rate is specified.

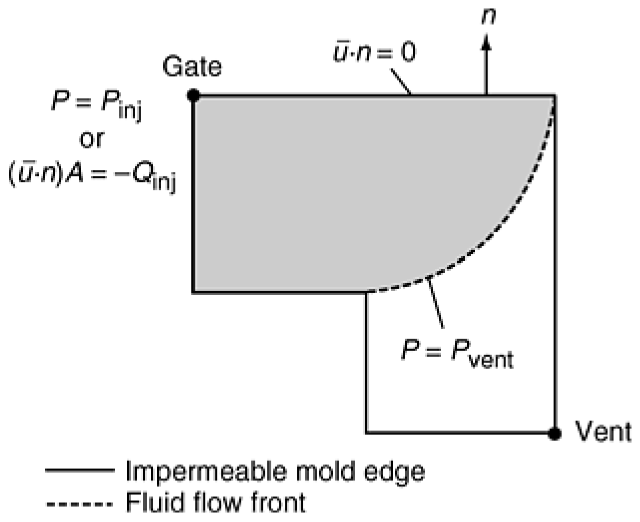

Fig. 6 Boundary conditions for a moving flow-front problem with Q_{inj} as the specified injection flow rate or P_{inj} as the specified injection pressure

Assumptions

In order to simplify the models, some assumptions are made. Certain assumptions can dramatically simplify a process model (Ref 1, 30). However, inappropriate simplifications can also lead to process behavior predictions that are not consistent with observations. Hence, it is important that the assumptions are well reasoned, based on experience, or validated with experiments. The common assumptions employed in one or more processes, depending on the phenomena of interest, are described in this section. These assumptions will not necessarily be employed for every process. For every phenomenon modeled, one should go through the exercise of justifying every assumption made to simplify the model.

Quasi-Steady State. Physically, a variable such as velocity, temperature, or pressure is in steady state. This means that from a stationary reference frame, the variable does not experience any change with time at that spatial location. Mathematically, steady state can be described by setting $\partial(\ )/\partial t = 0$. Quasi-steady-state assumption refers to approximating an unsteady or time- dependent flow with small inertial effects, as a succession of steady state flows. So, even if the problem contains time-dependent boundary conditions, one can solve it as a steady state problem at any instance of time, t. At that time, t, the boundary condition will be a constant value, so one can solve the steady state governing equation.

This is a reasonable approach if the momentum transfer from the boundary conditions is immediate and the material inertia plays an insignificant role. The kinetic viscosity v, usually governs the rate of momentum transfer. For polymers and polymer composites, this value is very high, as compared to water. The rate of momentum transfer can almost always be approximated as immediate at any instant in time. Another way to describe this is that when the viscosity is high and the process velocity is slow, the inertial effects will be insignificant.

Examples. A thermoplastic polymer is squeezed between two parallel disks with a constant force, F. It is desired to obtain the gap separation between the plates as a function of time. A quasi-steady-state assumption allows one to ignore the inertial terms in the momentum equation and solve the radial problem as a steady state problem at any time, t, for the instantaneous gap height. Other examples that use this assumption are the processes that simulate the mold-filling scenario. In these classes of problems, the solution domain in which one solves for the fluid pressure is bounded by the boundaries of the resin in the mold. The domain is bounded by the mold boundaries if the resin has reached the mold walls, and by the boundaries of the instantaneous resin front (also known as the flow front) if the resin has not reached the mold boundaries. After solving for the fluid pressure, one calculates the fluid velocities, advances the resin front based on the velocity field, and re-solves for the pressure for the new domain. This procedure is continued until the mold is filled. Thus the quasi- steady-state solution of the pressure is dependent only on the instantaneous material properties and the boundary conditions, which are functions of time.

Note that the justification of neglecting the transient terms in the equation of motion follows from the fact that the kinematic viscosity of polymers is high, and because the speeds are slow, the Reynolds number, which is

the ratio of inertia forces to viscous forces, is low. However, the thermal diffusivity of polymers is low, so the heat transfer is much slower, and one cannot always ignore the transient terms in the energy equation. Prandtl number, which is the ratio of momentum transfer to energy transfer, is very high for polymers, on the order of 100 or more. Thus, for nonisothermal processes, one usually cannot ignore the transient term in the energy conservation equation.

Fully Developed Region and Entrance Effects. When a system variable does not change along a certain direction, one proclaims that the variable is fully developed with respect to that direction. For example, if the temperature profile does not change along the *x*-direction, one can physically assume that the temperature is fully developed along the *x*-direction. Mathematically, one can express this condition as $\partial T/\partial x = 0$.

The assumption "fully developed flow and insignificant entrance effects" is widely used while developing process models for polymer and polymer composites processing. This assumption is again related to the rate of momentum transfer. The higher the kinematic viscosity, the faster the momentum transfer will be, and the sooner the velocity profile will develop.

Consider flow in a tube from a reservoir or from a pressure pot, as shown in Fig. 7. The entrance region of length, δ, is the region in which the flow profile is rearranging from plug flow to a parabolic profile for a viscous Newtonian fluid. Usually, this region is proportional to the diameter, *D*, of the tube and the Reynolds number, $\mathrm{Re} = UD\rho/\mu$, where *U* is velocity, ρ is density, and μ is viscosity:

$$\frac{\delta}{D} = 0.054\ \mathrm{Re}\ (\text{approximately}) \qquad \text{(Eq 4)}$$

If the Reynolds number is less than one, the entrance effects last for less than the tube diameter, and the assumption of fully developed flow will not influence the important physics or the solution.

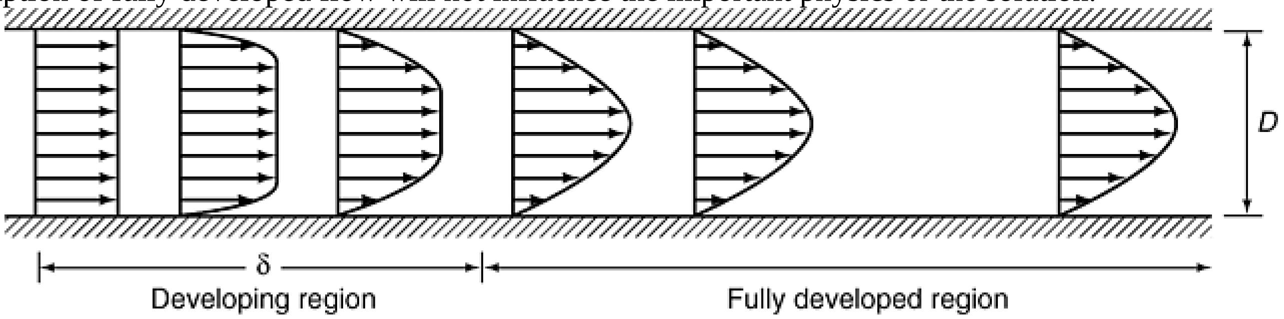

Fig. 7 Development of velocity profile

Similarly, if one wanted to assume a fully developed temperature profile along the flow direction, the following criteria need to be met:

$$\frac{\delta_t}{D} \cong (0.03\ \text{to}\ 0.04)\ \mathrm{Re}\ \mathrm{Pr} \qquad \text{(Eq 5)}$$

where δ_t is the length of the thermal developing region, and the Prandtl number is given by $\mathrm{Pr} = c_p\mu/k$, where c_p is specific heat at constant pressure, μ is viscosity, and *k* is thermal conductivity. In composites processing, this assumption is easy to justify for long tubes or long characteristic flow directions, but not for short tubes, because the Pr number can be on the order of 1000 for most materials. Also, if the temperature boundary condition is changing with time, a fully developed temperature profile cannot be easily justifiable. The other important number is the Graetz number, which relates the thermal capacity of the fluid to convection heat transfer. When it is small, one can assume that both the velocity and temperature profiles are developed in the direction of flow.

Fully developed flow is a common assumption used in polymer and composites processing, as compared to the fully developed temperature profile due to low Reynolds number flows. One of the most common situations in which the fully developed flow is used is in conjunction with the lubrication approximation. This allows one to simplify the equations of motion considerably, and retain the important physics of the flow in the process model.

Lubrication Approximation. Osborne Reynolds (Ref 30) coined the term *lubrication approximation* when he was addressing hydrodynamic lubrication analysis. The key requirements to apply this theory are that the flow should be viscous (the Reynolds number should be small), and the flow should take place in narrow gaps.

While processing composites, one usually is dealing with parts that are possibly meters in length and width, but only millimeters in thickness. Because they have low Reynolds number flows, lubrication analysis can be used to simplify the model.
Following is a review of how lubrication theory allows one to simplify the equations of motion for a Newtonian viscous material. The conditions that should be met before applying this analysis to a flow problem are:

- The material should be incompressible
- The flow should be isothermal
- The Reynolds number should be less than one (the inertial forces should be smaller than the viscous shear forces)
- The gap height should be very small compared to the in-plane dimensions
- If the gap height, *h*, is not a constant, it could vary very slowly with the in-plane dimensions. For in-plane dimensions *x* and *y*, dh/dx and $dh/dy \ll 1$.

An example is shown in Fig. 8. The parts manufactured by this process are about 2 to 3 mm (0.08 to 0.12 in.) in thickness (h_0) and can be as long as 1 to 2 m (several feet). One also assumes that the material does not slip at the surface of the walls. These two assumptions make it possible to effectively treat compression molding as a lubrication problem.

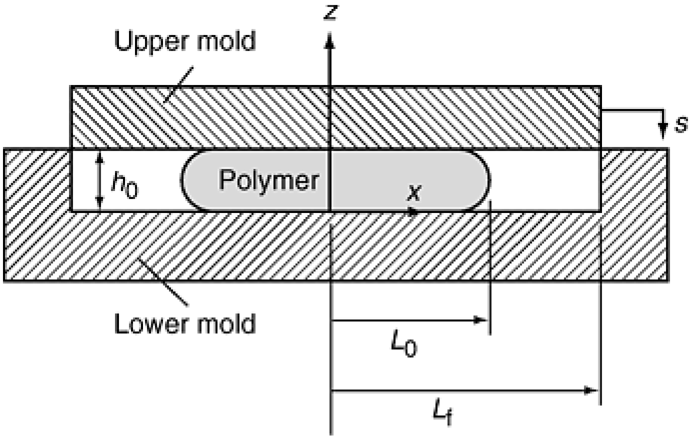

Fig. 8 Compression molding process can be modeled as a lubrication approximation, with $h \ll L$.

Thin Shell Approximation. If the no-slip at the boundaries is not satisfied, it may be difficult to justify the lubrication approximation. When there is full-slip, it is possible to model the flow as plug flow through the cavity thickness. For example, when Darcy's law (Ref 31) for flow of thermoset resins through a network of fibers is considered, one assumes a full-slip boundary condition along the mold surfaces. In such cases, the flow in the thickness direction can be ignored if:

$$\left(\frac{h}{L}\right)^2 \frac{K_h}{K_L} \ll 1 \qquad \text{(Eq 6)}$$

where *h* and *L* are the thickness and in-plane dimensions, and K_h and K_L are the permeabilities of fiber network in thickness and in-plane directions, respectively.

Experimental Validation

Almost all process models that are developed involve one or more assumptions, and many of them use constitutive or phenomenological equations to represent material behavior. Thus, it is important to check and see if the model predictions agree with experimental results.
If a simulation of a model has been developed, it can provide many details, such as the pressure and temperature distribution, and fiber orientation state at every location. An experiment can only measure finite quantities. Hence, the choice of which variables to measure, and where to measure them, becomes an important consideration.

There are many ways to validate a model. One may choose to monitor the history of just one of the governing variables in the experiment, or all of the field variables, and compare them directly with the predictions. For example, one may monitor the temperature of the resin at the midpoint of the mold as a function of time in injection molding process and compare it with the predictions from the nonisothermal simulations. Another approach may be to indirectly compare experimental findings with predictions. In curing a thermoset composite, one may monitor the final state of the cure after the composite is demolded by performing differential scanning calorimetry analysis on various samples cut from the fabricated composite (See the article “Thermal Analysis” in this Volume). The resulting cure distribution can be compared with the predictions of the model. A similar approach can be adopted for verification of the model for prediction of the crystallization state or fiber orientation state.

It is important to compare the proper variables when performing validation experiments. To validate the model for flow-induced fiber orientation, a simulation of injection mold filling is developed, assuming no variations in fiber concentration and fiber length distribution. A constitutive rheological model is used for stress- strain relationship, and fiber orientation is predicted. Next, the results are compared with the fiber orientation state measured from injection- molded samples. This is not a good validation of the flow-induced fiber orientation model, because in injection molding there are many other parameters that may have influenced the fiber orientation pattern. However, if one could create a suspension of fibers in simple shear flow, or other well-defined flows, and measure the orientation of the fibers in such flows, it would help validate the flow-induced fiber orientation model. Moreover, it would also elucidate the phenomena of fiber-fiber interactions, which could lead to refinement of the model (Ref 32).

Hence, the type of experiment is also an important factor in the validation studies of the formulated process model. Every process model usually consists of many phenomena and substeps, with assumptions at every sublevel. If possible, one should try to validate every submodel independent of the overall model. For example, in filament winding there are many submodels, such as thermochemical, fiber motion, stress, and void models. It will be useful to independently validate these models, rather than just comparing the final predicted mechanical properties with the measured properties. It is sometimes not feasible to validate every submodel, in which case one may want to consider indirect validation of some of the submodels.

It is crucial to validate the overall process model in addition to validating individual submodels, because this sheds light on the accuracy of the modeled interactions between the submodels. One may validate every submodel of the process model and assume that the process model is validated, but there may be assumptions about the interactions between the submodels that have not been verified. Thus, the validation of a process model is not complete until one also validates the final results with the predictions.

If the model predictions agree with the experiments, one has created a successful model that can be used for design, manufacturing, and control. One such example is shown in Fig. 9. The flow-front locations as predicted by the flow through porous media model for flow during resin transfer molding is on the right. A model experiment performed in a mold with transparent lid recorded the flow fronts seen on the left.

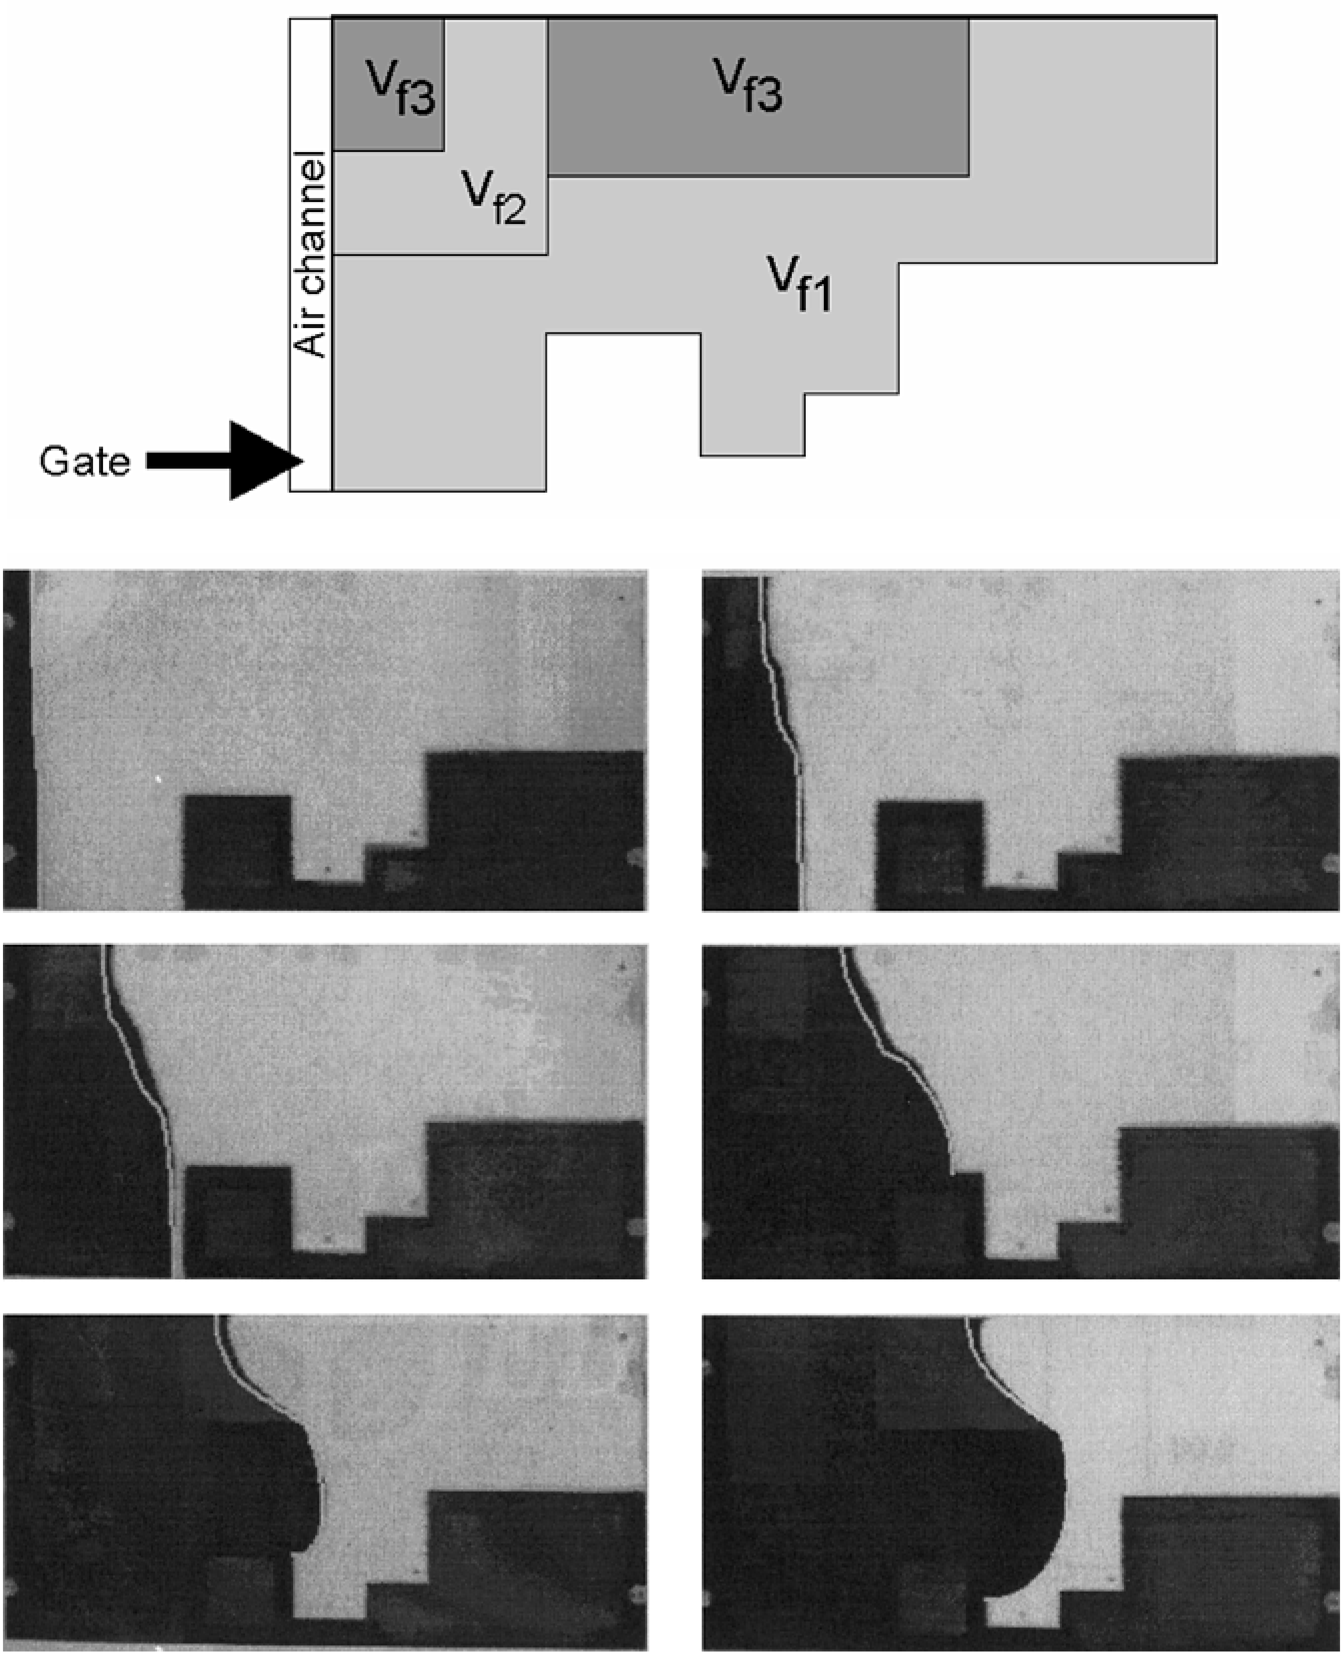

Fig. 9 Experimental validation of flow in an RTM. The mold configuration is shown at the top. The lower portion shows the numerically predicted flow fronts superimposed on the experimental images taken at 20 s increments. Source: Ref 33.

Reexamining the Parts of the Model

Reexamining Assumptions. In situations where the predictions and the experimental results do not agree, the modeler should revisit his assumptions and make sure the validation experiments honor those assumptions. The

modeler should have verified the simulation or the model with closed form solutions or with mesh refinements. Next, the modeler should question the constitutive law that is being used to represent the phenomena. Sometimes, the modeler can learn enough from the experiments to modify the law. For example, if the model is using a power-law fluid to represent the material behavior, and the experiment involves very low shear rates, the experimental results and predictions will not match. One may need to refine the model to using a Carreau fluid. In the same way, the fiber-fiber interaction may have been represented with a constant parameter in the flow-induced fiber orientation model. However, the model experiments may show that the expected orientation behavior is slightly different than the predictions. This may induce the modeler to think that the interactions cannot be constant under all fiber orientation states. One would expect the fiber-fiber interactions to be higher when the orientation state is in complete disarray (random) as compared to when all the fibers are aligned. Thus, the modeler may use this insight to improve the fiber orientation model.

Revisiting Laws. Usually the models can be improved or refined by including more material parameters. For example, in the cases suggested previously that included a switch from power- law to Carreau fluid, three parameters are needed instead of two. Similarly, if the fiber interaction parameter is made dependent on orientation, an additional equation may be needed that will allow this relationship to be determined. At other times, one may need to completely reformulate the constitutive law to accommodate the new phenomena being observed. For example, a random fiber preform clearly obeys Darcy's law, because it has been validated many times. However, some of the stitched or tightly woven fabrics have two scales of pores: very small ones between fibers, and large ones between fiber tows, as shown in Fig. 10 (Ref 33).

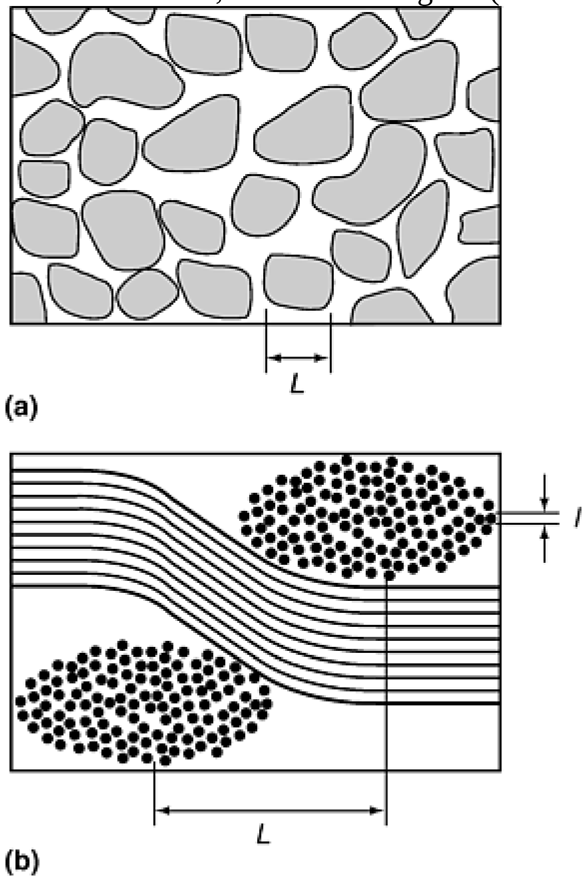

Fig. 10 Flow through porous media. (a) Schematic diagram of a simple porous medium exhibiting a single-length scale. (b) Schematic cross section of a woven fabric unit cell, demonstrating the dual-length scale porous medium

When the fluid impregnates these preforms, the pores between the fiber tows are filled at a much earlier time than the smaller pores between the fibers. This would require reformulation of the model, because it has been discovered that the saturation of the porous media with dual- length scale is not instantaneous, as in random preforms (Fig. 10a).

Reexamining Boundary Conditions. Sometimes the culprit may be the incorrect application of the boundary conditions, or the boundary condition may be unknown. If a convective heat- transfer boundary condition exists on the outside of the mold, one would need to specify a convective heat-transfer coefficient that itself requires a

constitutive law. One approach is to create validation experiments that do not use this boundary condition but use a specific temperature or heat flux.

Formulation of Models

Model formulations may vary, but they generally follow the plan outlined in Fig. 11 (Ref 5).

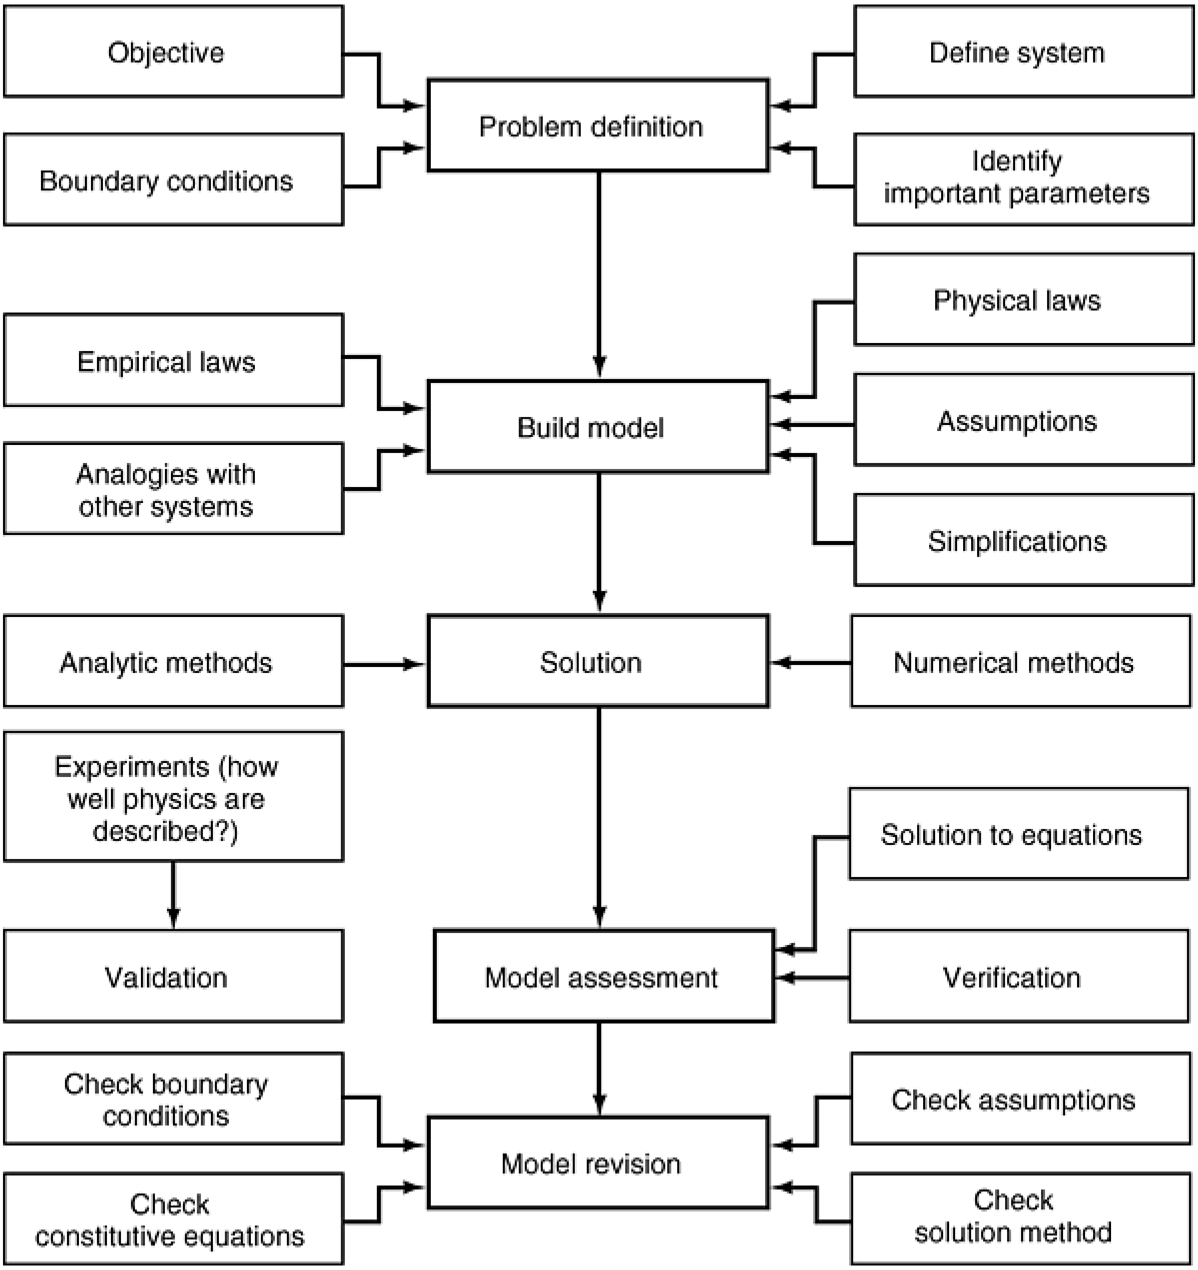

Fig. 11 Modeling flowchart

Problem Definition

The purpose of a model is to predict the behavior of a process for a range of inputs and conditions (Ref 34). Hence, one must define the physical process and its inputs. The physical process may not represent the complete composite manufacturing process, but may focus on a small aspect of the process during manufacturing. For example, in injection molding, mold filling is only one aspect of the manufacturing process. The model may treat the screw, the runner, and the spruce as only a source of fiber suspensions at a given flow rate. It is important to define the system that one is modeling and to draw a boundary around it. The other parts of the process, which can be modeled as other subsystems, can interact with the defined system by what they supply across the boundary (Ref 35).

The aim of the model should be defined, because it will influence what aspect of the model is emphasized. It is useful to identify the important responses of the process and what conditions and inputs should be represented. Depending upon the aim, different models for the same physical process can give different answers. For example, in processes such as RTM, some models merely relate the flow rate to the pressure. Others may provide detailed information about the flow-front locations in complex geometry. Still others may be limited to a few cavity shapes. Some models may even provide temperature histories and predict residual stresses. Models may only focus on the curing phase and ignore filling. Thus, there can be multiplicity of models for the same

process. The model one chooses will depend on what issues are important and how much time and effort one can devote to finding the answers.

Building the Mathematical Model

Once the system is defined and the important quantities are identified, one can build the model from physical laws, empirical and phenomenological observations, and/or from analogies with other systems. A mathematical model, which represents the physical process, describes the system behavior by a set of mathematical equations, with the quantities of interest as primary or secondary variables. Interactions between the chosen system and the surroundings are included as boundary conditions of the model.

Most composites manufacturing process models combine the fundamental physical laws of mass, momentum, and energy conservation with empirical observations, such as viscosity or permeability laws. The models can become complicated if one tries to include every known effect. The skilled modeler will try to simplify the model by making assumptions that will retain the important effects, while making it easier to solve the mathematical equations. Simplifying the model will reduce the number of parameters required. The results may be more easily understood.

As an example, RTM flow is important only in the in-plane direction when filling thin cavities, so one can simplify the governing equations from three dimensions to two (Ref 4, 15). To solve the equations, one needs to provide the permeability tensor. For the two-dimensional case, one needs only two principal permeability values, rather than three. The case for using a viscosity model is similar. A Newtonian fluid needs only one material parameter. However, if one chooses to use the Carreau fluid model, four material parameters must be determined. In addition, the equations are nonlinear and more difficult to solve.

Solution of the Equations

The formulated mathematical model may be a simple, ordinary differential equation with one independent variable and one dependent variable, or it may be a system of complicated and coupled nonlinear, partial differential equations with two or more dependent variables that rely on more than one independent variable. The simple equations could be solved analytically if appropriate boundary or initial conditions are specified. For models with partial differential equations to be solved in complex geometry, one can select standard numerical methods, such as finite difference, boundary element, or finite element analysis (Ref 36, 37, and 38). Special techniques may be required if the equations or boundary conditions are nonlinear, such as a moving boundary problem in the case of mold filling (Ref 39). The objective of the model also determines the method to be selected for solution, because the choice of numerical methods determines the time and cost of setting up and running a simulation. When implementing a numerical solution, it is important to consider pragmatic issues, such as reliability, portability, efficiency, and user interface of the computer software.

Model Assessment

Model assessment must consist of two parts: verification and validation.

Verification alludes to whether the selected method provides the correct solution to the formulated set of equations with the prescribed boundary conditions. One must always verify that the numerical technique does not have any programming errors or inconsistencies that can lead to inaccurate solution of the governing equations. If one has implemented a numerical solution, it can be compared to analytic or classical solutions for simplified geometry, or for steady state situations. If no analytic solution is available, one can refine the time step or the grid size over the domain and check for convergence of the solution. One can also perform global mass and energy balances over the domain to check if they are being conserved on a global scale.

Validation refers to how well the process model describes the physics of the selected phenomenon. Because assumptions were made, empirical relationships introduced, and boundary condition approximated, it is imperative to check that the important physics to be modeled are still retained in the model. Validation also allows one to check if any important phenomena have been missed in the process. At the same time, validation will uncover insignificant influences included in the process model that may not be necessary.

How does one validate a process model? The most common approach is with experiments. One can approach this at two levels.

First, to ensure the process model is capturing the correct physics, it is important to carry out a controlled laboratory experiment or a model experiment. If the goal is to validate the fiber orientation model due to flow in a Newtonian fluid, one could use a model fluid such as silicone oil and nylon fibers with tracer fibers to understand and record the orientation behavior. If the model results are compared directly with fiber orientation measurements taken from injection-molded plaques, other effects, such as viscoelasticity, fiber breakage, cooling of the polymer, and fiber clustering, may play a role in influencing fiber orientation in addition to the flow. Hence, it would be difficult to separate the influence due to flow on fiber orientation from these other effects that were not included in the process model.

Model experiments can many times reveal the underlying physics in a processing situation and block out the noise or deviations due to other effects. However, it is important to make sure that the noise is only noise and not an important effect in the process that the model is ignoring.

Although model experiments will provide useful information for validation of the “idealized model,” one still needs to know how well the “idealized model” represents the reality of the factory floor. The second level of experiments should mimic the manufacturing situation. One could have used random preforms in model experiments to demonstrate how well Darcy's law captures the physics of the flow in closed molds in thermosets processing. However, if stitched or woven preforms are the reinforcement choice in manufacturing, it is important to validate that these materials also exhibit Darcy's law, and if not, how far do they deviate from it. Questions such as “Is it necessary to develop a new model for such materials?” or “Can one estimate the error introduced due to the dual-scale nature of the preform?” will arise and need to be addressed.

Revision of the Model

If the model agrees with the experimental results, one has a successful model that can make useful predictions. However, in most cases there will be disagreement between the model and the experiments. It is important to methodically explore the possible causes of the discrepancy. First, one must check that the solution method used is not flawed. This requires looking for errors in the implementation of the solution method for the governing equations. Next, one must check if there are deficiencies in the model. The model may have used an erroneous assumption, inappropriate empirical law, a false hypothesis, an oversimplification, or inaccurate boundary condition. For example, if it is assumed that the fiber-fiber interactions during the flow are not important, and the experimental results do not agree, then reexamining this assumption in the model might be necessary. Thus, it is important to separate the deficiencies in the model from those in the numerical methods, because both of these are packaged into a computer program, and it is very easy to regard them as one entity.

Another simple cause of disagreement could be inaccurate characterization of material parameters. For example, in RTM, the model may use a constant value for the permeability of the preform in the mold. However, in the experiment, the material may exhibit large variations. The result is that the experimental fill times or inlet pressures will be very different from the predicted ones. Thus, the process model may be correct, but incorrect specification of material parameters can cause disagreements. It is also useful to make certain that the physics embedded in the process model is the physics being described by the experiment.

There is a common saying that when a modeler is presenting results from a model, nobody believes them, except for the modeler. However, when an experimentalist presents the results, everyone believes them, except for the experimentalist. Thus, it is important to make sure that the experiment was conducted under the same conditions assumed in the model. It is important that the laboratory methods and practices assure accurate and consistent results: no inaccurate calibration of the measurement probes, leakage of the resin, fluctuations in the flow rate, or temperatures that would make the experimental boundary conditions different than the ones assumed in the model. These could be the root cause of disagreement.

Models routinely disagree with experiments, and revisions should be considered as a natural and necessary component of the modeling approach. The revisions can include additional physics in the model to explain the observations made in experiments. The refined model will thus more closely mirror the physical process.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Introduction

COMPOSITE TOOLING is the making of tools from composite materials. Since the early 1980s the “black art” of making high-performance advanced composite molds and fixtures has evolved from company proprietary methods to more conventional industry standards. The advent of low-temperature curing prepregs for high-temperature service has changed the course of the advanced composite tooling industry. The ability to lay-up and process a production prepreg tool laminate directly on a master model or plug has greatly improved the accuracy of these tools, and at the same time eliminated the cost of producing expensive intermediate tools.

While prepregs are preferred for high-performance tooling, “wet lay-up” materials and processes are still used for many other applications. Modern lay-up methods and vacuum bagging techniques can be employed with long pot-life resins to achieve acceptable tool laminates. Many of the wet lay-up methods and techniques parallel those used to fabricate prepreg tooling, which is the primary focus of this article.

Tool designers have also begun to adopt methods of component designers. The integration of stiffening flanges and other molded features in the design of composite tools has greatly contributed to increased dimensional stability as well as vacuum and pressure integrity of the composite tools. The goal is to minimize weight while maintaining stiffness of the tool laminate, thus reducing the size and mass of any supporting substructure. The resulting tools will have desirable thermal properties and will be efficient in production.

Many of the principles outlined in this article are currently recognized as standard shop practice for designing and fabricating quality composite tools in today's modern tooling shops.

Louis C. Dorworth, Abaris Training Resources, Inc.

Advantages of Composite Tools

The primary advantage of composite tooling is that it is lighter than metal tooling. This weight advantage makes for ease of handling, transportation, and storage of composite molds and fixtures. In many cases, light-duty carts and tugs can be employed instead of heavy-duty overhead cranes and forklifts. Most small-to-medium-size composite tools can be lifted onto tables, carts, and racks without additional handling equipment. The lower thermal mass contributes to more desirable heating and cooling rates than metals.

Composite tool laminates are generally manufactured to a relatively constant thickness. This provides for an ideal thermal gradient in the part. Compared to a machined metal tool that may have a varying cross-sectional thickness, the composite tool heats and cools more evenly and thus provides a more uniform temperature profile when processing a composite part.

Carbon-fiber-reinforced tool laminates have a very low coefficient of thermal expansion (CTE) and can be manufactured to more closely match the CTE of a carbon-fiber part. This is most important when molding complex shapes. Glass-fiber-reinforced tool laminates have a greater CTE than carbon fiber laminates and should only be considered for use in molding composite parts with very low process temperatures, or if the geometry allows for thermal differential. (See Table 1 for comparative material properties.)

Table 1 Thermal properties of selected tooling materials

Material	**Specific gravity**	**Specific heat**		**Thermal mass**[a]		**Thermal conductivity coefficient**		Coefficient of thermal expansion

(a) Thermal mass is specific gravity times specific heat.

The lower thermal mass of the composites translates into energy savings for all molds that are heated.

The facilities and equipment necessary for fabricating composite tools are virtually the same as that required for other composite manufacturing. This makes it possible for most composite component manufacturers to make their own tool laminates in-house. A substantial cost savings can be realized.

Another advantage of composite tooling is the relative ease of fabrication and duplication. Tool laminates can be laid-up on compound contours and complex shapes without much difficulty. Additionally, duplicate molds can be made off of the same model with precision and accuracy. This is a real benefit when multiple molds or fixtures are required for production. The turn- around time for a set of composite tools can be significantly less than for a set of machined metal tools of the same size and shape.

Louis C. Dorworth, Abaris Training Resources, Inc.

Disadvantages of Composite Tools

Composite tools have less durability and damage tolerance than metal tools. The biggest complaint throughout the advanced composite industry is that composite molds begin to lose their ability to maintain vacuum and/or pressure integrity. This problem can be attributed to several factors:

- The tool laminate is usually thermally cycled in production. This causes the resin to microcrack and eventually creates a path for vacuum or pressure leaks. This is primarily attributed to the difference in CTE between the resin matrix and the fiber reinforcement. Certain woven forms, such as large yarn or plain weave fabrics, are more prone to this problem because they have large, open areas at the intersecting yarns that are either void- filled or resin-rich. (See Fig. 1 and 2 for fabric void potential.)
- The use of knives or other sharp objects against the tool surface by the operator during the part lay-up can created fine scores in the resin layer at the surface of the mold, which contributes to the degradation of the laminate. This can be further aggravated when the part mechanically sticks to the scored surface upon demolding. Subsequently, the surface is fractured.
- Composite tooling can easily be damaged during transportation and should be handled using extreme care. Flexing the tool laminate or impacting the edges of the tool during transportation can propagate the internal microcrack path, leading to an increased leak rate.

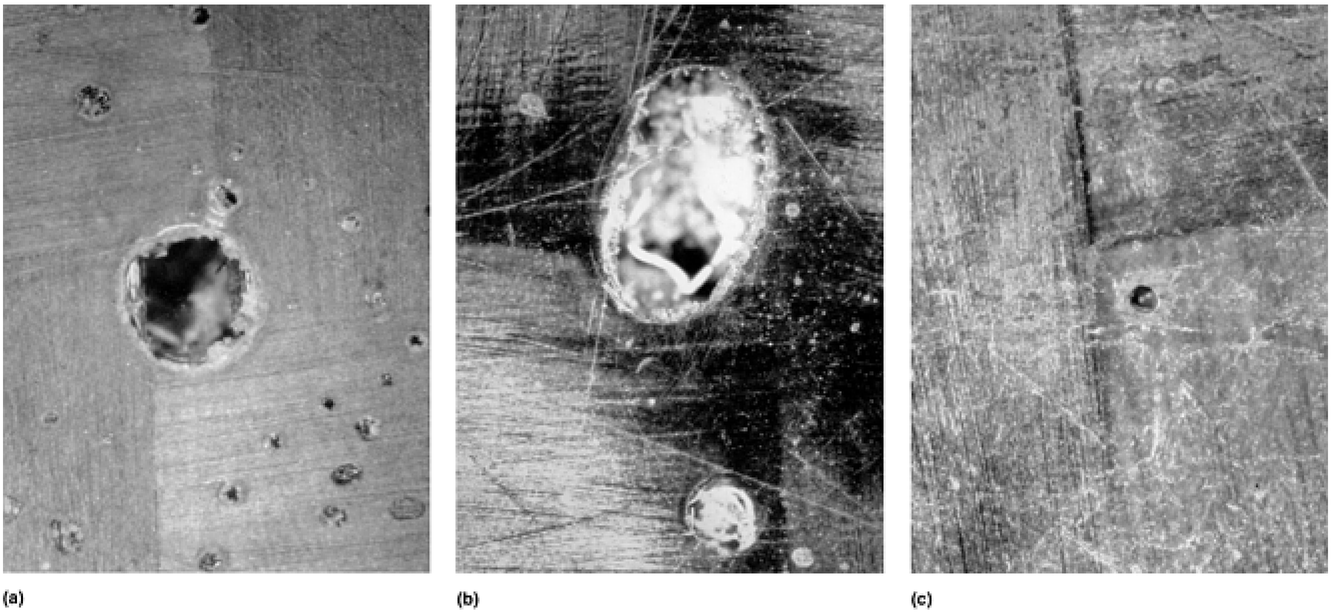

Fig. 1 Fabric influence on void potential. (a) 3K plain weave (b) 12K-2×2 basket weave (c) 6K-5HS satin carbon weave. 50×

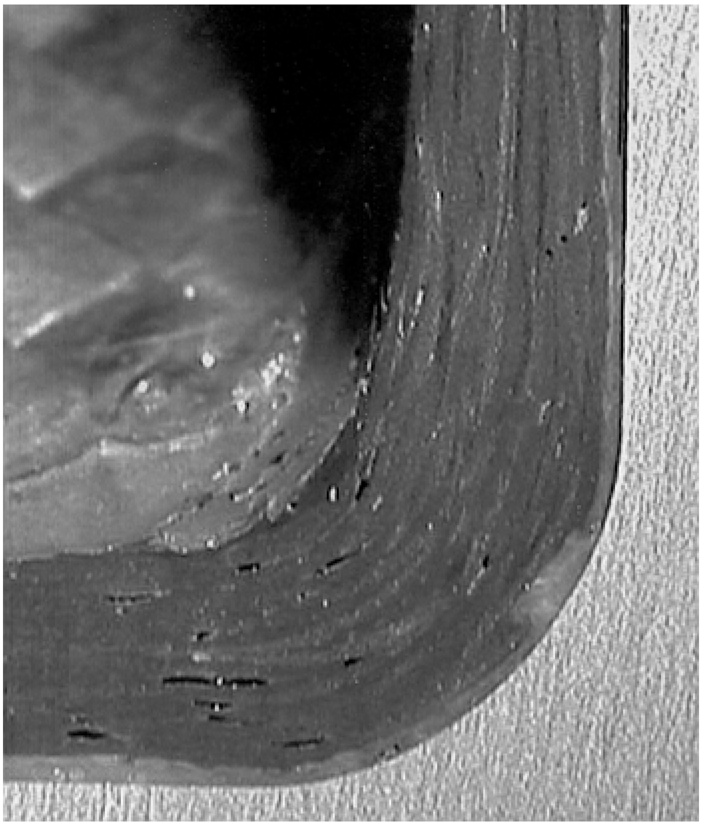

Fig. 2 Typical inner-laminar voids found in a laminate made with 3K plain weave carbon fabric. 200×

Another disadvantage to composite tools is that they are not easily altered or adjusted. While it may be possible to weld or machine a joggle or other detail on a metal tool surface, this kind of alteration is more difficult with composites. Any machining of the molded tool surface is sure to lead to decreased vacuum or pressure integrity. Modifying the composite tool surface once it has initially been molded is not recommended.

Designing composite tools with turnbuckles and other adjustment devices has proven to be difficult. The composite tool laminate is not ductile like metal. When bending a composite laminate, there are fibers in tension at the outer layers and fibers in compression at the inner layers. These forces can lead to dimensional distortion, especially at elevated temperatures. (The shape that was achieved at room temperature is not necessarily maintained at higher temperatures.) In addition, the flexing of the matrix of the laminate while performing adjustments can cause cracking and contribute to the potential for vacuum or pressure leaks.

The quality of a composite tool is highly dependent on proper selection of materials and workmanship. Outside procurement of good quality composite tooling can be problematic due to the myriad of materials and processes available. One vendor's idea of a high-performance composite tool may differ greatly from that of another. A tool built using wet lay-up/ vacuum bag techniques cannot compare to a tool made with prepregs in an autoclave process. It is wise to provide detailed tooling material and process specifications to all potential vendors, so that there are no questions as to what is expected in the tool construction.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Tool Design Overview

When designing composite tools, the first things to consider are the service requirements. Certain conditions such as the service temperature, vacuum/pressure requirements, production rate (number of parts or uses

required), and engineering dimensional tolerances for the final part or assembly will govern the decision as to what materials and processes are used when building a tool laminate.
The actual tool laminate construction, including thickness, ply count, and orientation of fibers are determined by the size and shape of the tool as well as the static and dynamic loads that will be applied to the tool in service.
A shape that is inherently self-supporting, such as an aircraft radome (Fig. 3), can easily be designed with integrated stiffening features and less substructure. Shapes that are flat or slightly contoured usually require more detailed analysis of added stiffness and more substantial substructure to provide rigid support.

Fig. 3 Aircraft radome tooling. Courtesy of The Advanced Composites Group, Inc.

Incorporating “bathtub” flanges that surround the tool laminate can be of great benefit to integrating stiffness into the design, especially for smaller molds and fixtures. Adding reverse flanges about the periphery so that the tool laminate does not directly sit on the edge will increase its durability (Fig. 4).

Fig. 4 Integral stiffening flanges

Simple add-on protective devices can preserve the integrity of a tool laminate. For example, the placement of an extruded rubber edge-guard material around the periphery of the tool laminate can protect the edge from minor impacts in production, such as contact with belt buckles.
Molded index fingers or locator buttons can be included in the design to provide accurate location for subsequent trimming, drilling, or assembly tools (Fig. 5). The use of standardized molded locators can improve vacuum and pressure integrity in high-performance tooling. Drilled locators and potted bushings or pins in these tools can lead to premature degradation of the tool laminate and often present maintenance problems in service.

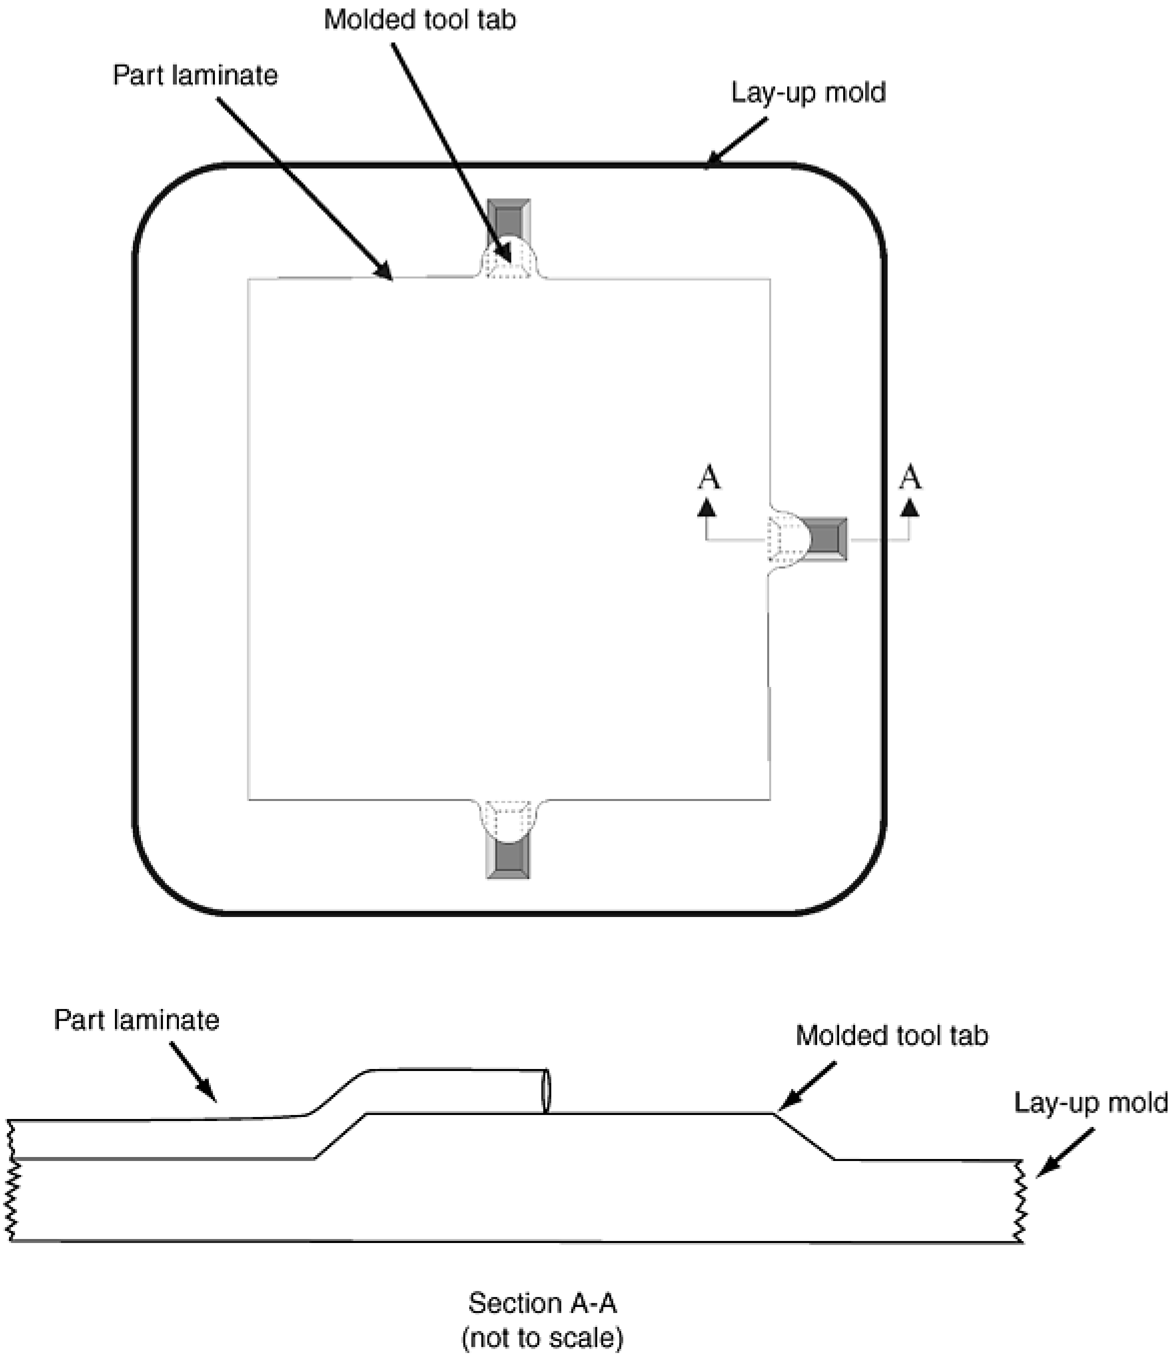

Fig. 5 Molded locator features

Integrated bushings or pins can be molded in place, however these types of locators can also be problematic at elevated temperatures. If tooling holes and pin locations are necessary in the final part, drilling them from a secondary fixture may be more accurate. Care must be taken to account for thermal expansion when designing locator or index features so as to ensure proper part location in subsequent tools.

Provisions for wedging or otherwise extracting the part from the tool should also be considered at the design stage. Many composite tools and parts are designed with little or no thought about this issue and are subsequently damaged during the demolding process.

The final tool design may include a secondary structure, frame, or cart that may or may not be attached to the tool laminate. There are many concepts for design of substructure, from simple, light tubular or monocoque designs to heavier “eggcrate” structures. Additional features such as V-groove wheels for the autoclave rail track, or permanent vacuum bag/plumbing might be necessary to accommodate production-specific requirements.

Calculating differential linear thermal expansion is required for determining tooling hole and pin locations and for design of secondary structures when materials with differing CTE are used and the temperature will be cycled.

The coefficient of linear thermal expansion is symbolized α_l, and $\alpha_l = L/L$ per degree, where ΔL is a change in length. The change in length is therefore:

$$\Delta L = \alpha_l \cdot L \cdot \Delta T$$

where ΔT is the change in temperature.

The preferred units for α_l are 10^{-6}/K (SI) and 10^{-6}/°F (U.S. customary). Values can be converted using the factors shown below:

To convert	**To**	Multiply by
10^{-6}/K	10^{-6}/°C	**1**
10^{-6}/K	10^{-6}/°F	**0.55556**
10^{-6}/°F	**10^{-6}/K**	**1.8**

Example 1: Calculating the Differential Thermal Expansion for an Aluminum Substructure. An aluminum substructure of 122 cm (48 in.) is heated from an ambient temperature of 21 °C (70 °F) to the processing temperature of 177 °C (350 °F), so the change in temperature is 156 °C (280 °F). A typical CTE for this aluminum is 23.2 × 10^{-6}/K (12.9 × 10^{-6}/°F). Calculating the ΔL in SI units:

$$\Delta L = (23.2 \times 10^{-6}) \cdot 122 \cdot 156$$

$$\Delta L = 0.442 \text{ cm}$$

Calculating the ΔL in U.S. customary units:

$$\Delta L = (12.9 \times 10^{-6}) \cdot 48 \cdot 280$$

$$\Delta L = 0.173 \text{ in.}$$

Example 2: Calculating the Differential Thermal Expansion for a Carbon Fiber Reinforced Plastic (CFRP) Mold. A CFRP mold also 122 cm (48 in.) in length is subjected to the same thermal cycle as in Example 1. The CTE of the CFRP in the direction of interest is 3.6 × 10^{-6}/K (2.0 × 10^{-6}/°F). Calculating the ΔL in SI units:

$$\Delta L = (3.6 \times 10^{-6}) \cdot 122 \cdot 156$$

$$\Delta L = 0.069 \text{ cm}$$

Calculating the ΔL in U.S. customary units:

$$\Delta L = (2.0 \times 10^{-6}) \cdot 48 \cdot 280$$

$$\Delta L = 0.027 \text{ in.}$$

It should be noted that the CTE for composite tooling depends on the ply orientation.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Master Model or Pattern Design

The master model or pattern from which the tool laminate is to be made must provide for all the tool features, such as the molded flanges, locators, and indexes. It must also provide a suitable quality surface and be capable of withstanding the process conditions the tool laminate will require. The heat transfer capability and the service temperature of the model or pattern must be considered when processing at elevated temperatures. The model or pattern surface should not leak when subjected to vacuum or autoclave pressure or deform when heated. A pre-lay-up vacuum and/or pressure check is necessary prior to committing materials to the model surface.

Appropriate draft angles should be designed into the model or pattern to ensure ease of parting when the tool laminate is later removed. Pre- positioned wedges or wax strips along the parting planes of the model or pattern

may also be considered to minimize forces when demolding the tool laminate. This forethought can improve the final quality of the tool laminate.

Locations for removable fences or planks should be included on the model or pattern when multi-piece tools are to be built. Parting planes can include molded self-alignment features and be designed to minimize difficulties in tool fabrication and subsequent manufacturing.

Designing flat surfaces, flanges, or parting planes on or parallel to the primary *X*, *Y*, or *Z* axis planes can be useful for rigging or setup of the subsequent tooling that is made from the model or pattern. Various materials can be considered for construction of the master model. Cast polyurethane or epoxy tooling planks can be bonded together and numerical control machined to shape. Other materials, such as wood, metal, plaster, and foam, have also been used for this purpose. The choice of materials is often determined by the capabilities of the shop and their familiarity with the material.

The master model or pattern may require the application of a surface sealer, and assuredly, a mold release agent prior to molding. The materials selected for sealing and releasing the model or pattern should be tested and deemed compatible with the resin system to be used in the construction of the tool laminate.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Fiber and Fabric Selection

E-glass and high-strength carbon-fiber fabric reinforcements are typically used in the construction of rigid tool laminates. On the basis of cost per weight, E-glass is the less expensive of the two materials; however, E-glass is heavier (2.55 g/cm^3) than carbon (1.76 g/cm^3) and is less stiff. Laminates made with E-glass have a higher CTE and thermal mass than laminates made with carbon fiber (Table 2). Aramid fibers are usually not used for solid laminate tools. Aramid-fiber- reinforced elastomeric products are available for use in flexible and semirigid tool fabrication.

Table 2 Resin temperature comparison

Resin	**Cure temperature**		Service temperature	
	°C	**°F**	**°C**	°F
Polyester	RT–121	RT–250	60–140	**140–285**
Vinyl ester	RT	RT	49–149	**120–300**
Epoxy	RT–177	RT–350	65–191	**150–375**
Bismaleimide	177–288	350–550	204–316	**400–600**
Cyanate ester	**121–177**	**250–350**	**93–288**	**200–550**

RT, room temperature

Long fiber fabric forms are preferred over short, random fiber (mat) materials for construction of high-performance tool laminates. Long fiber fabrics offer greater stiffness and strength. Unidirectional materials are generally not used in the construction of composite tool laminates. The incorporation of unidirectional layers in shear-web stiffeners or bathtub flanges may be useful, however.

The most popular fabric styles used in advanced composite tooling are twill, plain, and satin weaves. The plain and twill weave fabrics generally have a lower yarn count per inch than satin weaves. This makes the plain weave one of the least expensive fabric styles. The trade-off is that the plain weave is less drapable than the twills or the satin weaves, while providing less fiber load per ply. Another disadvantage of plain weave fabrics compared to the satin weaves is that they have a greater number of open areas at the intersecting yarns that are either void-filled or resin-rich (Fig. 1 and 2).

While helpful in quickly building thickness, the use of heavy double satin, 2 × 2 basket, modified plain, and leno weaves is discouraged for use in high-performance tool lay-ups because these materials tend to produce laminates with a very high resin and void content.

Louis C. Dorworth, Abaris Training Resources, Inc.

Fiber and Fabric Selection

E-glass and high-strength carbon-fiber fabric reinforcements are typically used in the construction of rigid tool laminates. On the basis of cost per weight, E-glass is the less expensive of the two materials; however, E-glass is heavier (2.55 g/cm^3) than carbon (1.76 g/cm^3) and is less stiff. Laminates made with E-glass have a higher CTE and thermal mass than laminates made with carbon fiber (Table 2). Aramid fibers are usually not used for solid laminate tools. Aramid-fiber- reinforced elastomeric products are available for use in flexible and semirigid tool fabrication.

Unidirectional materials are generally not used in the construction of composite tool laminates. The incorporation of unidirectional layers in shear-web stiffeners or bathtub flanges may be useful, however.

The most popular fabric styles used in advanced composite tooling are twill, plain, and satin weaves. The plain and twill weave fabrics generally have a lower yarn count per inch than satin weaves. This makes the plain weave one of the least expensive fabric styles. The trade-off is that the plain weave is less drapable than the twills or the satin weaves, while providing less fiber load per ply. Another disadvantage of plain weave fabrics compared to the satin weaves is that they have a greater number of open areas at the intersecting yarns that are either void-filled or resin-rich (Fig. 1 and 2).

While helpful in quickly building thickness, the use of heavy double satin, 2 × 2 basket, modified plain, and leno weaves is discouraged for use in high-performance tool lay-ups because these materials tend to produce laminates with a very high resin and void content.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Surface Coat and Surface Ply

The use of surface coat resins are typical in wet lay-up construction but may or may not be required for prepreg tool laminates. Prepreg surface ply materials have been developed for use in non-autoclave and vacuum bag tool laminate construction by at least one prepreg manufacturer. The prepreg surface ply is preferred in lieu of a surface coat with that system because it provides more uniform resin content with a higher fiber volume at the tool surface. Surface coat resins are generally not required for autoclave- cured tool laminates.

If surface coat resins are to be used in the construction of high-performance laminates, then application of a thin, consistent layer is crucial. One to two layers, totaling up to 0.5 mm (0.02 in.) thick is recommended. Thicker applications can lead to cracking and crazing of the surface when exposed to elevated temperatures.

To control the surface coat resin thickness, laminators estimate the area to be covered and calculate how much resin is necessary to cover the area at the prescribed thickness. Often, epoxy surface coats are applied by using hand squeegees and short bristle brushes to uniformly distribute the resin. Polyester surface coat resins are often sprayed on because they can be reduced to a spray-on consistency without affecting the surface quality.

As with any resin interface in the laminate, it is imperative that the surface coat resin be chemically active when the next layer is applied. Usually this means that the resin is allowed to partially gel and devolatilize prior to the application of the next layer. Timing the interface is critical to achieving a good bond.

Composite Tooling

Louis C. Dorworth, Abaris Training Resources, Inc.

Tool Laminate Construction Techniques

Precise lay-up of the composite tool laminate is the key to making a good production tool. A carefully laid-up laminate, employing much attention to detail, will result in a high-quality mold or fixture that resists leaks and will perform for many cycles.

As with other composite structures, it is recommended that a basic quasi-isotropic, balanced, and symmetrical laminate using 0º, 90º, +45º, and–45º angles of orientation be designated in most cases. For larger-sized tools, using either wet lay-up or prepreg processes, plies are generally cut into conveniently sized rectangles or “tiles” to make the lay-up more manageable. These tiles are cut with the warp yarns running in the long direction and then laid-up in such a manner that the warp yarns (or the length of the rectangle) match the orientation requirements for each layer.

It is accepted practice to overlap the finer (face) plies approximately 2 to 10 mm (0.08–0.4 in.) at all splice joints. The subsequent bulk plies are then butt spliced. Joint locations are then offset a minimum of 25 mm (1 in.) for each subsequent ply. Gaps between the butt joints can be filled with additional yarns if required to maximize fiber volume and to reduce the potential for voids or resin-rich pockets in the laminate.

Great care is taken to prevent bridging of the fibers in tight corners or joggles, both during lay- up and through subsequent processing. A good rule is to disallow continuous fibers through inside radii by splicing each layer at or near the corner. The use of separate 25 to 50 mm (1–2 in.) wide strips at these locations can aid in reducing bridging. The splice locations for these strips are typically alternated every ply so that no two adjacent plies are spliced in the same place.

Vacuum debulking is somewhat labor intensive but the benefits justify the labor involved in performing this operation. The use of a perforated release film, bleeder/breather materials, and a vacuum bag to debulk plies at selected intervals is one of the most valuable methods of reducing inner-laminar defects. Debulking every ply in the tool laminate stack allows the laminator to inspect every layer in-process. If there are any defects, such as small bridges in tight corners, gaps between butt-spliced pieces, or other abnormalities, these problems can be fixed prior to the application of additional layers.

It is important to be mindful of the working time or out time of the materials used in the construction of the tool laminate so that each layer or series of layers is applied within its recommended time. This will assure the best possible bond between each layer. For larger tools, if this is not possible, a portion of the laminate stack may be laid-up and partially processed prior to the completion of the lay-up. When this situation occurs, proper preparation of the previous surface is mandatory prior to proceeding. The use of a (non-release-treated) peel ply on the surface, then removed and followed by a careful scuff with a fine abrasive buffing pad is recommended to energize the backside surface prior to bonding. The surface should be cleaned and free of dust before additional layers are applied.

When using a wet lay-up process, an “interface coat” of laminating resin should be applied to the cleaned surface before proceeding. With prepreg materials, an interface coat is typically not necessary. (Consult the specific prepreg material manufacturer for recommendations.)

The final vacuum bag, bleeder, and breather stack should be designed to accommodate the materials and processing conditions to be used for curing the tool laminate. For example, a prepreg laminate with a net resin content that will be cured in the autoclave may require a “no- bleed” schedule that involves a release film layer sealed at all edges. It may also need to be covered with a thick, non-woven breather layer within the bag. A wet lay-up laminate with a high resin content, which is to be cured in an oven or under vacuum bag conditions at ambient temperatures, may require a porous peel ply, a bleeder layer, a separator film, and a breather layer within the vacuum bag.

Louis C. Dorworth, Abaris Training Resources, Inc.

Curing and Demolding

Depending on the resin system, curing may require allowing the laminate to sit at room temperature for a number of hours or days, or curing may occur in an oven or an autoclave at elevated temperatures. It is advisable to follow the resin manufacturer's instructions without deviation. Shortcutting the cure cycle can lead to a loss of structural and/or thermal properties in the tool laminate. Accelerating the cure with higher than recommended temperatures can also be detrimental. Generating an exothermic reaction in excess of the resin capabilities can lead to excessive shrinkage, reduced cross-linking, and/or microcracking within the laminate.

It is imperative that the initial cure be complete before the tool laminate is demolded. Often, low-temperature curing, high-temperature service resin systems require an initial cure cycle followed by an elevated temperature postcure cycle. The postcure is usually done after the substructure has been attached and the tool laminate is demolded from the model or pattern. This is called a “free-standing postcure.” Because the resin system is weak and not entirely cross- linked prior to postcure, it can easily be damaged if flexed or impacted at this time. For this reason, extreme care should be taken to prevent excessive force on the tool laminate when demolding.

Louis C. Dorworth, Abaris Training Resources, Inc.

Cutting and Trimming

Any cutting or trimming of the tool laminate should be done only after it has been cured and/ or postcured. For mold-quality tool laminates it is recommended that the lay-up be done in such a fashion that the postprocess trimming be limited to grinding or sanding off the sharp edges around the periphery. The vibration and heat generated during conventional machining operations can greatly affect the resin matrix at the edges of the tool laminate. This can lead to premature leaks in vacuum integral tool laminates.

If cutting or trimming is required, then the use of a high-speed circular saw or cutting wheel is preferred over a reciprocating saw. Carbide or diamond abrasive-coated steel blades work best for cutting carbon and glass-reinforced tool laminates. Waterjet cutting of the tool periphery might also be considered if available.

Substructure Design

Normally the direct substructure is built using the same or similar materials as that used in the construction of the tool laminate. Solid laminate panels or tubes are preferred over honeycomb- paneled substructures, because they are generally more durable.

If the tooling is to be used at elevated temperatures, then any potential differential thermal expansion between the tool laminate and the substructure should be examined. Dissimilar materials can be destructive at elevated temperatures if tied directly to the tool laminate. Some tool designers, however, have successfully used dissimilar materials such as steel framework, with advanced composite tool laminates by creating limited attachment points (Fig. 6).

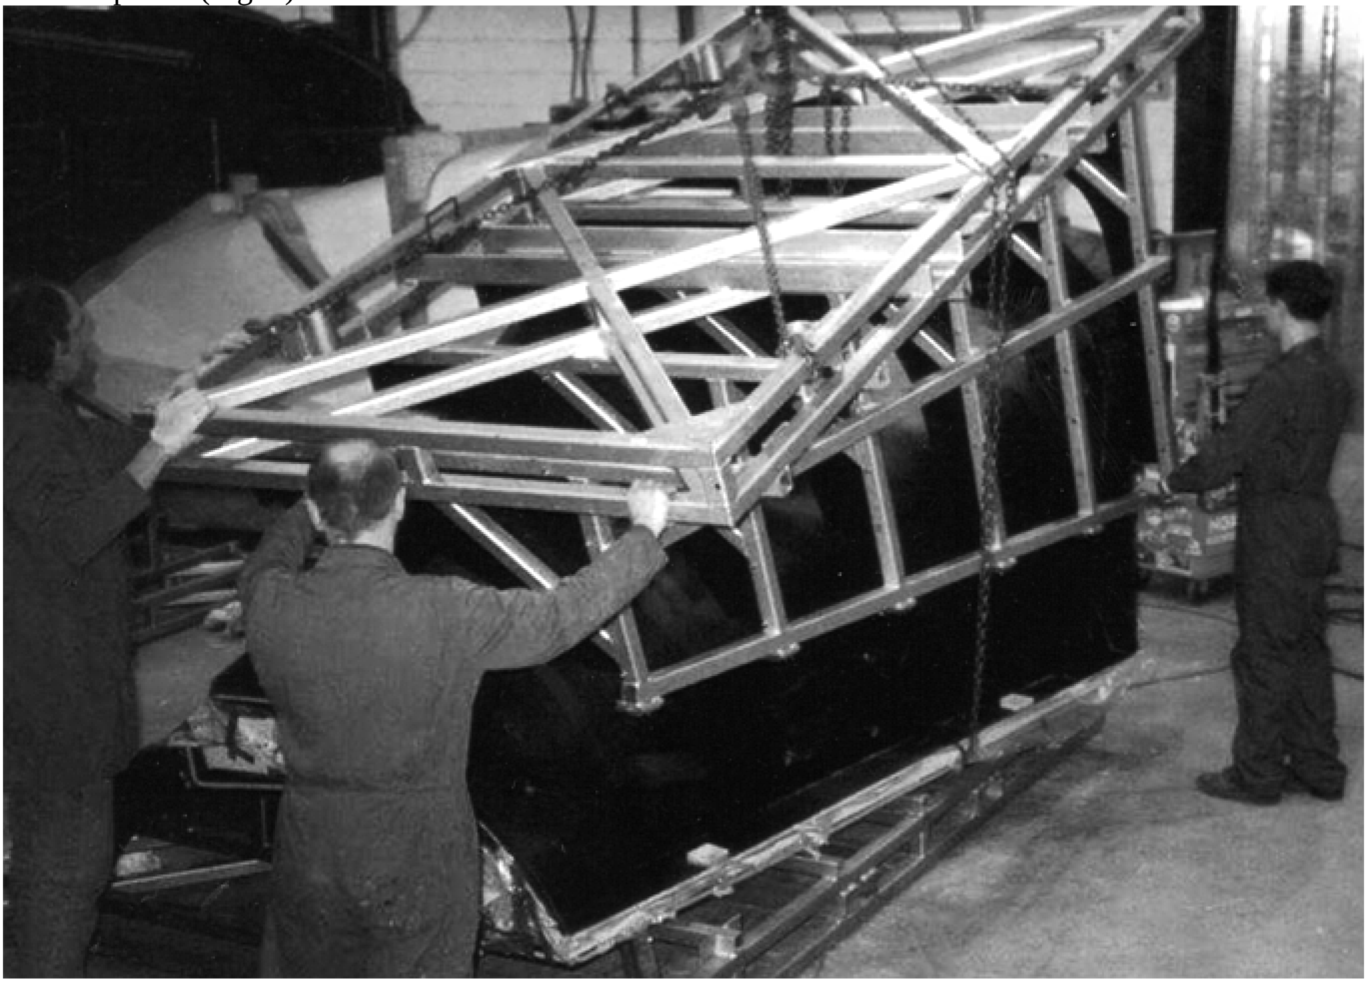

Fig. 6 Steel substructure attached to composite tool laminate. Courtesy of The Advanced Composites Group, Inc.

The best substructure designs provide rigid support for the tool laminate with the minimal addition of weight and mass. The conventional eggcrate designs of yesterday have come under examination as being inefficient and costly. Tool designers today are getting away from the old “box-crate” designs and are instead using smaller-sized “box-trussing” techniques (Fig. 7) or modular, tubular structures.

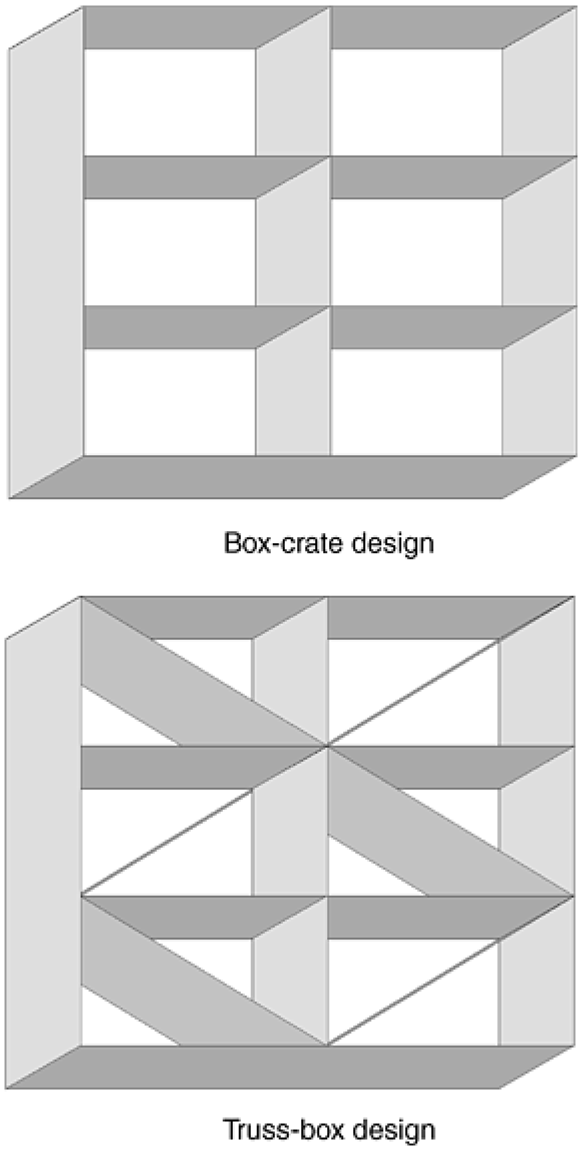

Fig. 7 Conventional box-crate vs. truss-box design

Some of the most efficient designs tie the box- truss type components to the integrally molded bathtub flanges of the tool laminate. The cross supports in this design are attached with strips of resin-impregnated cloth to the inside surface of the molded flanges at the base. These cross supports are typically only 25 to 50% of the height of the molded flange and may post up to the backside of the tool laminate as required to provide interim stanchions.

Another popular and effective substructure design includes the use of square or rectangular composite tubular components that are fastened and bonded together using factory-molded corners, tee fittings, and flat gusset plates. The modular design of these tubular structures makes construction fast and easy with minimal material waste. Like the box-truss-bathtub design, “spaceframe” tubular structures promote good airflow around the tool for elevated temperature processing in the oven or autoclave (Fig. 8).

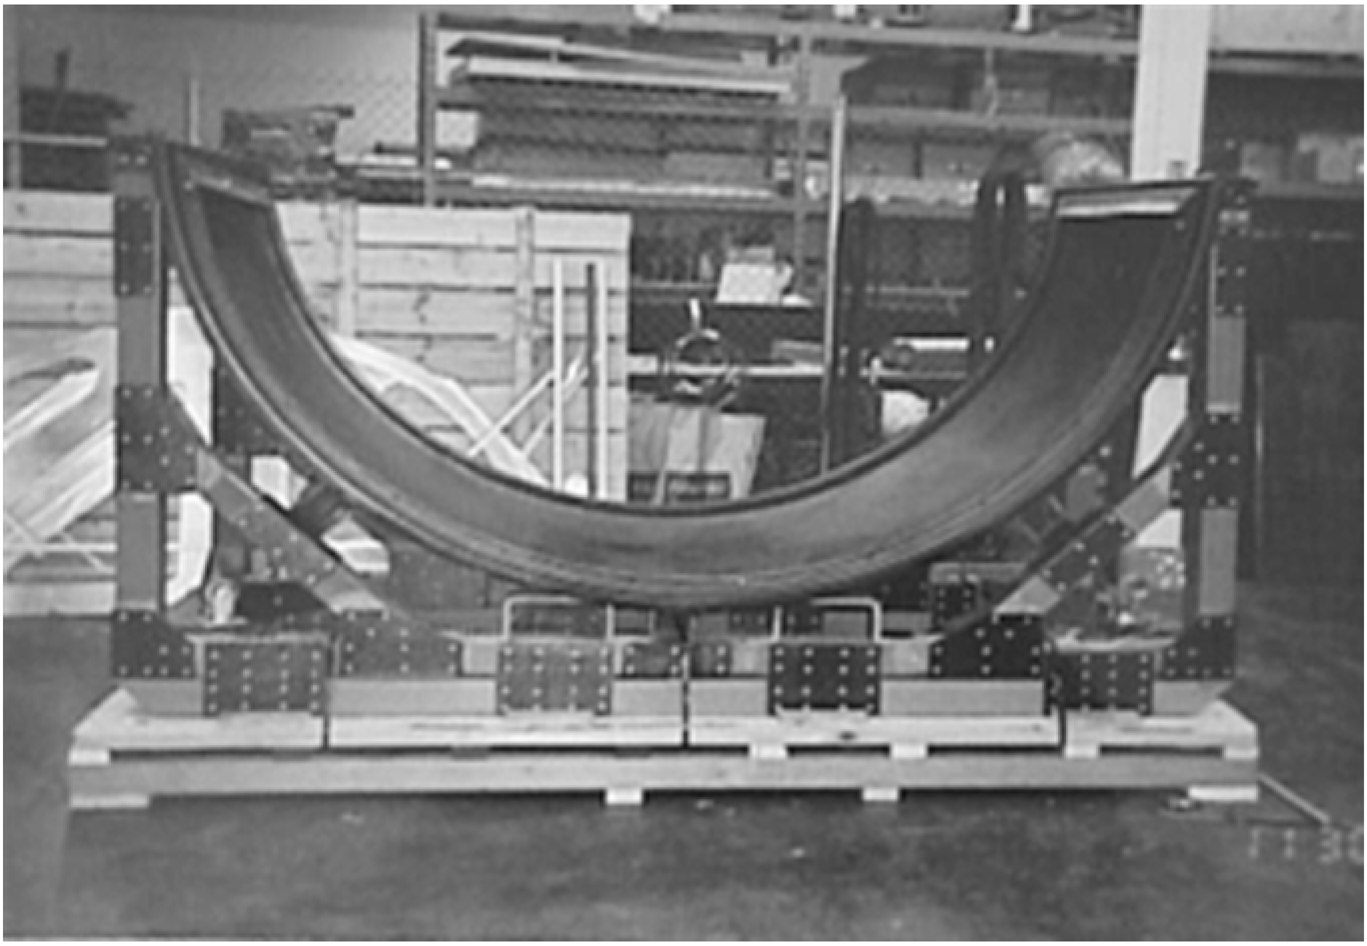

Fig. 8 Tubular spaceframe construction of substructure of cowl tool. Courtesy of Airtech International, Inc.

The use of a rigid steel frame structure in conjunction with a minimized composite substructure, attached through “free-floating” attachments, can also be considered. This is probably the most economical way to facilitate large-scale tool designs (Fig. 9).

Fig. 9 Carbon-epoxy tool "free floating" on steel frame. Courtesy of The Advanced Composites Group, Inc.

Some manufacturers have created designs where the substructure is not tied into the tool laminate at all. This "cradle" approach usually requires a more substantial substructure because it does not fully use the load-carrying ability of the tool laminate itself.

There are many ideas on how to attach the substructure to the tool laminate. One concept involves attaching the structure to the tool laminate with a thin silicone bead and fillet. This idea allows for the difference in CTE (if applicable) to be taken up by the silicone rubber. With this method, it is important to have a uniform thickness (3–5 mm, or 0.12–0.20 in.) of rubber between the substructure and the backside of the tool laminate. Of course, the silicone rubber must meet the service temperature requirements.

Other designs use the wet-fabric-tie-in technique. Usually several strips of fabric are tied to the tool laminate at equally spaced increments, constituting an approximate 50% area of "tie- in." Standard practice is to leave a nominal 5 mm (0.20 in.) gap between any header stock and the backside of the tool laminate, so as to reduce direct force contact and to minimize the potential heat sink in the area of the attachment.

To minimize possible distortion or shrinkage, if the substructure is a composite, the subcomponents of the substructure should be postcured before assembly. This is especially important when cross supports are to be bonded between integrally molded flanges in a monocoque tool design. As a general rule, the substructure assembly itself is cured and/or postcured prior to attachment to the tool laminate.

Steel or aluminum carts can be used for transportation of composite tooling. The carts may or may not be designed with universal features to accommodate a range of tools/sizes (Fig. 10). For large tools, the carts can be designed with V-groove wheels to mount on a track in the oven or autoclave.

Future Outlook

The use of prepreg materials for tool construction will continue to grow. Materials manufacturers are continually improving existing products and creating new products for use in tooling. Development of resin systems that have extended work life and low-temperature cures will continue to dominate the tool fabrication industry because they will produce the most dimensionally stable tools.

There is much promise for low-expansion, high-temperature-capable resins, such as polycyanate formulas, to come to the forefront in the fabrication of high-performance tooling in the future. The strength, toughness, and low CTE of this type of resin system make it a viable choice for tool laminate construction. Such properties are ideal for use with carbon-fiber reinforcements beause the CTE are similar. The somewhat high cost of this resin system is a limitation, however the cost may be justified if the tool laminate has resistance to vacuum leaks provides for more parts in production.

The use of elastomers in conjunction with the construction of tool laminates for improved durability and leak prevention is a well-known concept that is still to come to fruition. Many companies have perfected the use of elastomeric membranes for use as leak barriers in high-performance tools, yet the application of this concept is still limited. The use of coprocessed elastomers in tool laminates that require hinge joints and/or other flexible

features will also be more widespread. More development of these materials and processes will be seen in future tool laminate designs.

Manufacturers that have switched to metal alloys for production tooling will reconsider composites in the future. The lightweight advantage of composites combined with the lower costs and increased durability of the next-generation materials will encourage a swing in this direction.

Jim R. Logsdon, EMF Corporation

Electroforming Process

While the initial process of electroforming is identical to electroplating, it is the preparation of the mandrel and the removal of the electroform that differentiates the two processes. The surface of the metal deposited against the mandrel will replicate the surface finish and contour of the mandrel exactly so that very fine details, textures, or other finishes on the mandrel surface will be reproduced in the electroform. For a variety of reasons, electroforming is commercially done with only a few of the metals that are used in electroplating. These metals are primarily nickel, copper, and to a lesser extent, gold or silver. Copper electroforms are primarily used in applications where high thermal and electrical conductivity is required, such as microwave guides or circuit boards. The higher strength, hardness, and versatility of nickel has made it the material of choice for electroforming large parts such as molds. The wide range of mechanical properties that can be incorporated in nickel electroforms is a function of the type of electrolyte and the knowledge and expertise of the electroformer. The electrolytes used for electroforming are basically the same as those used for electroplating and the properties of the deposit can be influenced by operating conditions and solution additives. For example, the current density (i.e., the total amperage placed on the mandrel divided by its surface area) employed during the deposition process can affect the appearance and mechanical properties of the deposit, as can electrolyte pH and temperature. The addition of organic sulfur containing “grain refiners” to the nickel bath increases the hardness of the deposit, but the incorporated sulfur limits the maximum usable temperature. However, the addition of cobalt to a nickel solution will improve the deposit hardness without any temperature limitations. Thus, the electroformer has a wide range of options to consider when making molds.

The values that are listed in Table 1 are specific for a sulfamate nickel plating solution that typically produces a deposit having the lowest stress levels of all of the nickel plating solutions. Typical values for both a normal and a “hard” sulfamate bath (i.e., one containing a grain refiner) are tabulated.

Table 1 Typical properties of sulfamate nickel deposits at 25 °C (75 °F)

Deposit	**Hardness, HRC**	**Tensile strength**		**Elongation, %**	**Internal stress**		**Purity, %**	Application temperature	
		MPa	**ksi**		**MPa**	**ksi**		**°C**	**°F**
Normal	16–23	414–758	60–110	10–20	14–42(a)	2–6(a)	99+	>980	**>1800**
Hard	**30–50**	**862–1725**	**125–250**	**5–15**	**0–103(b)**	**0–15(b)**	**99+**	**>230(c)**	**>450(c)**

(a) Tensile.

(b) Compressive.

(c) Depends on grain-refiner content

Once the range of nickel properties is deemed acceptable for a planned mold, then some additional factors need to be considered. These include the shape and size of the mold, the expected durability of the mold, the required delivery time, and the manufacture and cost of the necessary mandrel.

Shape of the Mold. There are some contour limitations when using electroforming for mold manufacturing. Usually the cavity or female mold half is the easier of the two halves to electroform since electrodeposition will take place on the outside surface of a male mandrel, whereas the female mandrel used for the core or male mold half requires deposition on the inside of the mandrel. Thus, the male molds are typically more difficult to produce due to current density distribution on the inside of the mandrel. An experienced electroformer will recognize difficult geometries and take the appropriate steps to ensure a good electroform. Figure 1 shows examples of the deposit thickness distributions that can occur on different mandrel geometries. The electroformer can use shielding on outside corners or projections and/or auxiliary anodes in recessed areas to improve thickness uniformity, and the use of these processing aids also reduces the time required to finish the

electrodeposition phase of the mold manufacture. Experience shows that if a molder feels that the molded part can be removed from the mold without the use of movable cores or removable inserts, then the mold geometry probably would lend itself to the electroforming process.

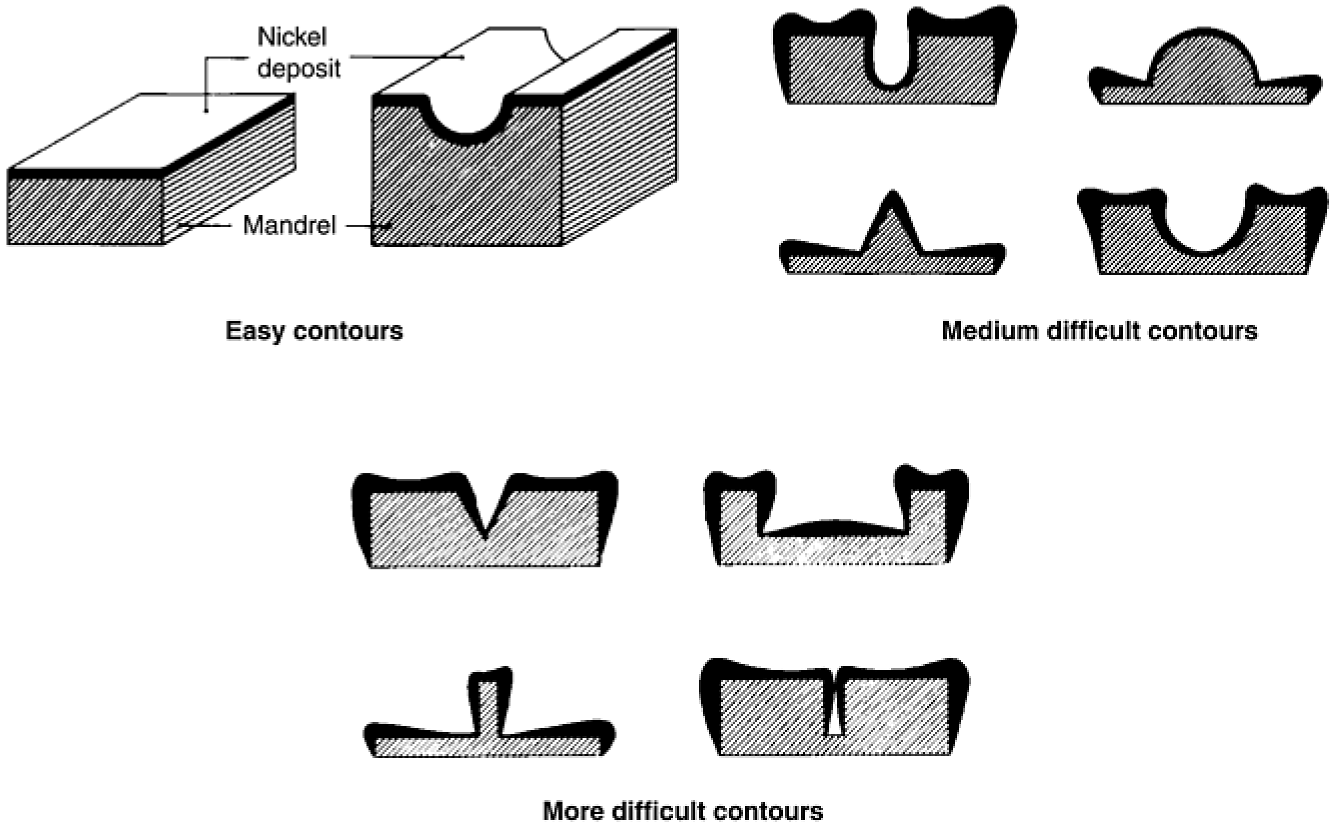

Fig. 1 Examples of deposit thickness distribution for various contours

Size of the Mold. The ability to produce large area molds by electroforming only requires an electroforming tank and solution that is large enough to submerse the mandrel for the amount of time required to deposit the desired thickness. Parts that have been produced by nickel electroforming have included lay-up molds in excess of 26 m^2 (280 ft^2) for aircraft part production and resin transfer molding (RTM) molds having a nickel area greater than 14 m^2 (150 ft^2) per mold half for making truck components. With nickel tanks as large as 11.3 by 4.3 by 4.3 m (37 by 14 by 14 ft) available in the United States, the electroforming capacity available for composite molds is almost unlimited.

Mold Fabrication Time. The time to complete a mold is a function of its size, shape, desired metal thickness, and type of mold. The metal thickness of an electroformed mold is a function of the average plating current during the deposition cycle and the total time of deposition. Typical thickness of nickel electroformed molds is approximately 5 mm (0.2 in.). For this thickness, an easy to medium-difficult geometry (see Fig. 1) may require 4 to 6 weeks for completion of the electroform. If the electroform is to be used for either autoclave tooling or an RTM preform mold as shown in Fig. 2 and 3, an additional 2 to 3 weeks may be required for final completion of the mold. If the electroform is to be the face sheet of a compression mold as shown in Fig. 4, then the addition of heating/ cooling lines, ejectors, leader pins, and/or side locks can add an additional 4 to 8 weeks depending on the size of the nickel electroform. Electroforms having more difficult contours may require as long as 6 to 10 weeks to complete the deposition process depending on the exact contour.

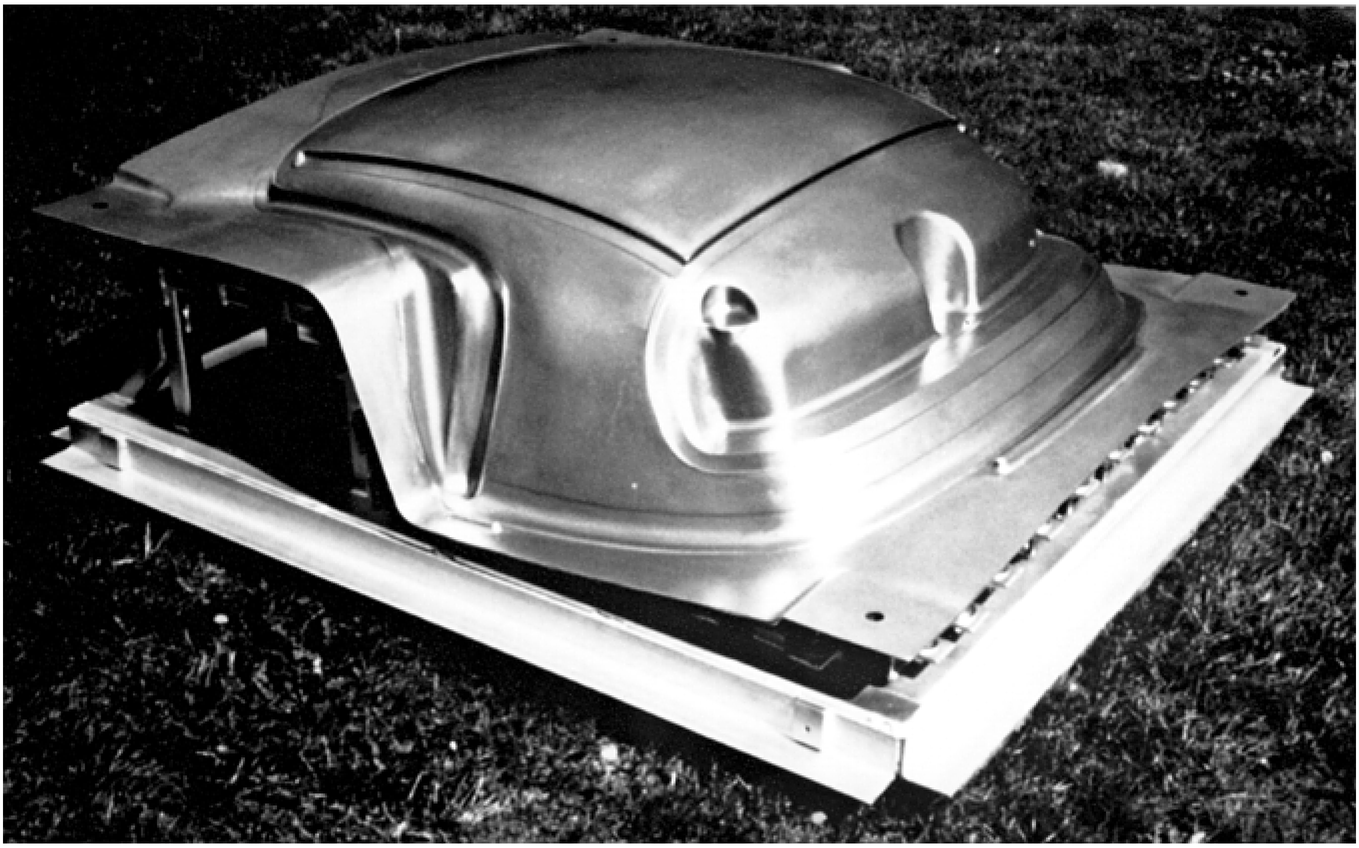

Fig. 3 Nickel shell male preform mold for composite auto roof

Fig. 4 Resin transfer molding molds for truck cab side fairings

Durability of Nickel Molds. Nickel molds have demonstrated an increased damage tolerance compared to the softer aluminum or fiberglass/resin molds. Cleanup of a mold with a hand-held scraper to remove excess resin can gouge a soft face mold, but may only leave a rub mark on the nickel surface. It is possible to repair a damaged nickel surface by soldering or welding a damaged area and then repolishing to the original contour. Such repairs, however, may be visible on the surface of a high-gloss molded part, even though they are hardly noticeable on the nickel surface. Chrome plating of the nickel surface can further increase its surface hardness to the same value as a chrome-plated steel mold.

Electroformed Nickel Tooling

Jim R. Logsdon, EMF Corporation

Mandrel Cost and Design Considerations

Mandrel fabrication guidelines can be supplied by most electroformers for customers furnishing the required mandrel. The manufacture of the mandrel and its surface is a critical stage in the production of electroformed molds. A poorly built, flimsy mandrel may distort during the electroforming process, resulting in contour variations in the electroform. Since the mandrel surface is exactly replicated by the electroform, surface blemishes such as pits and bumps will be reproduced in the surface of the electroform. This section briefly discusses mandrel fabrication by either the use of fiberglass/resins or by the machining of the mandrel directly from computer-aided design (CAD) data.

Fiberglass/Resin Mandrels. When a master model is available, the mandrel may be made by either making it directly off the model or by making a reverse or splash from the model and then making the mandrel from these expendable aids. In both cases, there may be some loss in contour tolerance due to the shrinkage of the resins used in the reverse and/or mandrel. If an existing mold needs to be replaced, it is sometimes possible to make the mandrel directly from that mold, depending on the surface quality of the mold. Again, some shrinkage of the resin may occur, resulting in the mandrel surface not exactly replicating the mold contour. The surface of

the mandrel is usually manufactured with several layers of resin face coats backed with as much as 10 to 13 mm (0.4–0.5 in.) of fiberglass/ resin. This face sheet must be supported in order to retain its contour, and this is done by a variety of methods. The two main ones use either laminates made of the same material as the face sheet that are attached to the back of the surface to give rigidity to the face sheet or steel or composite tubing or pipe attached to the back of the face. If a metal framework is used, it must be coated to prevent attack by the electroforming solution. All metal tubing must be sealed at the ends to prevent solution from entering and being trapped in the tube. This will eliminate carrying out the solution from the tank when the mandrel/ nickel combination is removed from the tank and will also prevent contamination of the solution by the dissolved metal tubing.

The backup structure provides the electroformer with a means to suspend the mandrel in the electroforming tank, but it must also be capable of supporting the weight of the deposited nickel on the face of the mandrel. For a nickel thickness of 5 mm (0.2 in.), the weight of the nickel hanging on the mandrel will be approximately 44 kg/m^2 (9 lb/ft^2) of nickel area. Since the nickel shell is not removed from the mandrel until it is mounted in a mold chase or frame, the added weight from the mold components during buildup of the mold may add as much as 732 kg/ m^2 (150 lb/ft^2) of additional weight on the mandrel.

The resins used in the construction of the mandrel must be stable in the nickel solution and fully cured before the mandrel is shipped to the electroformer. The expense of setting up and maintaining an electroforming tank to produce the low-stress deposits required for mold production is sizeable. The loss of production and expense of treating the solution in a large tank due to organic contamination from an uncured mandrel or use of an unproven resin could exceed $100,000. If the mandrel manufacturer is unsure of the materials being used, he or she should consult with the electroformer regarding the construction of the mandrel. A 30 by 30 cm (12 by 12 in.) sample can be easily placed in a small electroforming tank to check out the suitability of the proposed mandrel material.

The following guidelines, along with Fig. 1, can assist the mandrel manufacturer in producing a high-quality mandrel. Additional guidelines are provided in ASTM B 832 and the other sources cited in the list of Selected References at the end of this article.

- The quality of the face coat on the mandrel is important not only to ensure the correct contour, but also to produce a blemish-free nickel mold surface capable of producing the desired finish on the molded parts.
- External angles on the mandrel should be provided with as generous a radius as possible to avoid excessive buildup of nickel at these areas.
- Internal (concave) angles on the mandrel should be provided with a fillet radius at least equal to the thickness of the metal to be deposited. Where sharp internal angles are mandatory, the use of auxiliary anodes will be required and the electroforming time and the mold cost will increase.
- The mandrel should have additional area around the perimeter of the part to provide the desired mold run-out area and also to provide the electroformer with space to attach copper bus bar for electrical connection to the direct current (dc) rectifier.
- Silicone-based mold releases should be avoided in producing the mandrel. Such releases are difficult to remove completely from the mandrel and could result in separation of the nickel from the mandrel during the early electroforming stages. If separation occurs, the contour of the nickel in that area will be affected, which may necessitate the removal and disposal of the thin nickel deposit and starting the mandrel surface preparation anew.
- Types and locations of alignment pins and tooling balls for adjustment and location of the mold bases relative to the mold face and the other half of the mold should be coordinated with the electroformer to ensure the fabrication of acceptable molds.

Costs of fiberglass/resin mandrels typically are $2690/m^2 ($250/ft^2) or higher depending on the contour, size, and availability of a master model or splashes.

Machined Mandrels. At the time of publication, most companies have begun to use CAD in the design of their products. This widespread use of computers permits the transfer of data to vendors for the machining of master models or, in some cases, the direct machining of mandrels for the electroforming process.

The truck and automotive companies have preferred to generate a master model for their design personnel to approve, resulting in a fiberglass/resin mandrel being produced from that master with the possible loss of

accuracy in the contour as described earlier. The aircraft companies, on the other hand, have begun to machine the electroforming mandrels directly from tooling boards or mass cast modeling pastes in order to improve the contour tolerances of the finished electroform. The ease of machining lightweight foam blocks appealed to the fabricators of mandrels, but the weight or density of these blocks presented a problem to the electroformer due to their buoyancy in the electroforming solution. This forced the electroformer to attach heavy weights to the mandrel to counteract the buoyancy. These weights hanging from the mandrel support sometimes resulted in the distortion of the mandrel surface. In addition, two other problems arose: (1) the porosity of the foam after machining sometimes resulted in porosity in the electroform, and (2) the necessity of gluing the foam blocks together sometimes resulted in either depressed or raised areas in the nickel surface due to a mismatch between the thermal expansions of the foam and the adhesive when the mandrel was immersed in the nickel solution. In recent years, several manufacturers have begun to produce tooling boards having densities exceeding that of the electroforming solution, thereby removing the buoyancy problems. The adhesives used to cement these blocks together have been developed to more closely match the thermal expansion of the foam, thereby greatly reducing the glue-line problems on the nickel surface.

Regardless of the density of the foam used, a property of these foam block materials that must be considered before machining is the high values of their coefficients of thermal expansion (CTEs). For example, a mandrel machined to net dimensions at room temperature 21 °C (70 °F) from a foam having a CTE of 42.5×10^{-6}/°C (23.6×10^{-6}/°F) that is immersed in the electroforming solution at 49 °C (120 °F) will yield a nickel electroform at room temperature with dimensions that are approximately 0.25 mm (0.010 in.) larger than desired for each 30.5 cm (12 in.) of length or width. If this mandrel had tooling pins located 152.4 cm (60 in.) apart, the separation of those pins would be incorrect on the nickel shell by approximately 1.3 mm (0.05 in.). Corrections to the mandrel dimensions to compensate for the large CTE of the mandrel material can be incorporated during machining and will help ensure that the resulting electroform has the correct contour. If necessary, tooling pins and/or other critical details can be installed in the finished electroform after it has been removed from the mandrel.

The cost of a machined mandrel can be \$5380/ m^2(\$500/ft^2) or higher, depending on the tooling board or material that is to be machined, the labor costs for gluing and sealing the tooling boards, the hourly cost of the machine used, and the mandrel size and complexity.

Electroformed Nickel Tooling

Jim R. Logsdon, EMF Corporation

Comparison of Nickel and Other Tooling Materials

A thorough discussion of electroformed nickel molds for composite production would be remiss without comparing nickel to competitive materials.

Coefficients of Thermal Expansion. A tabulation of the various CTEs of the materials discussed in this article is presented in Table 2 for the consideration of mold designers. The user of nickel molds can incorporate expansion or shrinkage factors into the molds through the mandrel construction in the same manner that steel, Invar, or aluminum molds are machined to incorporate these factors.

Table 2 Coefficients of thermal expansion of selected tooling materials

Material	Coefficient of thermal expansion, 10^{-6}/K
Electroformed nickel	**13.1**
Steel	**12–13**
Invar-36	**2.7**
Aluminum	**23.4**
Fiberglass/epoxy (50–60 vol% fiberglass)	**9–12.6**

Thermal Cycles for Compression Molding. As faster cure times in the various compression molding processes are required by molders, the heat-up and cool down times of the molds used must be considered. The thermal cycling of nickel shell molds will be faster compared to machined steel and machined or cast aluminum molds due to the reduced mass of the nickel that must be heated or cooled. Cooling or heating lines located directly behind the thin nickel shell offer faster thermal responses than those molds having 1 or 2 in. of material between the lines and the face. Because the nickel shell can be thermally isolated to a great extent by using concrete or a resin behind the nickel, any heat generated during the cure cycle can be removed faster than if a large block of steel or aluminum had to be cooled. A rough calculation of the time required to heat various mold materials is based on the weight and heat capacity of each material. Table 3 shows the relative times that are required to raise the temperature of a 4.6 m^2 (50 ft^2) mold by 38 °C (100 °F) for a 5 mm (0.2 in.) thick nickel shell compared to three other mold materials. The amount of heat absorbed by each material was assumed to be the same, thereby permitting a comparison of the time required. Heat losses due to conduction, convection, or radiation into the support structure or backing materials were ignored for this calculation. Since the actual thickness of molds may vary depending on the material and the depth at which the cooling channels are drilled, Table 3 compares the thin nickel shell to a 25 mm (1 in.) thickness of the other materials.

Table 3 Relative heat-up times for various materials

Material	**Thickness**		**Weight**		Relative heat-up time
	mm	**in.**	**kg**	**lb**	
Electroformed nickel	5	0.2	210	462	**1**
Steel	25	1	927	2040	**4.9**
Aluminum	25	1	330	726	**3.4**
Fiberglass/epoxy	**25**	**1**	**202**	**444**	**1.6**

Thus, a 100 mm (4 in.) thick aluminum mold could take almost 14 times longer to heat up than the thinner nickel shell. However, if the heating channels on the aluminum mold were very close to the mold face, then the mold-face temperature may reach the desired operating temperature while the rest of the aluminum mass is still warming up.

Thermal Cycles for Metal Autoclave Molds. The use of nickel, steel, or Invar molds in the autoclave curing of aircraft composite parts is appealing to the aircraft industry due to their unlimited lifetimes at cure temperatures of 150 °C (300 °F) and higher compared to resin molds. Invar-36 is a 64%Fe-36%Ni alloy that is widely used in the curing of graphite/epoxy parts since its CTE closely matches that of the graphite parts. Based on a comparison of 1999 prices, the cost of an Invar mold may be several times greater than a nickel or steel mold, but depending on the contour of the graphite part, that cost may be justified. A comparison of the costs and heat- up times of comparable steel, nickel, and Invar molds has to include the thickness of the face sheet, the weight of the support structure, and the contour of the mold. Table 4 compares the costs and relative heat-up times for the three metals for a mold having a wing leading edge contour. The cost for the nickel mold includes a machined master model, a fiberglass/epoxy mandrel and the finished nickel mold. The costs for the steel and Invar molds includes machining of the surface and the welding and related costs for the support structures. The heat-up times are again compared relative to the nickel mold. The area of this mold was 3.5 m^2 (38 ft^2), and the support structure for the metal face of the mold was assumed to be the same design for all three molds. The support structures on the nickel and steel molds were welded steel, while the support structure for the Invar mold was welded Invar as required. The total weight listed below includes the face sheet and the support structure. The cost for the Invar tool could not be obtained for this geometry, but two aircraft firms have stated that Invar molds are costing \$2000 to \$3500/ft^2 yielding a price for this comparison of about \$76,000 to \$130,000.

Table 4 Comparison of nickel, steel, and Invar autoclave molds

Face material	**Thickness**		**Total weight**		**Total cost**	Relative heat-up time
	mm	**in.**	**kg**	**lb**		
Nickel	6	0.24	1093	2410	\$39,400	**1**
Steel	9.5	0.38	1148	2530	\$77,440	**1.06**

Invar	**12**	**0.5**	**1179**	**2600**	**(see text)**	**1.24**

These relative heat-up times are strictly theoretical since actual autoclave data are not available. The numbers do show the improved cycle times that could be obtained in ideal conditions when using nickel molds. In reality, these heating times can be skewed if the air circulation in the autoclave favors a particular area or if the support structure design prevents good air circulation around the back side of the face sheet in the autoclave.

Electroformed Nickel Tooling

Jim R. Logsdon, EMF Corporation

Comparison of Nickel and Other Tooling Materials

A thorough discussion of electroformed nickel molds for composite production would be remiss without comparing nickel to competitive materials.

Coefficients of Thermal Expansion. A tabulation of the various CTEs of the materials discussed in this article is presented in Table 2 for the consideration of mold designers. The user of nickel molds can incorporate expansion or shrinkage factors into the molds through the mandrel construction in the same manner that steel, Invar, or aluminum molds are machined to incorporate these factors.

Table 2 Coefficients of thermal expansion of selected tooling materials

Material	Coefficient of thermal expansion, 10^{-6}/K
Electroformed nickel	**13.1**
Steel	**12–13**
Invar-36	**2.7**
Aluminum	**23.4**
Fiberglass/epoxy (50–60 vol% fiberglass)	**9–12.6**

Thermal Cycles for Compression Molding. As faster cure times in the various compression molding processes are required by molders, the heat-up and cool down times of the molds used must be considered. The thermal cycling of nickel shell molds will be faster compared to machined steel and machined or cast aluminum molds due to the reduced mass of the nickel that must be heated or cooled. Cooling or heating lines located directly behind the thin nickel shell offer faster thermal responses than those molds having 1 or 2 in. of material between the lines and the face. Because the nickel shell can be thermally isolated to a great extent by using concrete or a resin behind the nickel, any heat generated during the cure cycle can be removed faster than if a large block of steel or aluminum had to be cooled. A rough calculation of the time required to heat various mold materials is based on the weight and heat capacity of each material. Table 3 shows the relative times that are required to raise the temperature of a 4.6 m^2 (50 ft^2) mold by 38 °C (100 °F) for a 5 mm (0.2 in.) thick nickel shell compared to three other mold materials. The amount of heat absorbed by each material was assumed to be the same, thereby permitting a comparison of the time required. Heat losses due to conduction, convection, or radiation into the support structure or backing materials were ignored for this calculation. Since the actual thickness of molds may vary depending on the material and the depth at which the cooling channels are drilled, Table 3 compares the thin nickel shell to a 25 mm (1 in.) thickness of the other materials.

Table 3 Relative heat-up times for various materials

Material	**Thickness**		**Weight**		Relative heat-up time
	mm	**in.**	**kg**	**lb**	
Electroformed nickel	5	0.2	210	462	**1**
Steel	25	1	927	2040	**4.9**
Aluminum	25	1	330	726	**3.4**

Fiberglass/epoxy	**25**	**1**	**202**	**444**	**1.6**

Thus, a 100 mm (4 in.) thick aluminum mold could take almost 14 times longer to heat up than the thinner nickel shell. However, if the heating channels on the aluminum mold were very close to the mold face, then the mold-face temperature may reach the desired operating temperature while the rest of the aluminum mass is still warming up.

Thermal Cycles for Metal Autoclave Molds. The use of nickel, steel, or Invar molds in the autoclave curing of aircraft composite parts is appealing to the aircraft industry due to their unlimited lifetimes at cure temperatures of 150 °C (300 °F) and higher compared to resin molds. Invar-36 is a 64%Fe-36%Ni alloy that is widely used in the curing of graphite/epoxy parts since its CTE closely matches that of the graphite parts. Based on a comparison of 1999 prices, the cost of an Invar mold may be several times greater than a nickel or steel mold, but depending on the contour of the graphite part, that cost may be justified. A comparison of the costs and heat- up times of comparable steel, nickel, and Invar molds has to include the thickness of the face sheet, the weight of the support structure, and the contour of the mold. Table 4 compares the costs and relative heat-up times for the three metals for a mold having a wing leading edge contour. The cost for the nickel mold includes a machined master model, a fiberglass/epoxy mandrel and the finished nickel mold. The costs for the steel and Invar molds includes machining of the surface and the welding and related costs for the support structures. The heat-up times are again compared relative to the nickel mold. The area of this mold was 3.5 m^2 (38 ft^2), and the support structure for the metal face of the mold was assumed to be the same design for all three molds. The support structures on the nickel and steel molds were welded steel, while the support structure for the Invar mold was welded Invar as required. The total weight listed below includes the face sheet and the support structure. The cost for the Invar tool could not be obtained for this geometry, but two aircraft firms have stated that Invar molds are costing \$2000 to \$3500/ft^2 yielding a price for this comparison of about \$76,000 to \$130,000.

Table 4 Comparison of nickel, steel, and Invar autoclave molds

Face material	**Thickness**		**Total weight**		**Total cost**	Relative heat-up time
	mm	**in.**	**kg**	**lb**		
Nickel	6	0.24	1093	2410	\$39,400	**1**
Steel	9.5	0.38	1148	2530	\$77,440	**1.06**
Invar	**12**	**0.5**	**1179**	**2600**	**(see text)**	**1.24**

These relative heat-up times are strictly theoretical since actual autoclave data are not available. The numbers do show the improved cycle times that could be obtained in ideal conditions when using nickel molds. In reality, these heating times can be skewed if the air circulation in the autoclave favors a particular area or if the support structure design prevents good air circulation around the back side of the face sheet in the autoclave.

Elastomeric Tooling

R.C. Adams and Marvin Foston, Lockheed Martin Aeronautical Systems

Introduction

ELASTOMERIC TOOLING uses rubber details to generate required molding pressure or to serve as a pressure intensifier during composite- part curing cycles. The rubber is made from castable room-temperature vulcanized (RTV) rubber compounds or calendered silicone rubber sheets (reinforced and unreinforced) in “B” stage form (fully compounded but uncured).

Composite materials are currently the materials of choice in the aircraft and many commercial industries. Composite parts have grown from simple-shaped parts to large, highly contoured co-cured structures. The fabrication of co- cured structures reduces or even eliminates fasteners, mate joints, part count, subassembly, and assembly operations.

Recently developed lean manufacturing approaches incorporate low-cost tooling methodologies in the Integrated Product Team component design. This includes a tooling policy that standardizes the hard-tool interface for all outer skins and substructure. The skins are hard tooled to inner mold line and substructure is hard tooled to outer mold line. This provides a controlled interface for assembly. This tooling approach with the increased usage of composites components has created new families of project tools, bag-side semirigid cauls.

These bag-side outer/inner mold-line cauls are required to improve surface quality, provide aerodynamic smoothness, and achieve more demanding part tolerances. The cauls reduce bagging time and eliminate bag wrinkles and the chance of a lay-up “bridge” that would result in bag failure, causing part rejection. To meet these requirements the bagside caul must be both rigid and flexible. Rigidity is required to achieve tolerance/configuration control, while flexibility ensures good compaction.

Elastomeric Tooling

R.C. Adams and Marvin Foston, Lockheed Martin Aeronautical Systems

Bag-Side Elastomeric Cauls

Commercially available caul systems are provided in two forms:

- *Form 1:* calendered reinforced and unreinforced sheets of rubber
- *Form 2:* calendered unreinforced sheets of rubber in combination with graphite or fiberglass/epoxy prepreg, which is used to selectively reinforce the caul as required

Form 1 Caul. A form 1 caul system has several unique advantages for simple contoured parts. The materials are low in cost, easy to lay- up, and have a wide processing window of 110 to 175 °C (235–350 °F). The calendered sheets of rubber can be purchased fully compounded in “B” stage form with or without fiberglass

reinforcement. Fiberglass reinforcement generally is not desired when high elongation is required. These materials are commonly used together.

Fabrication. Machined or plastic-faced plaster part models that represent the outer/inner mold line of the part should be used whenever possible to fabricate cauls, but cauls also can be fabricated on curing tools. The caul material can be cured at temperatures lower than 120 °C (250 °F). This advantage allows the use of sheet wax to produce an inexpensive “dummy” part that can be used to fabricate the caul. Figure 1 shows semirigid cauls built using the form 1 caul system. Figure 2 shows a curing tool that required a wax dummy part to fabricate the required reinforced caul, while the caul in Figure 3 was fabricated using a part model that was initially built to make trim tools. Both approaches eliminate the cost of building models specifically for use in caul fabrication. A review of the contour of the parts provides guidance as to which caul fabrication approach and caul system should be used.

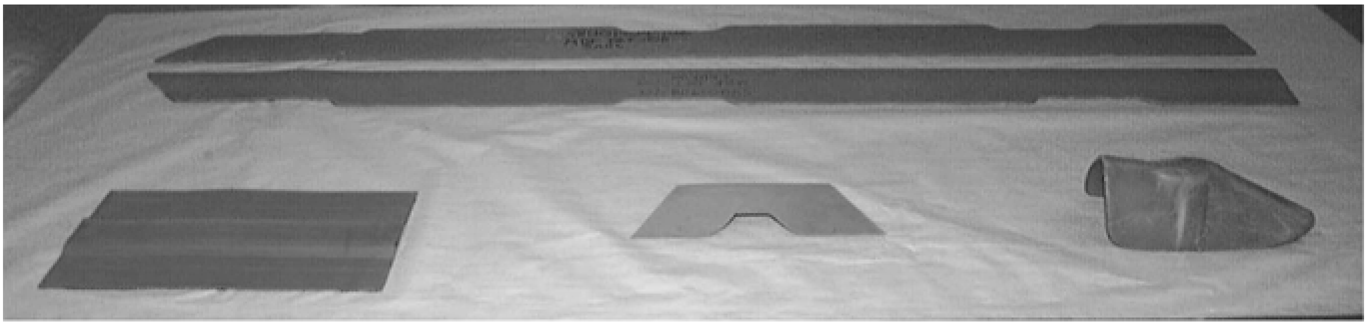

Fig. 1 Semirigid cauls built using form 1 caul system

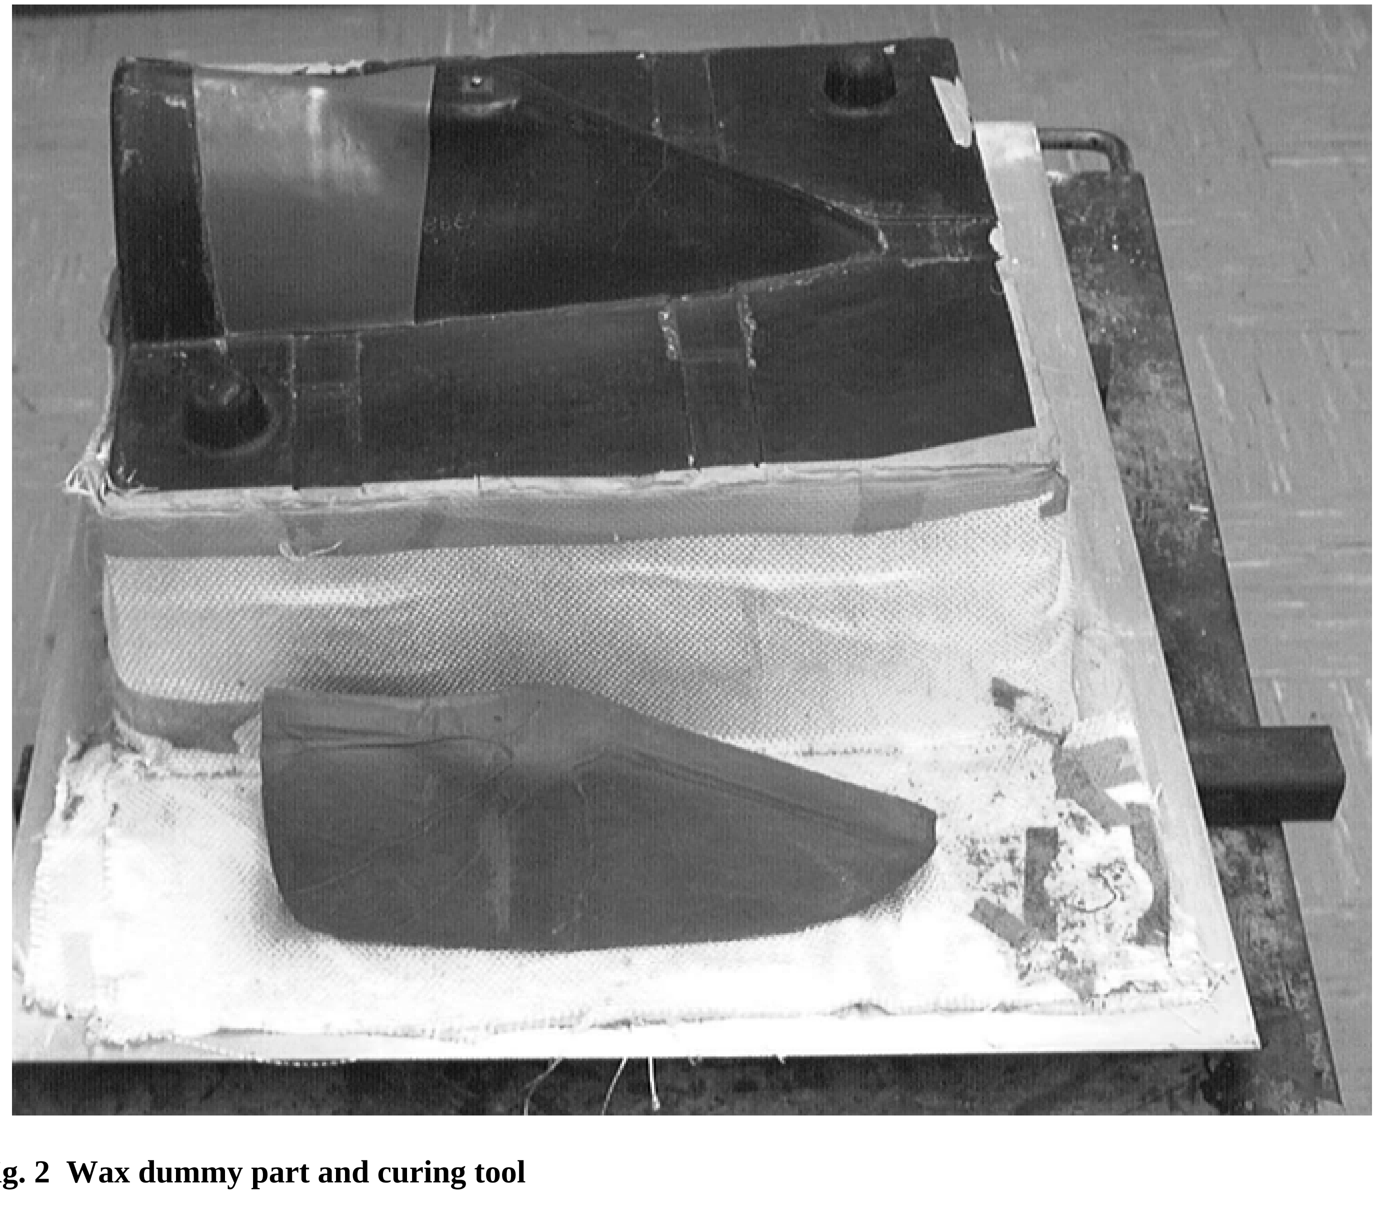

Fig. 2 Wax dummy part and curing tool

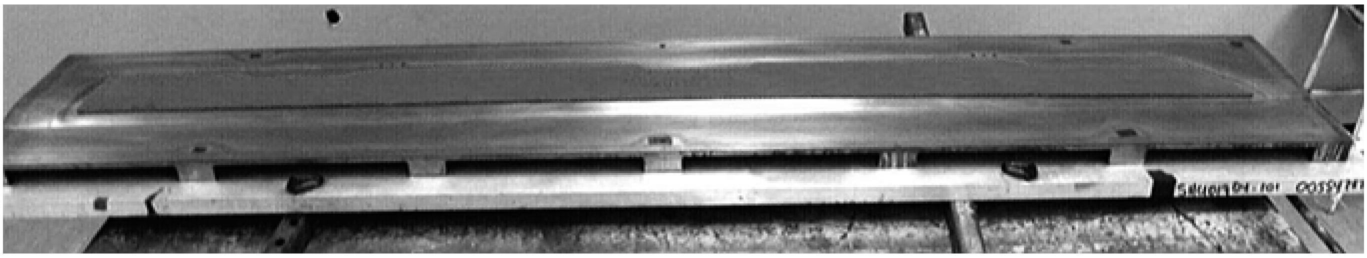

Fig. 3 Caul fabricated using part model initially built to make trim tools

To build cauls using the form 1 system, part model and curing tool surfaces are cleaned with alcohol to remove all dirt, grease, and oil. The curing tool is release coated and the part thickness laid-up with the required thickness of adhesive-backed wax sheet. Because adhesive is a silicone rubber contaminant, all butt joint seams between the wax sheets are filled with paste wax to isolate the adhesive. Adhesive contamination will prevent the rubber from curing in those areas. The surfaces of the part model and waxed curing tool are coated with a release agent, a commercial dishwashing detergent. A 5% detergent to 95% water mixture provides a good release for most rubber compounds.

Usually four plies are sufficient for this caul system, but the number of plies can vary. A combination of reinforced and unreinforced material is used to allow more expansion in tool radii. The basic lay-up is shown in Fig. 4. This orientation provides good surface smoothness and requires no special treatment for most ramps and drop-offs. Special treatment is required for most male and female radii areas, as shown in Fig. 5. This stacking arrangement creates a stretch joint to provide better radii compaction and caul elongation in two directions.

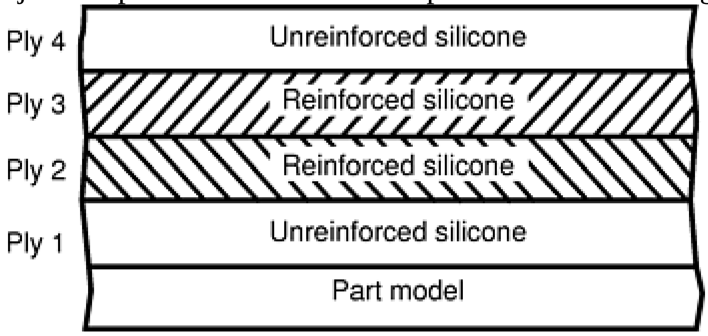

Fig. 4 Typical caul lay-up system

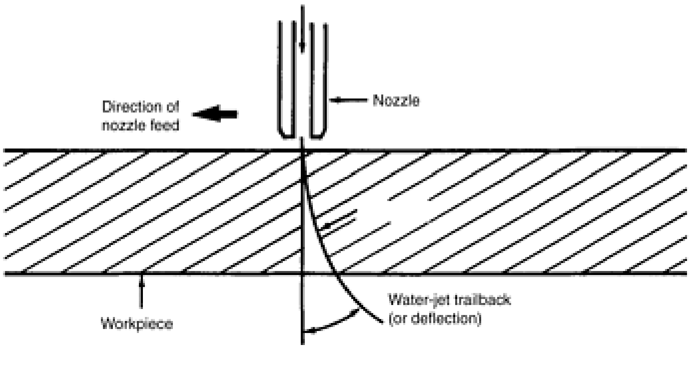

Fig. 5 Tooling radii stretch joint

The calendered rubber sheet material is laid up in manageable pieces, taking care to apply the sheet to surfaces without wrinkles or trapped pockets of air. The first ply is debulked at room temperature under full vacuum, and lay-up completed as shown in Fig. 4 and 5. The curing cycle for cauls laid up on curing tool with waxed part model buildups is shown in Fig. 6. Cauls fabricated on part models that can withstand temperatures as high as 175 °C (350 °F) is shown in Fig. 7. Cauls cured at low temperature are postcured unrestrained in an oven for 1 h at 175 °C (350 °F).

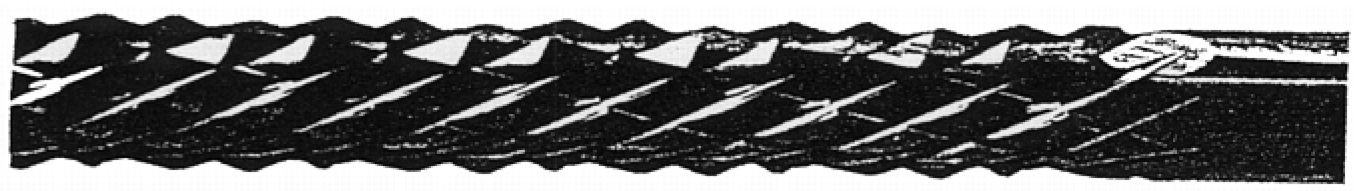

Fig. 6 Schematic of 110 °C (230 °F) cure cycle

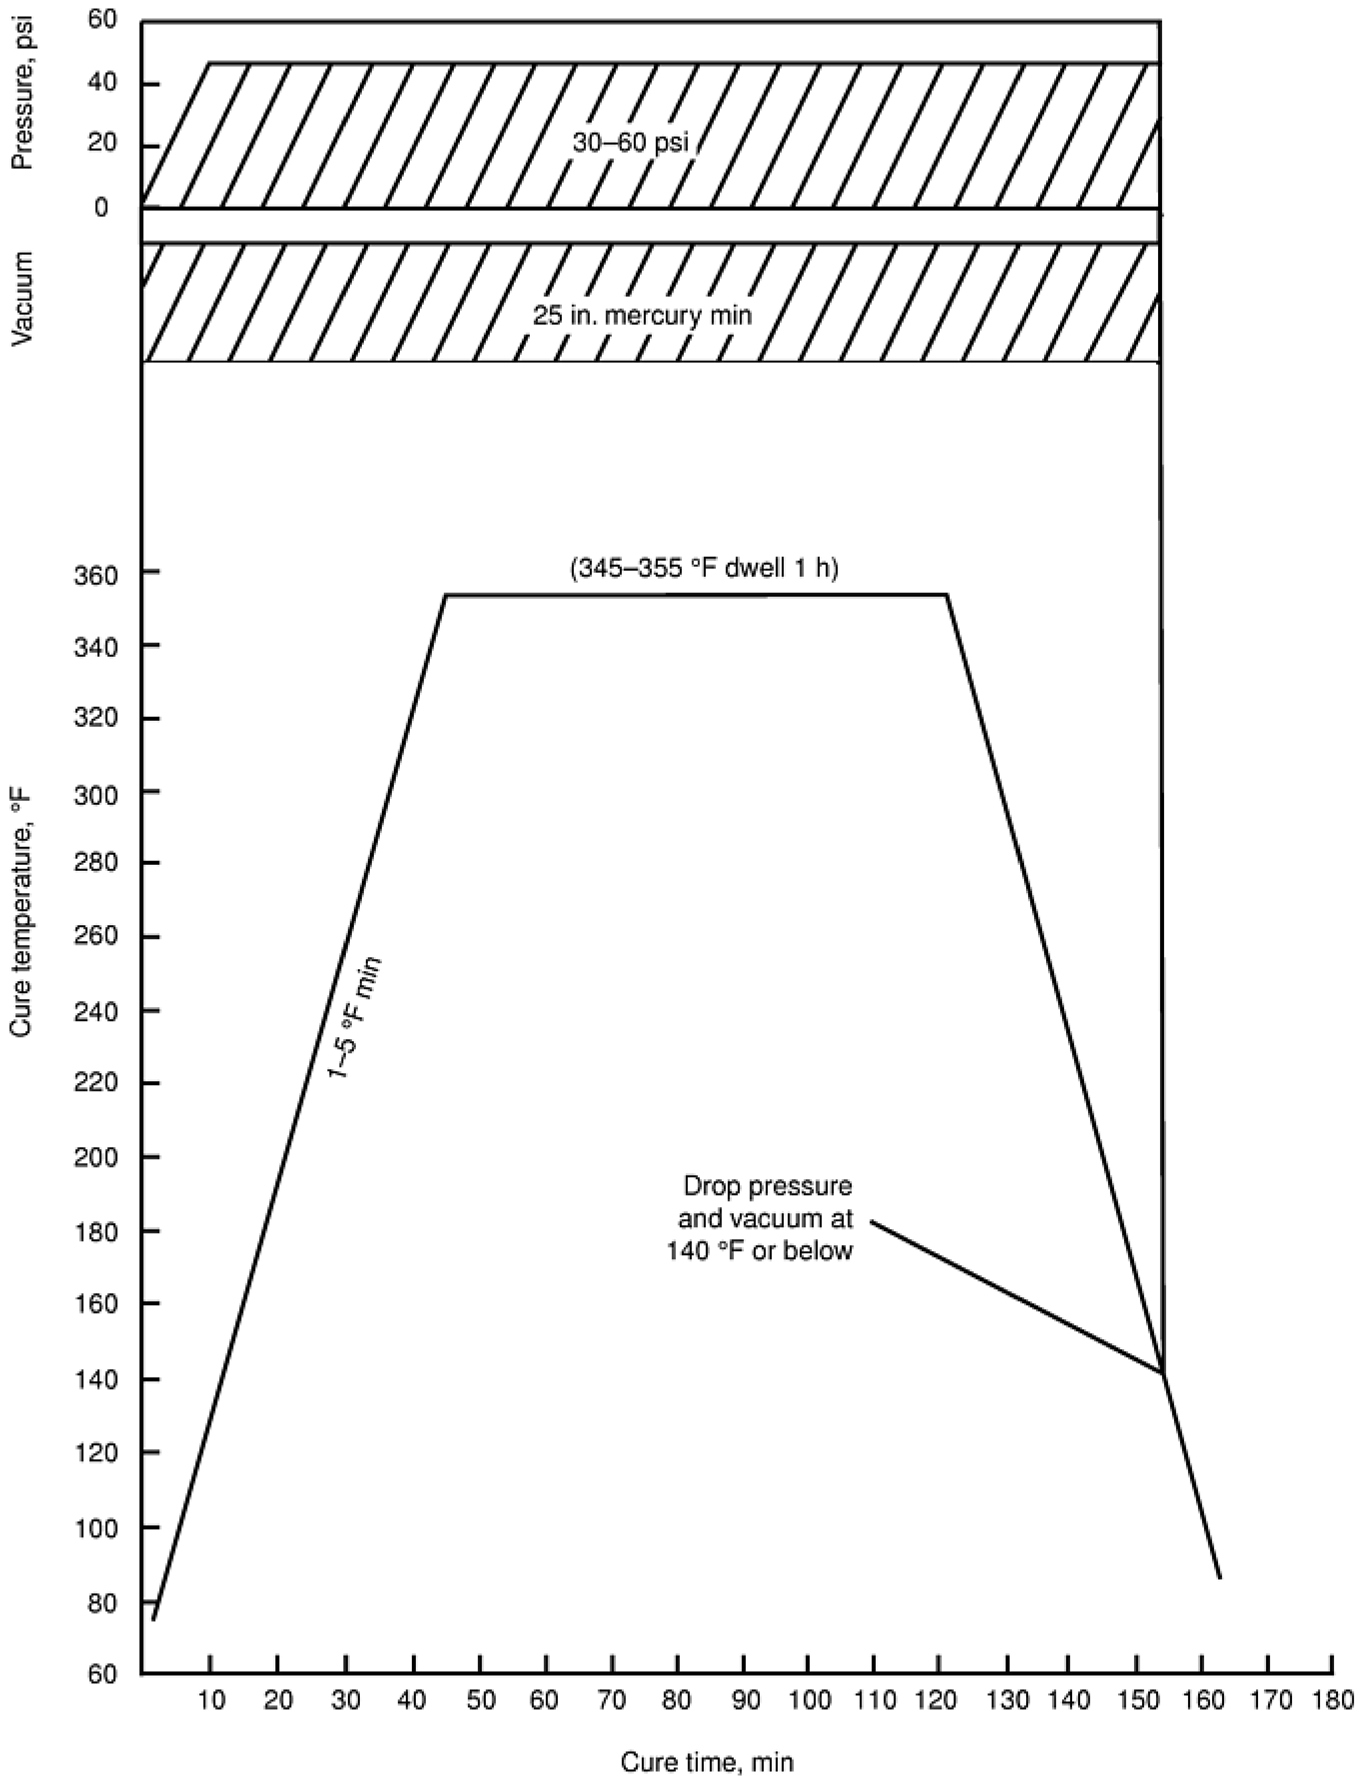

Fig. 7 Schematic of 175 °C (350 °F) cure cycle

Form 2 Caul. Some part configurations fabricated in the autoclave require a “matched- mold” type of caul to provide the bag- or caul- side part definition. Parts having one or more integral stiffeners or highly compound complex contour surfaces require cauls having tailored reinforcement in selected areas.

The caul system selected for matched-mold cases is a combination of pretreated calendered silicone and fiber/epoxy prepreg material that, when co-cured, provides a semirigid caul having predictable thermal expansion. The semirigid cauls built using this caul system are shown in Fig. 8. Figure 9 shows a stiffened graphite/epoxy panel with a ramped buildup around its periphery, which was successfully produced using a graphite/epoxy reinforced caul. This system was also used to fabricate the caul shown on the part model in Fig.10.

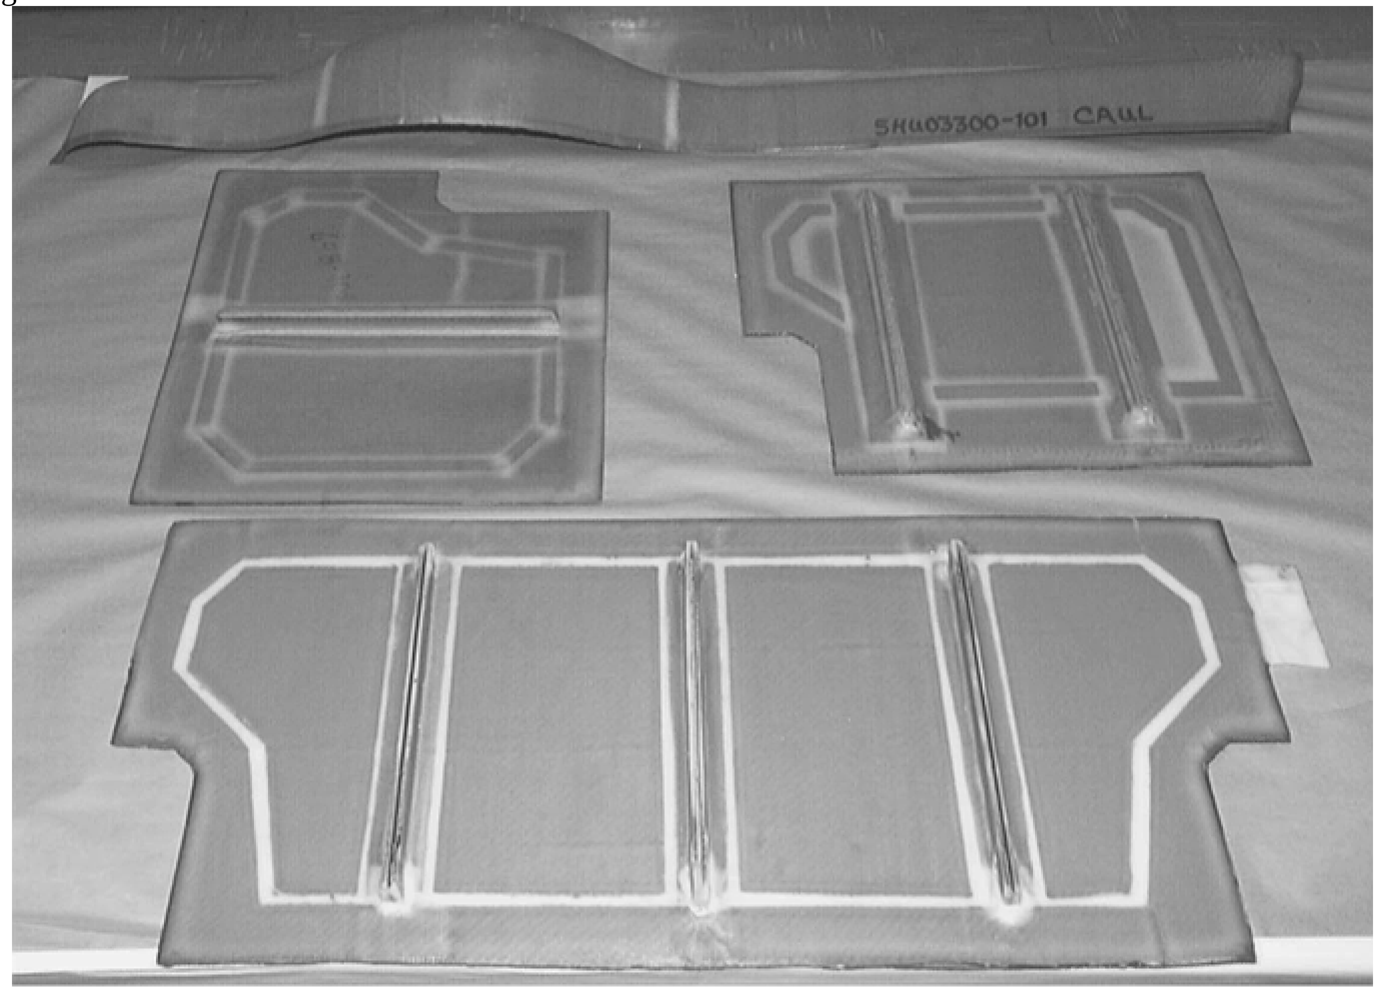

Fig. 8 Semirigid cauls built using form 2 caul system

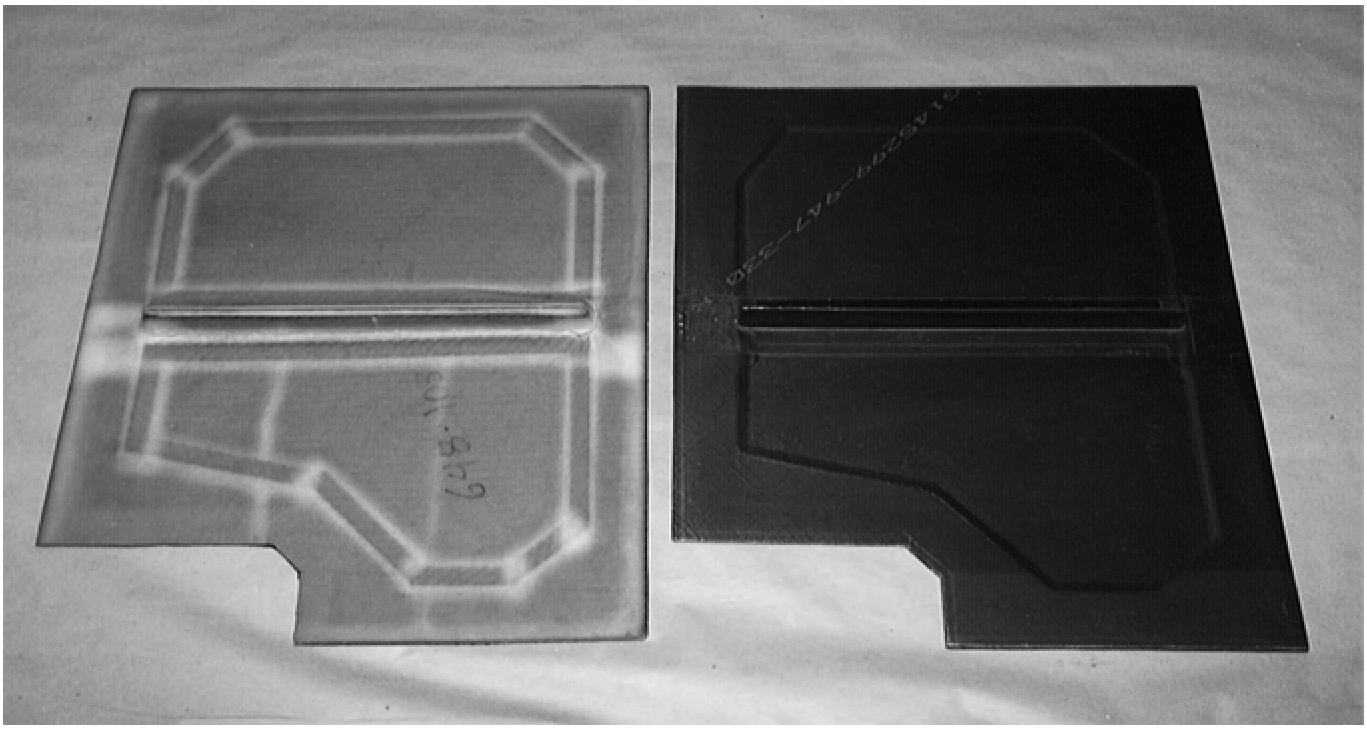

Fig. 9 Stiffened graphite/epoxy panel with ramped buildup around its periphery built using graphite/epoxy reinforced caul

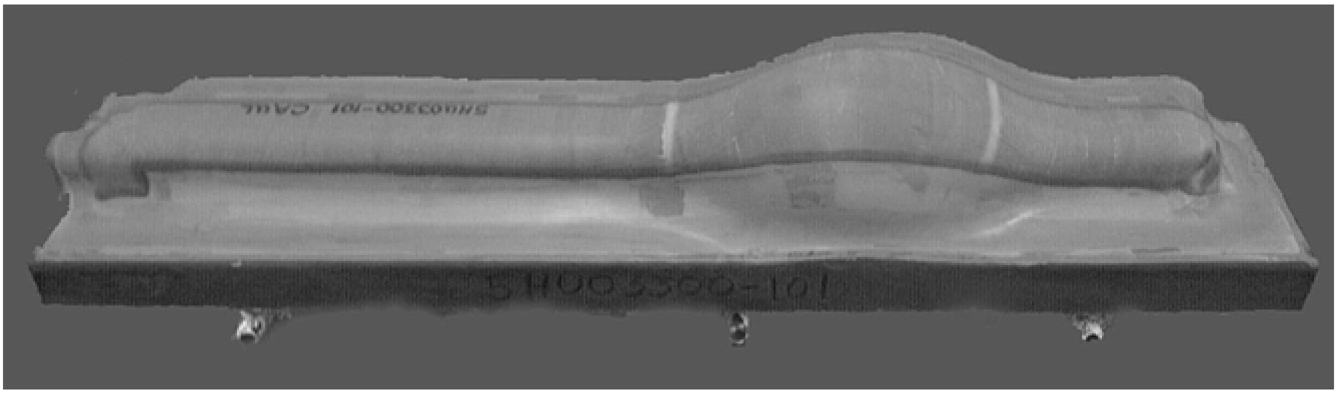

Fig. 10 Caul on part model built using graphite/epoxy reinforced caul

Fabrication. Building a caul with this system is similar to fabricating a simple contour caul. The exceptions are: The pretreated silicone requires a special release agent on the part models. A primer is needed on both sides of the graphite/ epoxy reinforcements to achieve a good bond to the silicone rubber. A different caul ply stack-up and radii treatment (Fig. 11), and cure cycle (Fig. 7) are required.

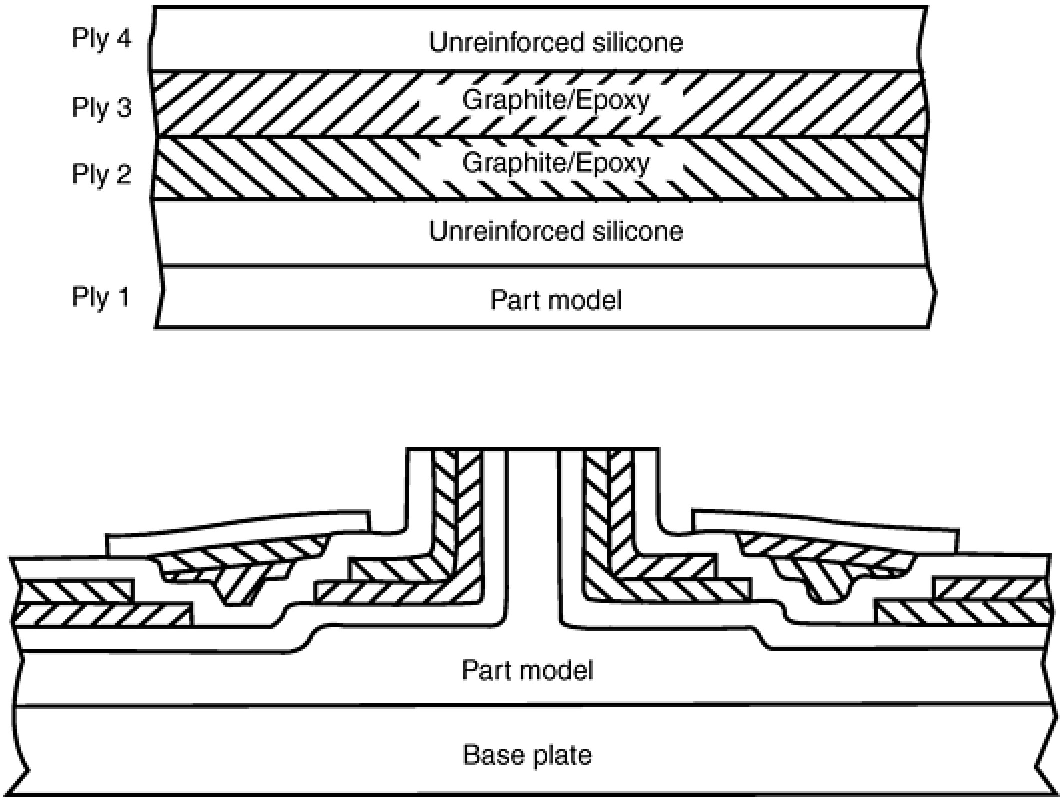

Fig. 11 Ply stack-up and lay-up system for dealing with joint radii

These caul systems can be used during debulking cycles of resin transfer molding (RTM) preforms. The preforms are debulked to eliminate excess bulk so they can be easily loaded in the matched-mold RTM tool. Conventional vacuum bags pull preforms too tight around the corners of debulking mandrels, which, combined with the increased bag pressure, overcompacts the preform fibers in these areas. Reinforced cauls can be built by waxing up the required debulk thickness and building cauls to this offset. The cauls control the debulked preform thickness uniformly over the desired mandrel surface area, which eliminates resin-rich areas on the corners of RTM parts.

Thermal Expansion Molding Methods

Two basic methods use the principles of thermal expansion molding: the trapped, or fixed- volume rubber method, and the variable-volume rubber method.

The fixed-volume method exploits the large difference between the coefficient of thermal expansion (CTE) of the elastomer and the CTE of metals. The elastomer is confined within a closed metal tool cavity; when heated, it expands into the cavity, exerting the pressure required to compact a composite laminate. One of the chief benefits is that it allows the manufacturing engineer to apply adequate pressure with or without a vacuum bag or autoclave.

Elastomeric mandrel compounds have been formulated to meet a wide range of pressure requirements. Compounds are available that can generate controllable molding pressure ranging from less than 7 to greater than 13,800 kPa (less than 1 to greater than 2000 psi) at cure temperature.

The variable-volume method offers more flexibility than the fixed-volume method because a precisely calculated volume of rubber is not normally required. In most applications, the rubber is simply "set back" to allow for the bulk factor of the molding material during assembly of the tooling details. If excess pressure is

generated during vacuum bag molding, it is vented against the vacuum bag. In press molding, the excess pressure causes the floating plate to retract the movable press platen.

In an airframe, thermal expansion molding is used primarily in boxlike structures such as rudders, vertical stabilizers, wing boxes, spoilers, and ailerons. Elastomeric tooling provides the means for fabricating integrally stiffened skins with a co-cured substructure in a single curing operation. Secondary bonding is thereby eliminated, substantially reducing direct manufacturing costs. The basic mechanism of thermal expansion molding is the transfer of uniform compaction pressure to an uncured composite laminate by an elastomeric tooling detail.

Molding Stages. During thermal expansion molding for a simplified, one dimensional case—using the fixed-volume rubber method— the rubber block freely expands across a gap and contacts the composite prepreg material, which is compacted under increasing pressure until the resin gels. At the gel point, the laminate has been compacted to its final molding thickness under pressure. The laminate is cured at the gel temperature for a time period determined from rheometric data. The cured laminate is then removed from the tooling and postcured unrestrained in an oven.

Postcuring following curing at the gel temperature eliminates the excessive pressure that would be generated if the temperature were raised to the final cure temperature, which could cause damage to parts.

Elastomeric Tooling

Volumetric Analysis

The significant properties that are required to characterize elastomeric tooling material are CTE, bulk modulus, hardness, and dimensional stability under repeated cycles of pressure and temperature. The nature of the thermal expansion process with an elastomeric material can be obtained by putting pressure transducers on three faces of a rectangular mold to permit the monitoring of pressure exerted by a rectangular brick in three directions. Using data from the rectangular mold model, volumetric relationships can be derived that are valid for complex as well as for simple tooling configurations.

The controlling equations for pressure in the fixed-volume rubber method of thermal expansion molding can be reduced to a single equation when two characteristics of the elastomeric material being used are determined through accurate tests. These characteristics are the percentage of volume by which the elastomer shrinks between being poured and being cured, and the pressure generated per degree of increase in temperature of a confined elastomeric specimen. Once these properties are determined, the volume lost to shrinkage can be restored during use by adding a suitable ΔT to the nominal positive gradient. This differential is known as the shrinkage compensation factor, or Δt_s (delta temperature allowance for shrinkage).

Numerically, the Δt_s is obtained by dividing the percentage of shrinkage by the volumetric expansion factor of the rubber material:

$$\Delta t_s = \frac{(x)\%}{B_r} \qquad \text{(Eq 1)}$$

where x is rubber shrinkage and B_r is the volumetric expansion coefficient of rubber.

The pressure compensation factor, Δt_p, may also be offset by determining the amount of temperature increase required to provide the desired pressure:

$$\ln \dot{\varepsilon} = -8.8 - \frac{4040}{T} + 0.0234\, r_s$$
$$= -4.74 - \frac{9270}{T} + \qquad \text{(Eq 2)}$$

where P is the desired pressure and P/d is the pressure generated per degree increase in temperature.

The basic equation controlling the thermal expansion molding process is:

$$V_{r2}=V_{r1}+V_{r1}\,B_r\Delta T_e \qquad \text{(Eq 3)}$$

where V_{r2} is the volume of rubber at the cure temperature at which pressure is equal to 0, V_{rl} is the volume of rubber at room temperature (RT), and ΔT_e is the effective change in temperature, which is cure temperature (–Δt_s–Δt_p–RT), where Δt_s and Δt_p refer to Eq 1 and 2. Note that Eq 3 is accurate to less than ±1% error.

The initial starting point in tool design for the thermal expansion molding process is at cure temperature. The geometry of the part at temperature is surrounded by the tool inner mold lines, and a cavity is then designed to hold the rubber detail.

The initial value for the volume of rubber at the cure temperature, V_{r2}, is obtained by subtracting the volume of the pan at temperature, V_{p2}, from the volume of the total tool cavity at temperature (V_{tc2}), with pressure equal to 0 psi:

$$V_{r2}=V_{tc2}-V_{p2}$$

where

$$V_{tc2} = V_{tc1} + V_{tc1}\,B_t\Delta T$$

$$V_{p2} = V_{p1} + V_{p1}\,B_p\Delta T$$

where B_t is the volumetric expansion coefficient of the metal details, B_p is the volumetric expansion coefficient of the material of the part, and

$$\Delta T = T_2 - T_1$$

where T_2 is the cure temperature (desired pressure application point) and T_1 is room temperature.

The clearance between the laid-up bulk thickness of the uncured part and the rubber at its room-temperature size should then be determined. This is to ensure that there is enough clearance for the tool assembly. If the clearance is inadequate, the depth of the tool cavity must be increased. This larger cavity, in turn, will call for a commensurately thicker rubber mandrel. Generally, the differences between the expansion factors of the hard tool material and the rubber is adequate for tool assembly.

After the proper tool cavity and rubber sizes are obtained, the rubber can be poured directly into the fabricated tool cavity. When this technique is used, the pan configuration and setback size are represented by wax. The volume of wax, V_w, required for setback is equal to the difference in rubber volumes:

$$V_{r2}-V_{r1} = V_w$$

The shrinkage can also be compensated for at any time after the rubber volume has been determined. One simply increases the physical dimensions by the percentage of shrinkage. Note that this volume of wax does not include the cured-part dimensions.

To ensure accurate geometry of the cured part, the tool designer must take into account the geometries of all three critical surfaces when the setback wax volume is distributed in the mold. The three geometries can be quite different when a strictly mathematical interpretation is taken. However, by using a two- or three-dimensional computer-aided design, maintaining the geometric configuration becomes straightforward.

Open Molding: Hand Lay-Up and Spray-Up

Finn Roger Andressen, Reichhold AS, Norway

Introduction

OPEN MOLDING, also known as contact molding, open laminating, and wet lay-up, is the method used longest in the polymer-matrix composites industry to make thermoset composite products, and it is still the selected production process for a wide range of composite products. It is a basic process that provides many of the advantages of composites processing, using relatively basic materials technology and processing methods.

The molding method involves placing reinforcements and liquid resin onto the surface of an open mold (which may or may not be precoated with gel coat), or onto other substrates, as, for example, when making a one-off sandwich construction, when making on-site repairs by applying a reinforcing vacuum-formed acrylic,

corrosion-resistant lining on steel, or when making on-site repairs of tanks and pipes. The hand lay-up version involves applying the reinforcements and the resin by hand, while the spray-up version uses tailored spray equipment to deposit both reinforcements and resin on the mold or an alternative substrate.
Open molding is a process typically used for low- to medium-sized series (from a few to 200–300 parts/yr), offering a number of process and product advantages. Producing large, complicated shapes as well as smaller and simpler composite products is possible.
The hand lay-up process involves low investment costs and little prior working knowledge of the process, while spray-up involves some investment in tailored spray-up machines and spray guns. Well-trained operators and dedicated facilities are required to produce components and products having high quality.

Open Molding: Hand Lay-Up and Spray-Up

Finn Roger Andressen, Reichhold AS, Norway

Process Characteristics

Open molding offers a number of process and product advantages over other high-volume, complex application methods and is therefore used for a number of specialized products. Process advantages include:

- Freedom of design
- Easy to change design
- Low mold and/or tooling costs
- Low start-up costs
- Low to medium capital costs
- Regarded as a simple process
- Tailored properties possible
- High-strength large parts possible
- Large-sized parts possible
- On-site production (one-off) possible

Disadvantages associated with the open molding process include:

- Low to medium number of parts/year
- Long cycle times per molding
- Labor intensive
- Evaporation, exposure, and emission of volatile organic compounds (VOCs)
- Not the cleanest application process
- Only one surface has aesthetic appearance
- Operator-skill dependent
- Sharp corners and edges limited
- Long reworking time per molding
- Limited amount of filler to modify properties

Laminate properties depend on resin quality and reinforcement type, but a primary benefit of open molding is the ability to tailor the properties of thermoset composite products. However, this is dependent on both amount (fiber fraction) and type (direction) of reinforcements used, as shown in Fig. 1.

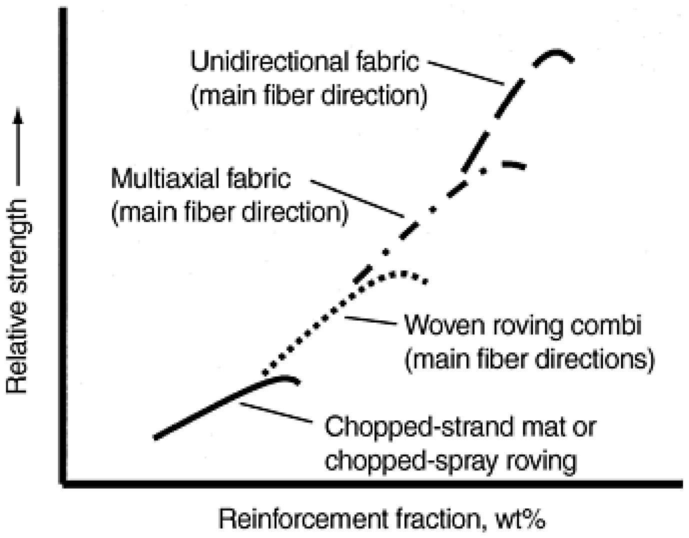

Fig. 1 Influence of reinforcement fraction and type on mechanical properties of open-molded fiber reinforced polymer-matrix composite laminate

Note, that too high of a fiber fraction for a given reinforcement type can result in a laminate that is too dry, that is, there is not sufficient resin present to wet and/or impregnate all the fibers by the manual consolidation operation (homogenization process). Consequently, this will result in a drop of properties, as indicated in Fig. 1. The use of woven roving (WR) and multiaxial fabrics makes it possible to tailor the direction of the continuous fibers in these materials, enabling the fabricator to place the properties where and in which direction is desired.

Open Molding: Hand Lay-Up and Spray-Up

Finn Roger Andressen, Reichhold AS, Norway

Applications

Thermoset composite parts are used in applications requiring high strength-to-weight ratio, corrosion resistance, antimagnetic properties, thermal and electrical insulating properties, freedom of design, ease of transport and installation, and so forth.
Typical products manufactured using prefabricated molds and tools, include products that have small to large surface area and simple and complex shapes, and they are restricted in size only by practical handling of molds. Typical products include:

- Boat hulls and decks (Fig. 2)
- Tanks and vessels (Fig. 3)
- Components for the transport industry (auto and train parts)
- Industrial parts
- Building parts
- Electrical parts and covers

The so-called one-off moldings are nearly unlimited in size; applications and products include:

- Reinforcement of steel and concrete structures
- Corrosion-resistant liners
- Large vessels and boats, normally sandwich constructions (Fig. 4)
- Large surface area subsea covers, normally sandwich constructions (Fig. 5)
- Reinforcing vacuumed acrylic sanitary parts

Process Description

Open molding typically involves depositing the reinforcements and liquid resin onto a mold surface or depositing materials onto other substrates, which are then integrated into the final composite part. The laminating principles are similar. The mold surface quality is of utmost importance when surface aspect requirements are high because the composite part surface replicates mold surface quality.

Molds and tools for the open-molding industry are often made of composite materials using a tailored mold and tool gel coat as the surface finish layer, which provides a durable, high-gloss surface. Cast molds, electroformed nickel-shell molds, and other metal molds are also used; these give a longer mold life in normal use.

The hand lay-up process is illustrated in Fig. 6. Before starting the actual laminating process, the mold surface has to be clean and prepared with a suitable mold-release agent, which must be properly cured before the catalyzed gel coat is applied. The catalyzed gel coat typically is applied after curing. Gel coat is a tailored pigmented or nonpigmented resin that typically is applied as the first 400 to 700 μm outer layer. It not only provides the surface quality, but it also functions as a protective layer against weathering and other exposure, protecting the final underlying reinforced laminate from direct environmental attack and consequent possible unwanted degradation of laminate properties. The recommended type and amount of organic peroxide (typically 1.5–2 wt% of a good methyl ethyl ketone peroxide) must be added to the preaccelerated gel coat before use; however, it often is preaccelerated by the supplier.

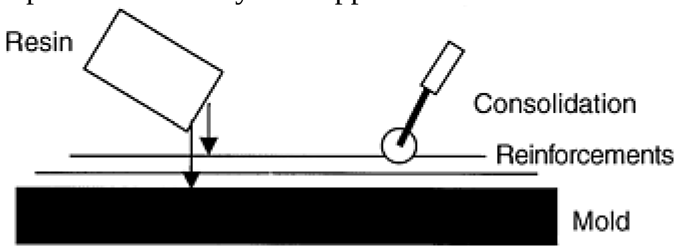

Fig. 6 Hand lay-up

In the case of pure hand lay-up, the gel coat is also applied by hand, using a suitable soft brush. Curing time is typically a few hours at ambient temperature, after which application of resin and reinforcements can start.

A suitable type and amount of a given curing system must be added to the resin before starting the actual laminating operation. This depends on the type of resin used, so it is recommended that the supplier be consulted for specifics.

In fabricating composite laminates for use in marine applications where surface aspects and resistance to osmosis and blistering is important, a skin laminate is often applied behind the gel coat. This consists of 1 to 2 layers of a 20 to 30 Tex 450 g/m^2 chopped-strand mat (CSM) of the powder-bonded type, preferably impregnated with a low-styrene, high-quality resin (Fig. 7). Such a skin laminate has good hydrolytic stability, low shrinkage, good toughness, and good curing properties at ambient temperature. A grooved metal roller is used to consolidate the skin laminate, ensuring that all fiber filaments are wetted and all air entrapments are removed (Fig. 8).

Fig. 7 Application of resin and chopped strand mat

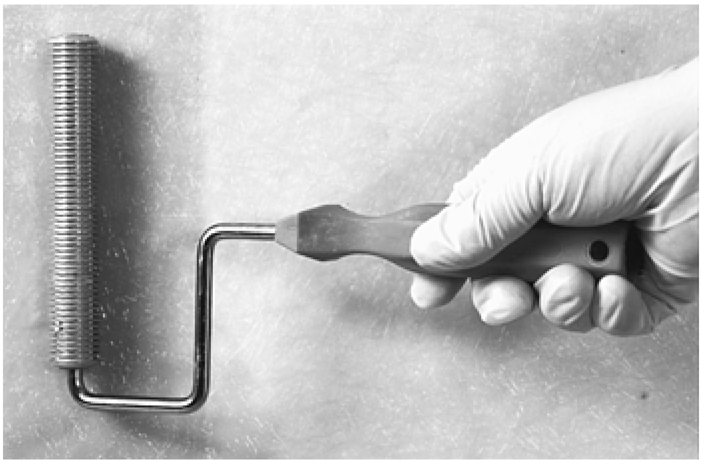

Fig. 8 Laminate consolidation using grooved metal roller

After a curing 8 to 24 h at ambient temperature, the construction of the structural, or load- carrying, laminate can begin. Liquid resin, to which is added the recommended curing system, is applied onto the cured gel coat surface (or the cured skin laminate) using a suitable soft brush or synthetic hair roller. The resin system is applied manually from a container containing the catalyzed resin, or via a resin-dispenser roller system. The latter is a cleaner application method, but requires a resin-pumping and connected roller system. The first layer of dry reinforcement is placed into this liquid layer, and more liquid resin is applied, in a quantity sufficient to properly wet the reinforcement layer. Consolidation using the metal roller is again necessary, and this sequence is followed until the required laminate thickness/part construction is achieved.
The curing system added to the liquid resin will start the chemical cross-linking reaction. After a proper curing period, a top coat (also a pigmented or nonpigmented tailored resin) is applied, for both cosmetic purposes of the inner surface and the protection of the underlying laminate.
Hand lay-up allows a wide selection of reinforcement type. Generally, reinforcements are in the form of mats ranging from simple CSMs to the more complex and sophisticated WR and/or multiaxial fabrics also often combined with chopped fibers, the so-called combimats. The choice of reinforcement influences the final mechanical properties of the laminate.
In the spray-up version of the open-molding process, the liquid gel coat (when required) is applied in the correct wet-film thickness using tailored spray equipment (Fig. 9). After a proper curing period of the gel coat, liquid resin and chopped fibers are simultaneously deposited onto the gel coated surface from specialized spray equipment and spray guns (Fig. 10).

Fig. 9 Gel coat spray-up

Fig. 10 Resin/glass spray-up gun

In fabricating laminates for use in marine applications, a 1 to 2 mm (0.04–0.08 in.) skin laminate can be applied using a silane-sized spray roving impregnated with a high-quality skin laminate resin system. After curing as with hand lay-up, building up the load carrying laminate can begin. The sprayed, catalyzed liquid resin will wet the reinforcement fibers, which are simultaneously chopped in the same spray gun. These chopped fibers replace the CSM typically used in hand lay-up. Additional reinforcements such as WR or multiaxial fabrics can be placed between the chopped-fiber spray-up layers, but these have to be wetted with liquid resin also, either by applying by hand or through the spray gun without chopped fibers. Between the individual layers of chopped fibers or WR/multiaxial fabric layer, the wet laminate is consolidated by rolling using a grooved metal roller. A typical chopped-fiber/resin laminate thickness between consolidations is 1.5 to 2 mm (0.06–0.08 in.) maximum. Spray-up, with or without hand-laid layers, is continued in this sequence until the total laminate thickness is applied. As for a handmade laminate, the inner surface is often coated with a top coat after curing the main laminate.

Workmanship is important for hand lay-up and spray-up. Proper preparation of the mold surface using correct mold-release application and preparation plays a key role in demolding the product. It is essential that the gel coat layer is applied in the correct thickness and evenly distributed over the total area, to avoid unwanted surface irregularities and reduced long-term protection of the part. Gel coat quality should match the application (hand brush or spray) to avoid unwanted sagging and to get good air release and "hiding" power.

For hand (brushing) application, the total gel coat thickness typically is applied in two operations. The first application of ~400 μm (~16 mils) wet film is applied as evenly as possible. After a setting period, a second ~400 μm layer is applied in a crosswise direction to the first to obtain the most even total film thickness possible. Because brushing is time consuming and difficult, spraying is used more often. Recommended spray-gun tip size, is an opening of 455 to 660 μm (18–26 mils) with a 40° angle.

Good workmanship also is important in the application of the reinforcements and resin (load-bearing laminate construction) behind the gel coat. The reinforcement must be placed correctly and evenly so that tapered overlaps and laminate edges are created. This is especially important when using hand lay-up to achieve correct thickness changes. When impregnating the reinforcements, it is important that the resin is evenly distributed to obtain the same reinforcement fraction over the total surface area and to obtain the required thickness.

For each single or double layer of reinforcement mat, the wet laminate has to be consolidated using a grooved metal roller. This is necessary to obtain air release and to split the individual strands in the reinforcement. Good splitting is essential to achieve good mechanical properties; the greater the fiber surface area available for the resin to impregnate and bond to, the better the properties will be.

Reinforcements in the form of mats make it difficult to handle corners and edges. Therefore, the design should have a sufficient radius in corners and over edges. Otherwise, the reinforcement mat tends to stretch in corners and buckle over edges, resulting in air pockets and/or resin- rich areas having low glass content. Corners and edges that are too sharp can also result in excessive rolling, causing thin laminates compared with the rest of the construction.

In the spray-up process, chopped-glass fiber and resin are deposited via a spray gun equipped on a custom pumping machine. It is important to follow the calibration and operation instructions set by the supplier. This is especially important for the resin spray patterns and the resin/ glass ratio. The spray pattern will influence the uniformity of the wet laminate, and glass content (and corresponding mechanical properties) is controlled by adjustment of the chopper. Consolidation is also important here, and it is always recommended to consolidate with the grooved metal roller between each 1.5 to 2.0 mm (0.06–0.08 in.) wet laminate. This will secure proper air release and splitting of fiber strands. Achievable glass content using only chopped-fiber roving (normal for spray-up), is lower than for hand lay-up. However, it is possible to combine spray- up laminates with one or more layers of WR and/ or multiaxial fabrics to achieve improved properties, either over the total area or in areas where the improved properties are required.

Regardless of the lay-up method used, the quality of the final part depends on the skills of the laminator, so trained workers will always be able to make better laminates and part-to-part consistency than untrained personnel.

Laminate quality is also affected by temperature, as viscosity and gel and cure properties are temperature dependent.

Resin viscosity guides the wet-out properties of a resin, and resin suppliers typically adjust the resins to optimal viscosity for the application process, generally for a temperature between 18 and 25 °C (65 and 77 °F). Too low of a temperature will result in higher viscosity, making it more difficult to consolidate and impregnate the laminate, and possibly causing unwanted air entrapment. Too high of a temperature causes viscosity to drop, which can cause sagging on more vertical areas. Low viscosity also tends to wet better, so the laminators automatically make less use of the metal roller, causing less fiber strand splitting and reduced mechanical properties.

Temperature also influences the gel and cure behavior of the resin. Low temperature inhibits gel and cure, which can affect part quality; the state of cure when the part is demolded and put into service is of utmost importance. High temperatures decrease gel time and increase reactivity; decreased gel time can cause the resin to solidify before proper part laminating is finalized, possibly resulting in a scrapped part. Increased reactivity (cure speed) can result in too high of a peak exotherm, which can cause discoloration, internal stress buildup, resin cracking and so forth. Therefore, control of material storage temperature and temperature of the work area is important.

Open molding using unsaturated polyester and epoxy vinyl ester laminating resins involves working in an environment containing styrene monomer, the reactive solvent in these resins. A certain amount of styrene will evaporate from the resin during processing. Because styrene is regarded and listed as a harmful constituent, precautions must be taken to protect workers from too-high styrene exposure. Maximum allowable styrene exposure levels are regulated nationally and vary from 20 to 100 parts per million (ppm). Using the so-called low-styrene emission (LSE) resins combined with adequate ventilation reduces styrene exposure and emission by at least 50% compared with a non-LSE laminating resin.

Optimal cross-linking (curing) reaction for open molding at room temperature might not be complete, so postcuring at elevated temperature is often recommended. Baking a part for a few hours at elevated temperature is often sufficient to achieve full cure; the temperature and baking time is dependent on resin quality. Table 1

lists necessary postcuring periods versus the heat-deflection temperature (HDT)—also known as the deflection temperature under load, or DTUL (as measured according to ISO 75, Method A)—of the resin system.

Table 1 Recommended postcuring temperature and time based on resin heat deflection temperature (HDT)

Postcuring temperature		Postcuring time for indicated resin heat deflection temperature, h			
°C	**°F**	**for HDT of 65 °C (149 °F)**	**for HDT of 85 °C (185 °F)**	**for HDT of 100 °C (212 °F)**	for HDT of 130 °C (265 °F)

Open Molding: Hand Lay-Up and Spray-Up

Finn Roger Andressen, Reichhold AS, Norway

Materials

The predominant matrix-resin materials used for open molding as described here are unsaturated polyester resins and epoxy vinyl ester resins. Other matrix materials including phenolics and epoxies are also used in specialized applications. The resins are delivered and used in a liquid state, usually made thixotropic to prevent sag tendencies on more vertical areas. Glass fibers are the predominant reinforcement materials used, but more sophisticated reinforcements, such as aramid and carbon fibers, are often used in combination with glass fibers. Material selections are made based on both short- and long- term end-product requirements.

Unsaturated polyester resins and epoxy vinyl esters can be formulated to have a wide range of properties, depending on the raw material combination and polymerization process. Orthophthalic resins typically are selected for parts exposed to normal weather and water resistance (general-purpose laminating resins); these resins can also be formulated to have very good corrosion resistance in humid conditions (high-quality orthophthalic laminating resins).

Resin systems based on dicyclopentadiene (DCPD), alternatives to general-purpose orthophthalics, typically are used where improved part surface cosmetics are required. This is due to their improved ambient-temperature curing behavior and their ability to be formulated for reduced shrinkage. Isophthalic and terephthalic resins generally are selected for use in more aggressive exposures, as these in general have a better chemical resistance than the orthophthalics and DCPD-based systems. Epoxy vinyl esters are used in applications requiring high chemical resistance. Within these three categories, the mechanical and physical properties can be wide, especially with respect to rigidity and heat, corrosion, and fire resistance.

Reinforcements are available in a variety of qualities and fiber design. The simplest form of glass fiber reinforcements is CSM, typically used in the hand lay-up mode, and gun-roving and/or spray-up roving, typically used in the spray-up mode. The amount and type of reinforcement dictate mechanical properties of the laminate, but only to a certain extent, as the fiber fraction normally has to be kept below 40 wt%. More sophisticated fiber reinforcements, such as the WR, WR combi, multiaxial fabrics, and multiaxial fabrics combi, must be used for higher mechanical properties, which are dependent on the fiber fraction and direction. These are also delivered in the form of mats, so they have to be laid by hand regardless of application mode for the rest of the reinforcements.

Finn Roger Andressen, Reichhold AS, Norway

Component Properties and Characteristics

Apart from being dependent on the component design, short- and long-term properties of a fiber reinforced composite laminate made using open molding may vary depending on material selection and workmanship. Material selection and workmanship and workshop conditions influence short-term properties. Long-term properties (i.e., how well the composite laminate can withstand different exposures and service loads during the expected lifetime) depend on the type and intensity of the exposure, as well as the material selection, workmanship, and state of cure when put into service. Typical short-term properties are:

- Mechanical properties
- Heat resistance
- Thermal conductivity
- Electrical properties
- Fire retardance
- Visual aspects

Typical long-term properties are:

- Weather resistance
- Water resistance
- Chemical resistance
- Heat aging
- Fatigue resistance
- Creep resistance

Mechanical Properties. The strength and stiffness of a composite laminate are dictated by the type, amount, and direction of the fiber reinforcement in the thermoset resin matrix. Glass fiber is the most widely used reinforcement for unsaturated polyesters and epoxy vinyl esters, but aramid and carbon fibers are used when increased mechanical properties are required. Glass fiber forms include CSM and spray roving, as well as WR, multiaxial fabrics/knitted fabrics, and unidirectional (UD) fabrics. Woven roving, multiaxial fabrics, and UD fabrics also are combined with chopped roving (combimats).
Woven roving, multiaxial fabrics and UD fabrics are normally used when increased mechanical properties are required, as glass content then is increased. Woven roving and multiaxial fabrics are used when increased properties in certain directions are necessary.
Woven roving aramid fibers are primarily used when lower laminate weight is required. Aramid improves mechanical properties, especially impact resistance, but at the expense of compression properties. Because aramid fibers are more expensive than glass fiber, they often are used together with glass fiber and are known as glass- aramid hybrids.
Carbon fiber is used as continuous roving or as certain fabrics and also often as a hybrid together with glass, due to its relatively high price. Carbon fiber increases mechanical properties; types having high modulus result in a laminate having low-impact properties and vice versa.
Table 2 lists representative properties for a standard laminate using a general-purpose orthophthalic laminating resin. Properties of laminates of different matrix resins reinforced with 30 wt% (17 vol%) CSM glass fiber are listed in Table 3. Table 4 lists properties of the same resins listed in Table 3, reinforced with WR combimat (800/100) of ~50 wt% (32 vol%) glass fiber. Expected achievable properties using a high-quality isophthalic/neopentyglycol (Iso/ NPG) resin as the laminating resin are shown in Table 5. Carbon fiber is used in cases where requirements for high mechanical and stiffness properties are dominant, and expected laminate properties are shown in Table 6. The laminates are made using a rubber-modified vinyl ester, and carbon fiber

multiaxial fabrics based on improved carbon fiber roving. Improved shear properties in vinyl ester laminates are also found (indicatively) if a smaller amount of chopped- glass fibers are used between the carbon fiber fabric layers.

Increased stiffness of a composite product can be optimized by intelligent design, by using stiffener ribs, making a sandwich construction, and/ or making the laminate thicker. A significant weight saving compared with a similar steel construction can be realized (at least 50%) regardless of the type of polymer composite laminate construction.

Visual Aspects. Three main visual aspects are color, surface gloss, and surface print-through. Suitable pigment pastes are added if a colored laminate is required. As described earlier, the gel coat surface layer provides the surface visual aspects, and the quality of the mold surface and the gel coat quality will have great influence on visual quality. The part surface replicates the mold surface, so a high-quality, glossy mold surface is required. Gel coat formulation will have impact on the surface gloss, color appearance, and so forth.

Surface print-through is an important factor affecting the cosmetic nature of the surface. The fiber print-through appears on the surface (normally the gel coated surface) as print-through of the reinforcement fibers in the structural laminate. This typically is caused by resin shrinkage in the laminate after part demolding, so that any reduction of such shrinkage after demolding the part is essential. Sandwich constructions can also show print-through (a print-through of the core material on the surface) especially when square cut core material is used. The degree of print- through is dependent on:

- The gel coat quality (reactivity, HDT)
- Skin laminate: correct fiber type and fraction, resin quality (shrinkage and reactivity)
- Structural laminate: fiber fraction and resin reactivity
- Demolding: state of cure when demolding

The Long-Term Properties. The change in short-term properties with time and exposure is primarily dependent on the resin used in the laminate. However, parameters including fiber quality and fiber fraction, laminate construction, workmanship, and state of cure when put into service all can have important influence.

The weather resistance of a composite laminate is generally considered to be very good for a normal, good-quality laminate constructed and designed for outdoor exposure. A composite laminate will not corrode as will steel and aluminum, but the laminate surface will be subject to attack by rain, wind, and ultraviolet (UV) radiation, which can cause a change in color and surface gloss, and in some cases fiber blooming (one can see and feel fibers on the surface) for non-gel-coated parts.

Mechanical properties, of a good quality laminate with a proper surface protection are little influenced in the long term. Such laminates will retain >90% of their initial short-term values even after years of normal outdoor exposures, despite color and gloss changes. However, when a composite laminate gets or has a surface defect of some kind (which often is attributed to bad workmanship), the properties can be reduced more rapidly, as moisture and other “weather impurities” can penetrate into the laminate and thus cause breakdown in the structure.

To avoid this unwanted penetration, the structural parts of a laminate should always be protected, either by using a sufficiently pigmented gel coat layer or making a resin-rich surface by using one or two layers of a suitable surfacing veil. Making this resin-rich layer as free from voids (pinholes, craters, etc.) as possible is important to avoid possible sites for moisture penetration into the load-bearing structure of the laminate.

Two principle concerns with respect to water resistance are resistance to osmosis and blistering in parts such as boat hulls, swimming pools, bath tubs, and whirlpools, and so forth. Normal water resistance is discussed together with chemical resistance in general.

Blistering is generally caused by osmosis, and blister resistance is consequently determined by:

- Water quality: less osmosis in salt water than fresh water
- Gel coat quality: a high-quality, hydrolytic stable gel coat preferred
- Gel coat layer thickness: 500 μm (20 mils) min cured film preferred
- Gel coat layer porosity
- Gel coat layer state of cure
- Skin laminate quality behind the gel coat: fiber quality and resin quality, no air entrapments, and good state of cure. Postcuring at elevated temperature can be required.

Chemical resistance, including water resistance requires special attention, because the long-term behavior of a composite part exposed to aggressive conditions depends largely on resin system and reinforcement quality,

laminate construction, curing/postcuring, workmanship, and so forth. Use of a general-purpose orthophthalic resin generally is not recommended in this case. Also the type and intensity (concentration and temperature) of the chemical exposure influences service life.

To achieve a good barrier between the structural laminate and the corrosive medium, it is always recommended to make a laminate having a chemical-resistant liner to protect the structural laminate from chemical exposures (Fig. 11). It is further recommended that the total laminate should be made with the same kind of resin used for the chemical-resistant liner. However, it is a well-accepted practice to build the structural laminate with a less chemical-resistant resin system to reduce total part price. For example, a suitable epoxy vinyl ester can be used for the liner, and the structural laminate made of a good isophthalic resin having good HDT.

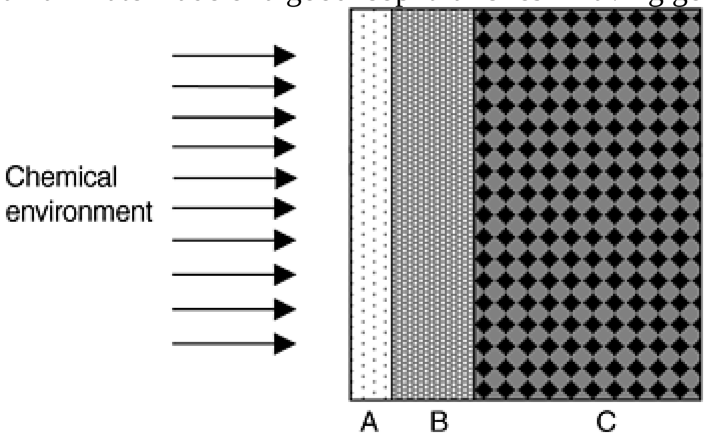

Fig. 11 Recommended chemical-resistant laminate construction. A, layer with surfacing veils impregnated with 90 to 95% resin; B, two-layer laminate having 450 g/m^2 powder-bonded mat, preferably with 20 Tex ECR fiber, or an equal thickness made of a silane-sized ECR spray roving (glass content should be 20–30%); A + B, chemical-resistant liner (preferably 2.5–3.5 mm, or 0.01–0.14 in. thick); C, structural laminate

To obtain the optimal chemical-resistance performance, a postcuring cycle at elevated temperature is recommended. A good postcuring cycle involves a 16 to 24 h cure at ambient temperature (>18 °C, or 65 °F) before postcuring at a higher temperature. Recommended postcuring temperature can be related to the chemistry of the resin and mostly related to the HDT of the resin (see Table 2).

Open Molding: Hand Lay-Up and Spray-Up

Finn Roger Andressen, Reichhold AS, Norway

Basic Design Guidelines

When designing a composite part, one should never try to make a part-to-part substitution of a metal part. For example, thermoset composite materials have lower stiffness (modulus) compared with metals, so a composite part has to be intelligently designed to overcome its lower stiffness. This can be accomplished by designing a part having ribs, a sandwich construction, and/ or increasing section thickness where required.

Using the reinforcement possibilities intelligently will also contribute to overcoming the lower stiffness properties. That is, one can use directed reinforcements (unidirectional or multiaxial) placed strategically where the part is likely to encounter higher stresses.

In a sandwich construction, core materials are imbedded into the laminate where higher stiffness is required, while still keeping part weight low compared with a similar metal part.

Corners and edges of the laminate should always have a minimum radius of 6 mm (0.2 in.) for the lay-up to follow the surface and prevent the occurrence of resin-rich areas. Designs incorporating undercuts are difficult to mold, but not impossible if a multipart (split) mold is used. Draft angles should be a minimum of 2° to allow easy part demolding.

Proper placement of reinforcements is very important to preclude sharp changes in thickness where stress concentrations and consequent delamination and warping can occur. Such sharp changes are avoided by carefully tapering the lay-up plies. If the total laminate is made wet- in-wet, there is the possibility of part warpage.

Unsaturated polyester and epoxy vinyl ester have a certain shrinkage upon cure; therefore, a laminate tends to become marginally smaller than the mold it is built in. As an indication, the shrinkage of standard unsaturated polyester laminate is 1 mm/1000 mm (0.01 in./10 in.). This requires designing and building a mold to compensate for part shrinkage. Shrinkage is dependent on design, laminate thickness wet-in-wet, fiber fraction, and so forth.

Finn Roger Andressen, Reichhold AS, Norway

Outlook

Use of fiber-reinforced thermoset composites as a competitive construction material is expected to grow. Open molding will likely continue to be an important fabrication method due to its competitiveness for short production cycles and large complex parts for a variety of end- product applications. However, this potential growth will be dependent on the evolution of better and easier-to-use application equipment and improved materials, both resin systems and reinforcements.

Open molding with styrenated resin systems causes evaporation, exposure, and emission of VOCs and hazardous air pollutants (HAPs). Therefore, it is important to reduce these hazards. This can be solved and/or improved by the use of both better application equipment and thermoset resin systems having low or no VOC/ HAP, but still maintaining the good and easy application properties of the unsaturated polyesters and epoxy vinyl esters.

More effective spray-up equipment needs to be developed—easier-to-use spray guns and nonatomized applications—to reduce VOC/ HAP emissions caused by the application equipment. Development of new resin systems must address low/no VOC/HAP requirements.

Further improvement in gel coat technology, that is, gel coats having improved water-weather and UV resistance, will enable the open-molding industry to make composite parts having improved long-term surface stability (color and gloss), which will be more competitive in applications requiring good, long-term surface-aspect stability (especially in the building industry),which is not achievable with existing technology.

Introduction

COMPOSITE MATERIALS are used in a wide range of marine vessel applications, from kayaks of a few meters in length up to military and commercial vessels of more than 70 m (230 ft). The reasons for the use of composites vary greatly, depending on the type of application. Composites dominate the market for mass-production small pleasure craft because of the flexibility and efficiency of manufacturing methods, good durability, and low maintenance requirements. For large luxury vessels, it is the ability to obtain a very high class finish, combined with low maintenance requirements and good performance from lighter weight structures, that drive the use of composites. In military applications, high specific strength, shock resistance, ability to incorporate stealth features, and low magnetic signature are key issues. For commercial craft, strength, stiffness, and durability provide composites with competitive advantages.

The most innovative use of marine composites is in the production of one-off custom sailing yachts, such as racing or luxury pleasure craft. For these vessels the high specific stiffness and strength, good toughness, high corrosion resistance, and excellent fatigue life of modern composites, combined with the development of very flexible manufacturing processes, have enabled composites to compete very successfully with aluminum. The availability of a wide range of specialized reinforcement and core materials and resin systems tailored to low-temperature manufacturing techniques have also been key factors in the growth of composites use in this field.

This article focuses on the design process, materials, and manufacturing techniques used for one-off and low-volume production sailing craft. These include racing yachts of typically 10 to 20 m (33 to 66 ft) length for short coastal events (Fig. 1), 20 to 25 m (66 to 82 ft) ocean racers (Fig. 2), 24 m (79 ft) America's Cup racing craft, multihull racers of 35 m (115 ft) or more (Fig. 3), and large (40+ m, or 130+ ft) luxury cruising craft.

Yacht Structure

A typical yacht structure can be considered to be comprised of three different types of components: the main hull/deck assembly (Fig. 4); the above-deck "rig" consisting of mast, boom, spinnaker pole, and sail furling systems; and the below-water appendages, the keel and rudder. Composites are used for all of these components; however the design requirements, structural solutions, and manufacturing methods are different for each.

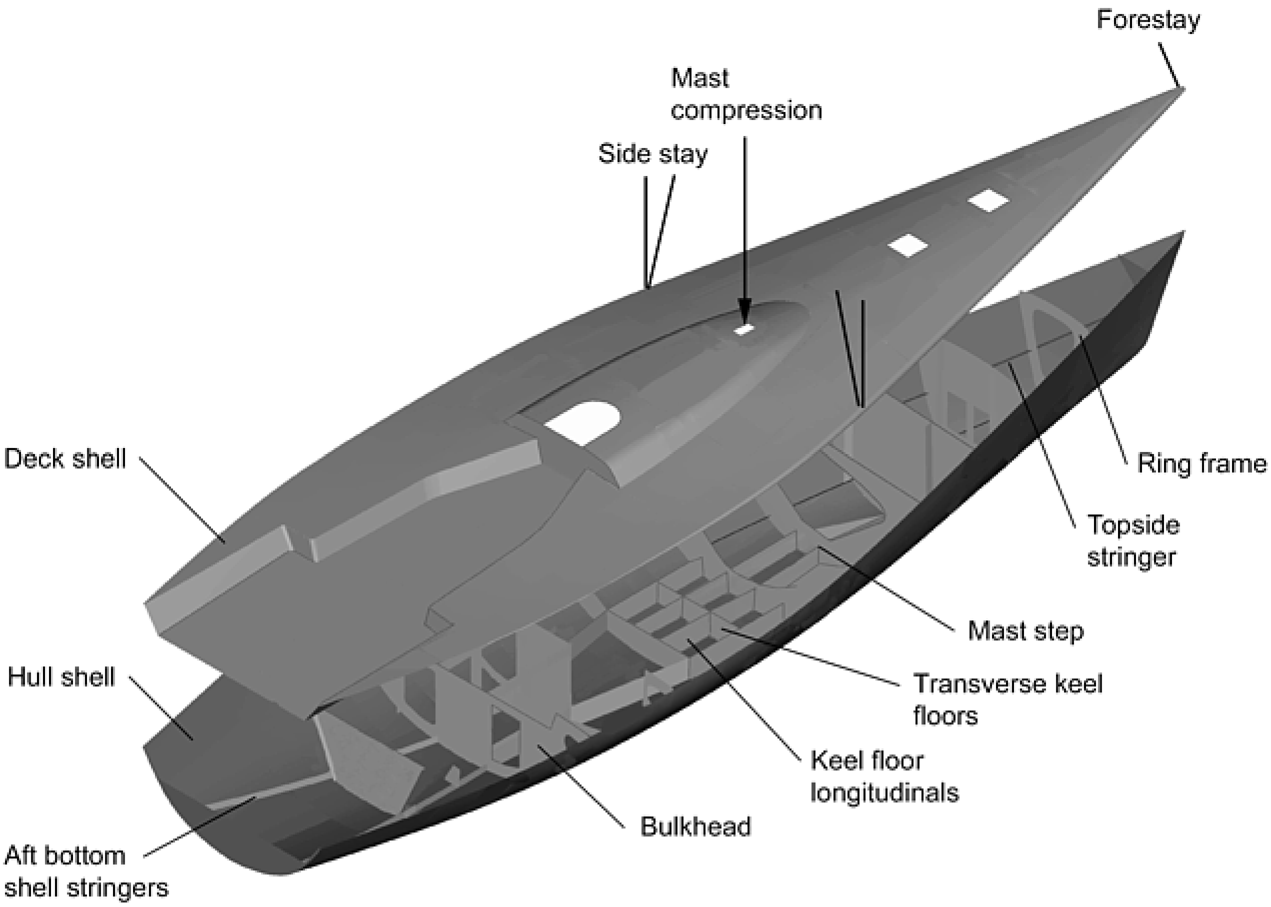

Fig. 4 Exploded view of typical yacht structure

The primary function of the hull and deck assembly is to provide a watertight buoyant structure that can maintain the correct hydrodynamic shape when subjected to applied loads from the water and from the rig and appendages.

The mast, in conjunction with its associated rigging, transfers the forces from the sails to the yacht hull, thereby propelling the vessel through the water. The pretension of the rigging results in extremely high compression loads in the mast tube and bending in the fore-aft direction, which is used to optimize the sail shape. In addition to distributed sail loads, the mast is also subjected to torsion from offset loads, such as the boom, and localized loads from the rigging.

Other tubular components include the boom, which is subjected to sail loads and concentrated loads from the mainsheet and vang, resulting in high compression and bending loads; the spinnaker pole, which is primarily subjected to compression; and the spreaders, which act to triangulate the rigging loads.

The purpose of the keel is to counteract the transverse aerodynamic force produced by the sails, thereby enabling the yacht to travel in a forward direction, and to provide stability by resisting the associated heeling moment. Shaped as a foil, the keel is subjected to hydrodynamic loads and also large bending loads, due to the mass of lead in the bulb. The rudder, which also provides lift to counteract the transverse aerodynamic forces and controls the steering of the yacht, is also subjected to large hydrodynamic loads, generating high bending loads at the top of the foil where it reduces in cross section to enter the yacht hull.

A yacht structure operates at the interface between water and air, making loads variable and very difficult to predict. Forces from wind and water can combine to produce dynamic loading on all of the structure at the same time. The loads are also significantly influenced by how the yacht is sailed, with human error being a significant factor in failures, particularly in the mast and rig.

The costs of manufacturing these types of vessels vary greatly depending on the intended use of the boat. As an example, Table 1 summarizes some indicative costs for typical high-performance 18 to 20 m (59 to 66 ft) monohull racing and performance cruising yachts. The racing yacht would have a very basic interior, with no joinery, mostly unpainted interior laminates, and only what is absolutely necessary to live on board. In the year 2000, the overall cost of such a boat was approximately $1.8 million, with a total of approximately 35,000 hours of labor involved in the design, construction, and fitting- out to the stage of launching the boat in the

water. Labor constitutes approximately 40% of the total cost, the next largest component being materials for the hull, at approximately 34%. The cost of the cruising yacht would be approximately $2.0 million, with the interior being a much larger component of the total cost.

Table 1 Cost comparison for typical 18–20 m (60–66 ft) racing and cruising yachts

Design Guidelines

The structural design process for a sailing yacht endeavors to combine the geometry constraints, imposed by the hull shape and interior arrangement, with the material properties and construction processes to meet the applied loads with an acceptable safety margin. Considerable progress has been made in defining achievable materials properties, given the limitations of the building process. Similarly, there have been advances in design tools, such as finite-element analysis, enabling more refined analysis of complex geometries. However, the science is still severely constrained by the lack of in-depth understanding of the applied loads. The definition of the dynamic forces applied to a sailing yacht, particularly in extreme conditions, is complex. As a result, the design process is based on past experience, simplified load scenarios, gross assumptions, and acceptable safety margins.

Hull and deck shells are typically designed to resist a spectrum of static pressures. Decks are only occasionally subject to a head of water, typically in the order of 1 to 2 m (3 to 7 ft) at most. The hull bottom, especially forward, can be exposed to higher slamming loads when sailing in waves, and hence the design pressure might equate to a 5 to 8 m (16 to 26 ft) head. An arrangement of internal structural support (bulkheads, frames, and other local stiffeners) is developed with due consideration to the interior accommodation requirements. This is matched to a suitable plating specification (selection of core and skins dependent upon the unsupported panel span and design head), such that deflection criteria and safety margins are met. Overlaid on this is the localized treatment of high stresses generated by the mast and rigging attachments, deck hardware, keel and rudder, and the engine. This often involves additional patching and specific framing in order to spread the load into the surrounding structure. On larger (>20 m, or 66 ft) vessels, overall bending deflections under both rig and wave load scenarios may be calculated, because fore-and-aft rigidity is critical to sailing performance.

The definition of loads in the rig is a little easier than for the hull shell. Sail forces can be estimated, and from this, the rigging supporting the mast sized. Factors are then applied to account for inertial loads as the boat pitches in the fore-and-aft direction when sailing over waves. The major use of composites in rigs is in the mast tube itself, which can be treated as a supported column under compression. Given a slender section to minimize wind resistance, the design problem becomes one of buckling, often leading to the use of higher-modulus carbon reinforcements (Fig. 5). In addition to the specification of a section shape and laminate capable of sustaining the compressive forces, there are equally important secondary loadings to consider, such as at the interfaces with the supporting rigging. In a mast with a wall thickness of nominally 6 to 8 mm (0.24 to 0.31 in.), the reinforcement in the region of stay terminations can increase the thickness locally to 15 to 20 mm (0.59 to 0.79 in.).

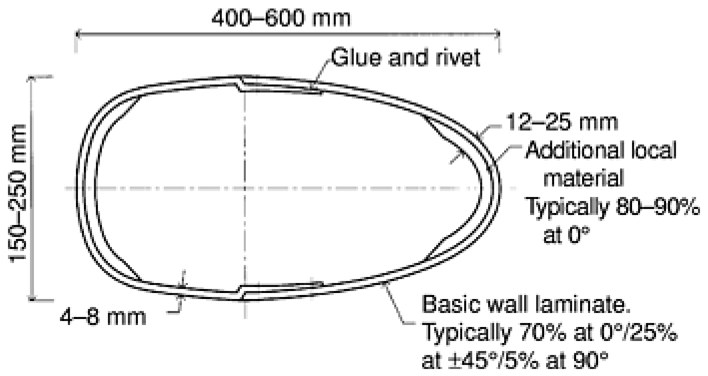

Fig. 5 Typical mast cross section

Keels and rudders are similarly apparently straightforward. The maximum load that can be applied to a ballast keel can be estimated by a static analysis of a severe knockdown in which the vessel lies on its side. The hydrodynamic forces applied to the rudder can be calculated based on understanding of the section shape and expected speed. Often the angle of attack of the foil is limited by the ability of the steering system to apply sufficient torque, and this can result in a load lower than might be calculated from first principles. In order to produce efficient foil shapes for both the keel and rudder, there are restrictions on the section size, and hence the design becomes dimension-limited. In most cases, ultimate strength is the primary design constraint, but increasingly with deep slender foils, stiffness is also a concern, because excessive deflection can lead to loss of performance. As with the rigs, this drives the design toward the use of carbon-fiber reinforcements.

The design process is not entirely an “engineering” exercise. In addition to the loading scenarios and strength or stiffness criteria described previously, the specification has to take into consideration constraints imposed by the level of technology available to the builder, as well as the requirements of independent regulatory authorities and organizers of specific racing classes. These rules and regulations are usually a summary of the best available knowledge at the time and are intended to ensure safety and/ or control costs. However, they are sometimes unable to keep pace with developing technology, hence limiting opportunities for innovative structural solutions.

Yacht-building technology ranges from production female molded construction, based on materials and processes little changed since the 1980s (polyester resin, chopped strand mat and woven rovings, hand laminating), to elevated- temperature cure, vacuum consolidation, and unidirectional prepreg tapes with honeycomb cores. Most custom or one-off builders use epoxy-resin systems with some form of vacuum-assisted consolidation to reduce resin content. Sandwich construction is also widespread. Nevertheless, the design engineer needs to be aware of the fiber content the boat-building yard is capable of achieving with their processes. For a cross-ply, unidirectional glass laminate (either distinct plies or a multiaxial fabric), this could range from a low of 50 to 55% by weight through to better than 70%, depending on the resin rheology, form of the reinforcement, and consolidation process. The choice of core material can be influenced by the builder's ability to meet processing constraints. Elevated-temperature cure raises issues related to outgassing and stability of foam cores. Because most boats are manufactured in relatively uncontrolled working environments, humidity during the manufacturing process can be highly variable, leading to concerns over use of balsa or Nomex (DuPont) cores.

Material selection can also be influenced by the class rules for the particular yacht. Carbon- fiber reinforcements and honeycomb cores are not permitted in the Volvo 60 class for racing around the world (Ref 1). Consequently, the designs are based on aramid fibers, with some S- glass, and either foam or balsa cores. The intention, when the rule was written, was no doubt to limit cost. In the intervening period, carbon reinforcements have become more cost-competitive, yet the rules are slow to change, because this would penalize existing yachts. Even in the America's Cup (Ref 2), where cost is not a major constraint, the carbon used in the hull construction (Fig. 6) is limited to standard-modulus grades, although intermediate-modulus material is allowed in the rigs. Some rating rules try to assess the benefit that use of advanced construction materials can generate in terms of reduced weight and improved performance. While higher-performing materials are not excluded, their use is penalized in the handicap calculation. This can lead to use of lower technology than is optimal if the penalty is inconsistent with the actual performance advantages.

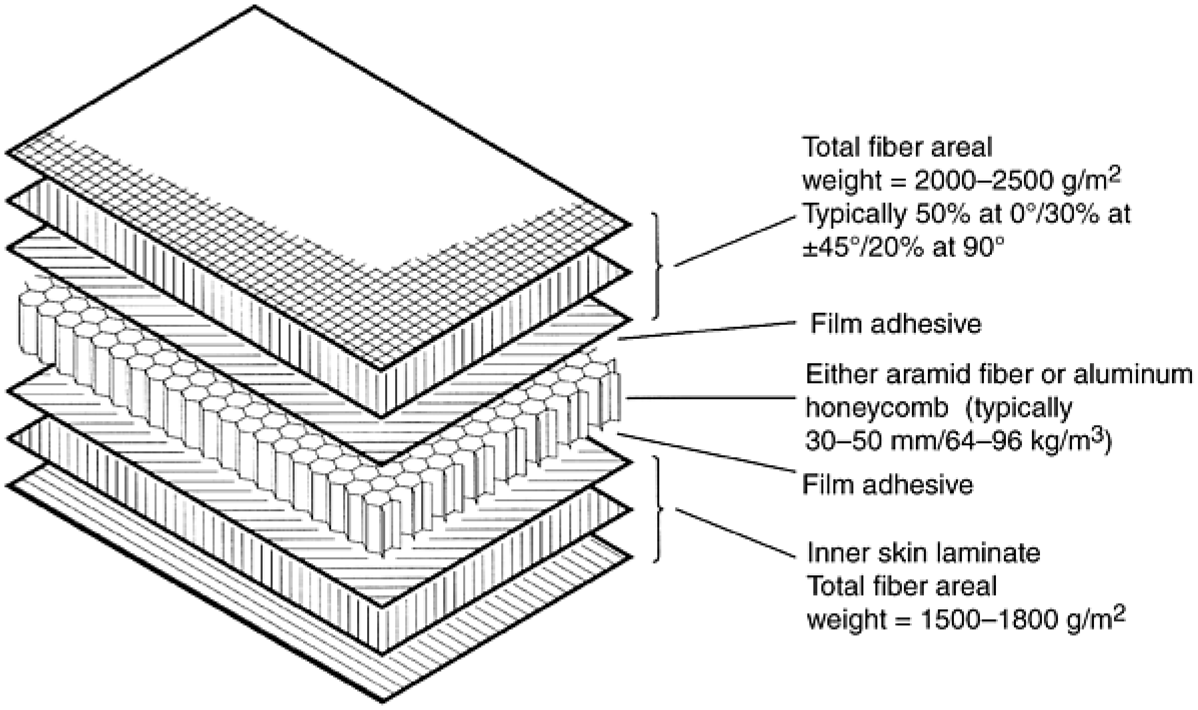

Fig. 6 Typical laminate for America's Cup hull skin

Given a portfolio of materials acceptable to the builder and allowable by the racing rules, the designer then addresses constraints that may be imposed by a scantling code, if applicable. For a period, racing yachts were covered by an American Bureau of Shipping (ABS) guide (Ref 3), and most events required plan approval prior to construction. This guide has been withdrawn, and ABS is no longer certifying racing yachts, although some event organizers and racing classes still require the yacht to be designed to meet these requirements. With modern sandwich design, the limiting factor tends to be the minimum outer skin thickness, a criterion based on durability and unrelated to frame spacing or shell properties. The design begins with the selection of an acceptable skin thickness, and from there develops core specification to suit the unsupported panel dimensions, or defines framing to suit the shell properties. Often the result is well in excess of the minimum requirements for local panel stiffness and strength, as laid down in the guide, and may appear "over-engineered" simply because the skin thickness constraint dominates.

Luxury performance craft not necessarily intended for racing may need to be built to comply with one of the international scantling rules (Ref 4, 5, 6, and 7). This can be a requirement of the owner for added surety in the design and build process and to reduce insurance premiums, or a statutory requirement if the vessel travels internationally. Most of these rules have been developed for a wide range of craft, and the intended construction method was conventional polyester chopped strand mat/woven roving (CSM/WR) female molding. Often the higher-fiber content, epoxy- based specifications devoid of any interlaminar chopped strand plies are more than adequate in terms of strength and stiffness, but fail to meet specific requirements aimed at a lower-technology process. An example would be the mandatory use of a chopped strand mat layer next to the core surface, desirable to improve adhesion in a production process, but unnecessary in a one-off process where the core is bonded using vacuum bag techniques and epoxy adhesives. While most scantling authorities allow some scope for variations, this is typically an expensive process, requiring significant analysis and testing to validate the proposed change.

Typical Design Solutions. Despite the constraints ranging from costs through scantling authority rules, there are still numerous possible solutions to the design of any vessel. Different emphasis on the trade-off between weight and cost, acceptable levels of toughness, and materials availability can result in widely varying specifications for what is essentially the same design. Individual designers also have preferences based on experience and can favor one material or style over another for no apparently rational reason. The following example is therefore not necessarily representative of the industry as a whole, nor ideal in all situations, however, it provides a general overview of a typical structure.

A 20 m (66 ft) performance cruising yacht, built with no regard to a specific racing rule, would most certainly be a sandwich construction, with a mixture of aramid, carbon, and E- glass reinforcements. The hull shell

would be based on a core thickness of 30 to 40 mm (1.2–1.6 in.), depending upon the interior arrangement, with bulkheads and partitions providing support for the shell. Without secondary stiffeners, such as transverse frames or fore-and-aft stringers, a thicker core is likely. Core material is likely to be a rigid polyvinyl chloride (PVC) foam of 80 to 100 kg/m^3 (5.0–6.2 lb/ft^2) density, with either linear foam or higher-density end grain balsa used in the slamming areas toward the bow of the boat.

The outer skin would be in the order of 2.5 mm (0.010 in.) thick and consist of a combination of aramid and glass reinforcements, with individual plies in the 300 to 800 g/m^2 (1.0–2.6 oz/ft^2) areal weight range. The aramid is included for durability and to achieve a minimum skin thickness at low weight, and would constitute about 50 to 70% of the skin thickness. The fibers are likely to be aligned with the principle loads, with two-thirds running fore-and-aft and the balance athwartships. The glass fibers, possibly laid off-axis (±45), reduce cost and simplify the fairing process if used for the outermost ply, because sanding through the fairing compound into the aramid is not recommended. The inside skin is generally in the order of 70 to 80% of the thickness of the outer skin, due to reduced concern over impact. For this reason, carbon is likely to be specified, particularly in the bottom shell running fore-and-aft where it is most effective with regard to overall hull bending loads.

Allowing for additional reinforcement in the region of the keel, core bonding adhesive, and fairing compound, the average panel weight is in the order of 12 to 14 kg/m^2 (2.4–2.8 lb/ft^2), yielding a bare hull shell of less than 2 tonnes (2 metric tons, or 4400 lb).

The deck is of a lighter construction, with a core thickness in the 20 to 30 mm (0.8 to 1.2 in.) range, and varying depending upon the local support. If weight is of primary concern, 48 kg/ m^3 (3.0 lb/ft^3) Nomex is favored over 80 kg/m^3 (5.0 lb/ft^3) foam, and there will be a higher percentage of carbon, with perhaps aramid used only in the high-traffic areas, such as the cockpit. With skin thickness of 1.8 mm (0.07 in.) outside and 1.1 mm (0.04 in.) inside, there is a requirement for considerable local reinforcement in the region of fittings, such as winches and sail tracks. Overall, an average panel weight of less than 10 kg/m^2 (2 lb/ft^2) can be expected, with a bare shell weight of around three-quarters of a tonne (1650 lb).

Internal structure consists of transverse bulkheads and longitudinal bottom girders, with local transverse floors in way of the keel and mast. The bulkheads and girders are sandwich, with a 15 to 25 mm (0.6 to 1.0 in.) core of either foam or possibly Nomex in some cases, with 1.5 to 1.8 mm (0.6 to 0.7 in.) E-glass skins (fibers typically at ±45) and local unidirectional carbon capping on exposed edges. Floors are typically 100 mm (4 in.) wide and 150 to 200 mm (6 to 8 in.) deep on centerline tapering outboard, of lower-density nonstructural foam, and covered with up to 5 to 8 mm (0.2 to 0.3 in.) of E-glass orientated at ±45 to carry shear loads in the webs. Bending properties are improved through capping of 7 to 10 mm (0.28 to 0.39 in.) of E- glass unidirectional, although in some cases a thinner carbon capping is justified on the basis of reduced weight.

The composites structure would weigh approximately 3.5 to 4.0 tonnes (3.9 to 4.4 tons), a small percentage of the overall weight of the vessel of typically 18 to 20 tonnes (20 to 22 tons), which can include as much as 6 to 10 tonnes (6.6 to 11.0 tons) of lead ballast at the bottom of the keel.

The carbon mast has a high percentage of 0° fibers, in the range of 65 to 70%, with a small percentage (5%) at 90° and the balance at ±45°. The tube itself is approximately 370 mm (14.6 in.) fore-and-aft by 195 mm (7.7 in.) transversely and has a basic wall thickness of 7 to 8 mm (0.28 to 0.31 in.) of carbon unidirectional prepreg, autoclave-cured at 3 bar (300 kPa) pressure to a volume fraction of 57 to 58%. This is designed as an Euler column subjected to a working load of approximately 500 kN (112×10^3 lbf), due to the forces exerted by the supporting stays. Transferring the high local loads from the stays, supporting spreaders, and other rigging into the tube demands quite detailed specific local reinforcing. Wall thickness in the region of openings and fittings could increase to 10 to 15 mm (0.4 to 0.6 in.), with the additional patching tending toward a quasi-isotropic laminate.

The rudder stock, or main spar, is a rectangular section to allow a relatively narrow (10 to 12% chord) foil shape (Fig. 7), with a buildup locally in the region of the bearing to approximately 300 mm (12 in.) diameter. The sides of the stock, where most of the transverse bending load is carried, are of the order of 25 to 30 mm (1.0 to 1.2 in.) thick at the intersection with the hull and are likely to have upwards of 60 to 75% of the fibers aligned with the stock, and the balance at ±45°. On the fore-and-aft faces, the 0° content is reduced, because these webs primarily carry shear. The laminate tapers considerably along the length, in line with the varying bending moment requirements. The stock is typically made over a non-structural, high-density foam former from standard-modulus carbon unidirectional, often in prepreg form and consolidated in an autoclave.

Material Types and Forms

The high-performance requirements of the modern sailing yacht are the primary drivers for lightweight construction, leading to a focus on high-fiber-content laminates based on advanced reinforcements. A range of techniques has been developed by custom yacht builders to achieve the relatively high fiber fractions required. Each of these processes creates its own constraints on the materials selection.

By far the simplest and most widespread is the "wet-preg" approach, which requires a long open-time resin system, can make use of a wide range of dry reinforcements (unidirectional tapes and broadgoods), and is compatible with most core materials. A prepreg construction is more restrictive in terms of material options. While broadgoods are available, they are more costly than collimated unidirectional tapes. There are few, truly

low-temperature cure systems, and hence the selection of core materials is limited to those suitable for elevated cure.
Resin infusion has its own constraints. Open cellular cores are not readily adapted to this system, and depending upon the resin system used, some of the foam materials may also be excluded, due to interaction with styrene under vacuum. Reinforcements need to be designed to assist flow through the laminate during infusion, and consequently, tight, highly anisotropic unidirectional tapes are not favored.
Reinforcements. Despite the apparent drive toward high-performance fibers, the majority of hull and deck structures are built with a high proportion of E-glass. On a “cost per unit of weight saved” basis, it is rare that a project will warrant extensive use of carbon or aramid fibers, although there are many areas where selective placement is effective. Chopped strand mat and woven rovings have been almost universally replaced by multiaxial knitted reinforcements (0/ 90 biaxial, ±45 double bias, and triaxial), typically in the 600 to 1200 g/m^2 (2.0 to 4.0 oz/ft^2) range. Heavier quadraxials in excess of 2000 g/ m^2 (6.6 oz/ft^2) are used in female molding; however, the side lap causes problems in one-off male molding. To minimize the side lap problem, some fabrics are supplied with tapered edges, where the warp fibers are removed along the side of the roll to reduce thickness buildup. Application of multiple plies of lighter unidirectional fabrics (250 to 400 g/m^2, or 0.8 to 1.3 oz/ft^2) is still popular despite the increased labor, because adjacent layers can be butted to avoid sidelaps. While the design engineer might favor a particular form due to enhanced (potential) properties, it is often the builder's criteria with regard to handling, ease of wet-out, and the ability of the material to follow compound curves that dominate the selection decision.
Reinforcements of carbon and aramid are readily available in woven cloth (150 to 350 g/ m^2, or 0.5 to 1.1 oz/ft^2) and unidirectional (200 to 500 g/m^2, or 0.7 to 1.6 oz/ft^2) forms, with limited multiaxial options, primarily double-bias (±45°). The styles used are often those that have been originally developed for aerospace applications, which can be more costly than necessary due to the associated higher quality assurance requirements. A more limited but cost-effective range of marine-specific reinforcements is available, with specifications typically limited to the use of 200 and 300 g/m^2 (0.7 and 1.0 oz/ft^2) carbon or aramid unidirectionals, 200 g/m^2 (0.7 oz/ ft^2) carbon cloth, and 175 and 300 g/m^2 (0.6 and 1.0 oz/ft^2) aramid cloth. There are a few glass/ aramid hybrids, both cloth and unidirectional, also available in the 400 to 800 g/m^2 (1.3 to 2.6 oz/ft^2) range.
With dry reinforcements, the choice of carbon fiber is very limited, unless a significant volume justifies a custom production run. In general, the designs are based on high-strain, standard-modulus material, except for top-end, unlimited budget race boats. In prepreg construction, the options are much greater, and occasionally intermediate- or even high-modulus material is specified longitudinally in the hull and deck structure to improve rigidity, where the construction rule permits. The specific stiffness is particularly valued in the rigs, and here the use of higher-modulus fibers is quite common, especially in the larger (>40 m, or 130 ft) spars of superyachts (yachts 30 m, or 100 ft, or more in length).
Resins. The choice of resin system is very much based on practical considerations. Long working time, enabling the use of on-site impregnators and vacuum consolidation, compatibility with a wide range of cores, and low toxicity have driven the market toward epoxy systems, for both wet and prepreg applications. Some yards continue to use polyester resins; others have moved from polyester to the intermediate step of using vinyl-ester resins. Interestingly, the overall cost differential is negligible, despite the apparent two- to threefold cost increase associated with epoxy systems. As a proportion of the overall cost of materials, the resin is less than 25%. Cost increases from reduced resin use due to higher fiber content are offset by the elimination of the need for chopped strand mat (because of the better interlaminar properties of epoxy) and less waste due to more controlled processing techniques.
Cores. The most common core material used in one-off construction is closed foam, either rigid (cross-linked) PVC (Herex, Divinycell) or tougher, higher-elongation linear developments (Airex, Corecell). Typically, the minimum density used is 80 kg/m^3 (5 lb/ft^3), because thin skin laminates on lighter foams tend to bruise under local point loads. In the hull shell, it is not uncommon to see cores in the 100 to 130 kg/m^3 (6 to 8 lb/ft^3) range in the forward slamming areas. Selected-density end grain balsa has become an attractive option with prepreg construction, due to problems associated with outgassing and thermal stability of some foams. Honeycomb cores are also popular with prepreg construction. Nomex has been the most widely used, typically 48 to 64 kg/m^3 (3 to 4 lb/ft^3), both small-cell hexagonal and overexpanded. Recently, the higher specific performance of aluminum honeycomb has been attractive in the America's Cup and large offshore racing multihulls (such as

the *Playstation*, Fig. 3), but there are concerns over the longevity of the core when combined with carbon skins due to electrolytic corrosion in a marine environment.

Custom Sailing Yacht Design and Manufacture

Technique Characteristics

The manufacturing techniques for the different components of a one-off or low-production yacht vary significantly to suit the requirements of each part of the structure. Manufacturing methods are generally highly labor-intensive, without extensive automation. Building conditions in most boatyards are much less well controlled than typical aerospace clean rooms. Approaches range from ambient or low-temperature cure wet lay-up, often using a “wet-out” machine, to autoclaved prepregs. The development of specialized materials, particularly lower-temperature cure resins with long out-life and low- temperature cure prepregs, has been a significant factor in the development of current manufacturing techniques. Autoclaves or vacuum bagging techniques are widely used to ensure good laminate consolidation and to minimize excess resin and hence, weight.

Hulls and decks are nearly always manufactured from either prepreg or wet preg materials. The latter is a development of traditional hand, wet lay-up techniques, but with a resin developed to have extended gelation time at room temperature. The reinforcements are passed through an on-site wet-out/impregnation machine, then taken directly from the machine and laid into the mold. This gives the builder the versatility of curing at low elevated temperatures (typically 50 °C, or 120 °F), the ability to control and vary resin content on-site, very good draping characteristics, and extended working time (typically 6 to 48 h).

The other major method widely used is based on low-temperature prepregs, which typically cure at 75 to 120 °C (170 to 250 °F). Prepreg- based processes (Fig. 8) provide the convenience of very clean working conditions and the luxury of long open times for the resin (typically 20 to 40 days), thus allowing smaller laminating teams. Fiber volume fractions and overall weight of the structure are also very well controlled, but are predetermined off-site when the prepreg is manufactured. This approach requires more care in tooling design and construction to ensure that the tooling will maintain adequate dimensional stability at the elevated curing temperatures. In addition to the higher cure temperatures, close management of the cure cycle is also required. Significant planning is required to order suitable materials ahead of time, particularly if particular volume fraction materials are required to meet racing-class rule constraints. Unlike wet lay-up materials, prepregs do not drape, therefore requiring careful cutting and placement to avoid overlaps. Debulking is also commonly required during the lamination process. These factors usually result in greater labor costs and higher use of materials, such as vacuum bagging consumables.

Fig. 8 Prepreg hull on male mold prior to consolidation

The requirements of tooling for the hull and decks of one-off or low-production vessels are very different from those for large-production components. Low cost is the primary constraint, long-term tooling durability is not a major issue, and the cycle time for laminating the component is not as critical as for high-production levels. The most cost-effective tooling for a hull or deck shell is often a mold constructed from particle board, timber stringers, plywood, and timber framing, using fabrication techniques reminiscent of traditional wooden boatbuilding. Male molds are commonly used for hulls, while female molds are generally used for decks. These types of molds are adequate for low-temperature cure; for higher-temperature prepregs, the selection of mold materials and fabrication techniques requires more care to ensure stability of the tooling at higher temperatures.

Spars are usually manufactured from prepreg materials and often autoclaved in custom-built, long autoclaves, typically at temperatures of 120 °C (250 °F) and pressures of 3 to 5 bar (300 to 500 kPa). The tooling requirements are quite different than for a hull or deck. If the structure is being autoclave-cured, the thermal stability of the tooling is critical, often leading to the use of carbon/epoxy for construction of the molds. Molds are often designed so that different-sized masts can be constructed from the same mold by using only part of the length or depth of the tool. The stock (shaft) of the rudder is also normally a single-skinned hollow section, so techniques similar to mast manufacture are often used. Other processes used for the rudder and minor components, such as spinnaker poles, booms, stanchions, tillers, steering wheels, winch driveshafts, and tubes for use internally, include resin infusion, closed mold with internal bladder, filament winding, and tube rolling. (Separate articles in this Section--for example, “Vacuum Infusion,” “Filament Winding,” and “Tube Rolling”--provide more information about these processes.)

Hulls and Decks. The following sections discuss tooling, laminating practice, curing, mold removal, and quality control for manufacturing hulls and decks using composites.

Tooling. The aim of the tooling for hull and decks is to build a low-cost, accurate tool that can withstand curing temperatures with little or no distortion and give a clean release to the molding. Tooling cost is very important, because it typically has to be amortized over very short production runs of one to twelve boats. The hull and deck can be built successfully in either a male or female mold; however, hull shells are commonly built on a male plug to achieve greater fairness of the hull shape and to minimize tooling costs. A well-faired male mold

used with a well-prepared core can produce an immaculate paint job with an average of less than 0.5 mm (0.02 in.) of lightweight fairing compound, far lighter than most gel coats or similar products.

Male molds are generally constructed using techniques that have evolved from traditional wooden boatbuilding. Timber frames are constructed to define the section shape at regular intervals or stations. Each frame is often cut and shaped accurately as two half-frames alongside each other, which are then joined at the centerline of the boat to produce a totally symmetrical shape. Wooden bracing is then used to restrain the frames in their correct orientation and spacing. Accurate datum points are critical to enable the builder to constantly reference back to a known centerline, station, or waterline to ensure accuracy of the build. Not only does a one-off vessel need to be perfectly symmetrical for performance reasons, but many such vessels are subject to rating rules, such as the America's Cup, where the hull shape is measured to the millimeter.

A variety of wood-based materials are used for cladding of the mold. Sheet particleboard or plywood can be used for flat or single-curvature surfaces. Compound curves, such as on a female deck mold, will normally be either planked with two layers of diagonally orientated plywood, or strip-planked with cedar or similar straight-grained workable timber. In the case of molds that will be subjected to prepreg curing temperatures, it is imperative that cracks do not appear in the mold during the cure cycle, causing loss of vacuum integrity. For these molds, the sheet material will often be scarfed rather than joined with a butt join, and all timberwork (framing and cladding) will be sealed on both sides with a high-temperature resin. Once completely clad, the mold is sheathed with one to two layers of 200 to 300 g/m^2 (0.7 to 1.0 oz/ft^2) boat cloth (fine plain-weave E-glass cloth). The mold is then faired and painted prior to application of a release agent. Often a high-gloss surface is not required; as long as the surface is fair, even a nongloss surface sanded with 120 grit can be perfectly adequate to get a release.

The male mold can be used to build the boat or as just the pattern to mold a female fiberglass or carbon-fiber tool. Female molds are used for some prepreg constructed hull and deck shells, where the increased cost is offset by advantages of weight savings, dimensional stability, and vacuum integrity during the high-temperature cure cycle. The release agent is applied to the mold surface just before the job commences, to reduce contamination risks.

Laminating of hull and decks is usually done manually by a team of laminators working from scaffolding above and alongside the mold (Fig. 9). Careful preparation and planning is the key to achieving a high-quality result, with each piece of reinforcement laid onto the mold in the correct orientation and position relative to adjoining layers. Wet lay-up materials have a limited working life, and prepregs need to be removed from refrigeration ahead of time in order to reach ambient temperature.

Fig. 9 Laminating a male molded hull

For both prepreg and wet preg laminates, the first layer is often a peel ply, either prepreg or dry fabric saturated with a controlled amount of resin through an on-site impregnator, commonly known as a wet-out machine (Fig. 10). These enable accurate control of fiber-resin ratios with wet resin systems. The dry fiber is saturated as it is pulled through the tight tolerance gap between two drive rollers, which contain a pool of catalyzed resin.

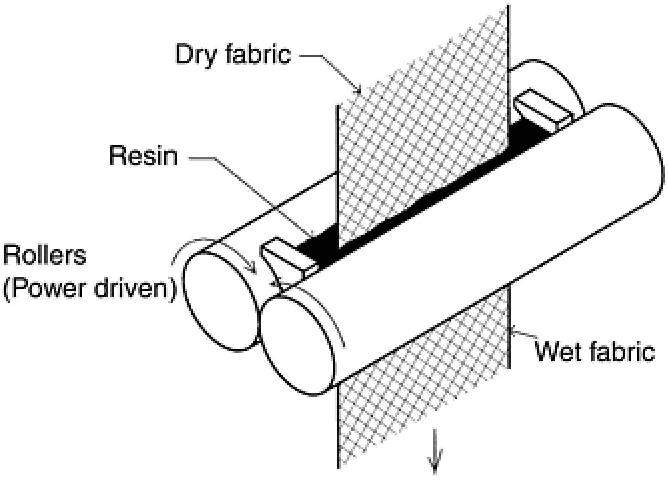

Fig. 10 Schematic of impregnator/wet-out machine

The rolls of reinforcement and resin are rolled out and initially compacted by hand, using small rollers and a rubber "squeegee" tool, then the edges trimmed. Width and length are constrained by handling considerations related to the weight of the impregnated roll. Rolls of up to 50 linear meters (165 ft) of unidirectional tape 200 to 300 g/m^2 (0.7 to 1.0 oz/ft^2) and 300 to 500 mm (12 to 20 in.) wide are typical. For wider broadgoods (1200 to 1500 mm, or 47 to 59 in., wide) and heavier weights (600 to 1200 g/m^2, or 2.0 to 4.0 oz/ft^2), lengths are restricted to approximately 10 linear meters (33 ft).

A hull shell will usually be laid up with full- length runs of unidirectional or cloth (0°, parallel with centerline or waterline), or off-axis transverse drops, with the only cutting and lapping necessary at the gunwale (sheer) and centerline. Decks often take much more careful detailing to cut, fit, and lap layers of reinforcement (often cloth rather than unidirectionals) into the corners of a mold.

Fitting sheets of core, whether structural foam or honeycomb, is a relatively straightforward process, typically performed by vacuuming the core down onto a predetermined amount of wet epoxy slurry or a prepreg glue film. A form of strapping or ties is often required for plain sheet foam or honeycomb that is bent around a male mold to hold it in place while the vacuum bag is sealed down and evacuated. Using female molds can provide an advantage, because the sheets will bend and can naturally lock themselves in place. Unlike typical production boat manufacturing, contoured, or scrimmed and cut, foam is rarely used for one-off vessels, because of reduced core mechanical properties and the addition of significant weight in the form of core adhesive. Once the core has been carefully faired with long sanding boards to remove any undulations, it is then rebated for any laps or thickness buildups for localized reinforcing in the next skin. Then the final laminate is applied and again, the entire assembly is bagged and cooked. The final cook may often be of longer duration to give all the laminates their full postcure, whereas on previous cures, it may have only been partial to preserve the mold.

Placing the vacuum bagging materials on a 80 to 250 m^2 (860 to 2690 ft^2) hull shell can take many hours. Layers of peel ply, release films, and breather/bleeder felts need to be carefully cut and fitted prior to the bagging material itself, which is usually a giant blown nylon or polythene vacuum bag.

Curing. The first stage of the curing cycle is to evacuate the air from the vacuum bag. This is, again, a combined effort from a team of workers to ensure that the bag is positioned correctly as it clamps down upon the laminate and vacuum stack. Without care at this stage, excessive wrinkling and small bridges or spans of vacuum bag across the internal radii of a deck mold can cause wrinkles and voids in the corners in the actual laminate.

An oven is erected around the mold, or the entire assembly moved into an existing oven. Ovens typically consist of thin alloy or plywood panels with a polystyrene core for insulation, or simply a polythene bag with fiberglass batts laid over for insulation. Heat is generated by gas furnaces, electricity, or steam. Requirements of a good oven are quick heating of the tool and air space and very even temperature dispersion. Quick ramp rates are essential for prepregs that may require ramp rates greater than 150 °C (270 °F) per hour. These can lead to high energy-input requirements and a number of fans and ducting when dealing with large structures, such as the hull shells.

Ovens will generally contain 12 or more movable thermocouples that can be attached to the vacuum bag or inserted into the laminate to check for even temperature distributions. Test “cooks” involving only the mold are often used to ensure that the oven will reach the desired temperature (typically 90 to 120 °C, or 195 to 250 °F) within the ramp rates required, and also that all parts of the mold heat evenly. This is particularly important for hull shells, where the centerline of an inverted hull shell may reach excessively high temperatures while 4 m (13 ft) lower in the oven the gunwale only reaches 70 °C (160 °F). Fans are used to circulate air into problem areas. If the tool entraps large pockets of cooler air, these can act as insulation, making it impossible to heat the surrounding air enough to achieve the desired ramp rate. Similarly, a thick tool with significant thermal mass can also cause heating problems.

Often, vacuum pressure monitoring equipment may be necessary to ensure that a bag does not leak during the cook. For a low temperature cook for wet preg boats (40 to 70 °C, or 105 to 160 °F), it is possible to enter the oven for brief periods to audibly check and make quick repairs to a bag; for the higher-temperature cooks, this is rarely an option, so everything must be correct and double-checked before the cook is started.

Removal from Mold and Fitting of Internal Structure. Prior to release from the tool, a thin layer of low-density, filled fairing compound is applied to the cured outer skin. Where weight is critical, care is taken to only fill the hollows, rather than cover the entire surface. The manual process of sanding, refilling, and resanding is time-consuming, hard labor, but necessary to achieve a smooth fair surface suitable for a high- gloss paint finish.

Throughout the process, consideration is given to releasing the item from the mold by ensuring that the molding has sufficient lifting points to raise it clear of the mold. This process can also be done by removing the mold from the molding using a crane with slings to lift and rotate both the mold and molding and then lifting the mold from the structure.

The molded shell structure (especially the hull) is relatively flexible without any internal framing, so it must then be braced, leveled, plumbed, and set up to the exact same beam widths as it was on the mold. Keel floors

are then fitted and bonded in their correct positions. These can be manufactured in a variety of ways, from female molding keel floors and post-fitting, to hand laying them up in place over foam and timber formers. Timber may often be used in the region of the keel floors and mast step and then encapsulated in glass. In the case of the mast step, it will be used in an end grain orientation for its capacity to withstand the high compression loads. Bulkheads will often be manufactured on a flat table using the same processes as used on the main structures, that is, either prepreg or wet preg laminates vacuum consolidated and cooked on either side of a core. These will be accurately fitted and then secondary bonded in place. Secondary bonding will generally involve carbon or E-glass double-bias tapes hand- laminated in place.

Quality control is a crucial part of the laminating process. A mistake made in the laminating, or inadequate control of laminating processes and curing processes that lead to material not consolidating or curing correctly, can mean the scrapping of many costly materials, project time, and man hours. Scantling authorities often want to quantify the laminating premises and may also require the production of specimens before and during lamination for mechanical testing. When the laminating starts, the quality controls and procedures need to be well defined and understood by the laminating team. This includes prior testing of compatibility of release systems and resins. During the lamination, the humidity is monitored and controlled, if possible. All rolls of prepreg are recorded as used, so that traceability, weight, and waste control can be tracked.

Quality control plays a very important role in not only making sure that all material conforms as far as curing properly and meets established weight or quantity parameters, but also in ensuring that by having well-formatted plans and procedures accompanied with check lists, the laminating team can operate together efficiently. On completion of the laminate, this enables the builder to be sure that the team of workers placed all the required layers in the laminate, with the correct proportion of resin, in their correct positions and orientations.

Masts. Mast tools (Fig. 11) are typically constructed from a high degree of unidirectional fibers for length stability, and may often be constructed from four quadrants that bolt together to form the complete section, allowing flat sections to be added to the mold to increase the size of the section.

Fig. 11 Mast tooling. Courtesy of Marten Spars

Conventional prepreg application processes need to be modified to cope with building a mast tube. Typically, the female tooling is in two parts, and a considerable number of layers need to be applied. In some areas, well over one hundred plies at varying angles are required to distribute local stress. Because of differential thermal properties of the tool (often low-cost glass composite) and the component and extreme dimensions (up to 50 m, or 165 ft, long), it is desirable to cure the laminate in one operation to avoid prerelease or demolding. This requires a long out-time prepreg, because the lay-up process can take a number of weeks, as well as careful intermediate debulk stages and critical control of the cure cycle to avoid potential excess exotherm of thick sections and to ensure adequate flow and consolidation.

While shorter off-axis plies can be precut, the longitudinal layers are taken directly from the roll in situ. Relatively low-tack prepregs are used, with local hot air flow required to aid drapability. Some hand consolidation with small rollers is necessary to avoid bridging across internal radii (Fig. 12). A stack of perforated release film and breathers intended for minimum bleed is applied, and a vacuum pulled. The complete tool is slid on rollers into the autoclave, typically 800 to 1000 mm (30 to 40 in.) in diameter, but up to 50 m (165 ft) long.

Fig. 12 Laminating a prepreg mast section. Courtesy of Southern Spars

Cure is at 2 to 3 bar (200 to 300 kPa), and generally follows a slow, controlled ramp, with dwell periods to even out temperature. Maximum cure temperatures are in the order of 120 to 130 °C (250 to 265 °F). The two C-shaped sections are fitted internally with rigging, pulleys, and other components, such as instrumentation wiring, before being joined with adhesive in a single-lap detail on the mast sidewall. Rivets are used to provide clamping pressure for the wet, ambient-temperature cure adhesive.

Many other methods to produce mast tubes have been tested and, in some cases, developed to commercial level for specific size-range products. These include wet lay-up over tapered mandrels, bladder molding of prepregs for small internal sections, and filament winding or braiding for small components. However, for the larger vessels, the two-piece autoclaved approach has proven to be the most successful.

The rig consists of more than a bare tube. Intricate fittings, where rigging terminates and spreaders are used to support the mast column, create challenges for the use of composites. Geometry and high local loads lead to

complex stresses, especially in areas subject to bearing loads and thick sections with tight radii of curvature. Construction techniques are very component-related and range from wet lay-up to prepreg autoclave cure and bladder molding.

Appendages. Manufacture of the rudder and the keel use almost all the skills the boatbuilder has to offer. Accurate sectional shape and profile are critical to the handling performance of the yacht. Great care has to be taken by the builder to achieve a shape that is symmetrical, dimensionally correct, and has a well-finished surface. A rudder blade or stock may be almost 4 m (13 ft) long for an America's Cup yacht, making it a challenging task to maintain its symmetry to the nearest millimeter during a 100 °C (210 °F) cure.

Keels come in many configurations, sometimes with a bulb at the base, or just as a straight fin. They can also be completely constructed from lead with an internal steel support frame, or only consist of lead in the lower half or bulb. In this case, the top part or all of the keel fin is typically constructed from either carbon fiber or high-tensile steel materials.

The requirement for accurate dimensional tolerances has lead to the widespread use of computer numerically controlled (CNC) machining for rudder and keel tooling. This is normally produced by machining a male pattern from laminated particle board or foam, with final surface preparation by the builder. Split female molds are then made from this pattern. In the case of a keel bulb and fin foundry, work is required, with tons of molten lead or steel being poured into concrete or sand molds, respectively, with all keel bolts and internal framework in place. The casting will require a great deal of surface finishing to achieve the desired end result; quite often the surface is initially cut back by CNC machining, followed by labor-intensive grinding, sanding, and painting.

Rudders are typically a complicated composite structure. The backbone or rudder stock (Fig. 13) is nearly always a rectangular carbon-fiber section that is built to the maximum dimensions that the diameter of the bearings and the thickness of the blade will allow. This shaft can be manufactured in much the same way as a spar: by laminating the carbon over a foam core. Other approaches include split female molding, using vacuum consolidation or inflatable bladders. Because the wall thickness is critical to both the shape and strength, accurate quality control is necessary to ensure that the correct fiber volumes are achieved. During the curing process, the stock or mold must be clamped into a jig that will stay straight. Localized buildups are then laminated in the region of the upper and lower bearings and machined in a lathe. The alignment of these bearings is crucial for correct operation of the rudder.

Fig. 13 Rudder stock. Courtesy of Yachting Developments

The blade is typically manufactured in either a female mold as two halves or hand shaped from a structural foam or Nomex honeycomb. When female molding, once the skins have been laminated, provision is made to accept the stock. The two halves are then glued and clamped about the stock, the remaining volume being filled with either structural foam or Nomex. In the case of shaped foam, two halves are typically used to help maintain symmetry about the centerline. The blank is bonded to the back of the stock, along with the nosepiece, and then the entire blade is laminated with a thin skin of carbon fiber. This is vacuum-consolidated and cured while clamped straight, to maintain an accurate shape. In both cases, the final manufacturing stages involve manual fairing and painting to achieve the correct shape with a high-quality surface finish. Accurate templates are used to check the sectional shape during the finishing processes.

Outlook

Custom, one-off construction will continue to be a part of the marine market. The opportunity to create a unique, tailored solution for the discerning client will always be attractive, particularly where cost is not necessarily the only criterion, be it a race boat with improved performance or a luxury cruising yacht designed to meet the specific requirements of the owner. In volume terms, one-off construction will always be small relative to the female molded production output, but will continue to be the incubator for development of new technologies. The trickle-down effect is well proven, with the mass market now accepting of sandwich construction and experimenting with resin infusion and wet-preg epoxy techniques.

In the near future, construction using prepreg systems is likely to increase as new lower-temperature cure cycles are developed to enable low- cost, stable, one-off tooling. Structural design tools will be refined, with more confidence in finite-element techniques as the definition of applied loads is improved. This may lead to more complex structural arrangements and details that are better suited to prepreg techniques, due to extended working time and the ability to apply selective unidirectional tapes in line with defined load paths. Environmental concerns over solvents and the health aspects of working with wet resins will also be a driver toward prepregs.

Despite reductions in the price of carbon as more high-volume, nonaerospace commercial applications become available, the likelihood is that the construction will still be dominated by E-glass. The full potential of this material is yet to be realized, and developments in forms that allow reduced resin content and higher properties along with improved design and building processes will see continued improvements in the performance of simple E-glass structures. Carbon and other advanced fibers will find greater acceptance in specific areas of the vessel, such as masts and appendages, where the higher cost can be justified due to significant weight savings.

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Introduction

MANUFACTURING PROCESSES for advanced composites share common attributes. Fibers and resins are engineered, and raw materials are cut, shaped, and cured to meet the performance requirements of the end products. As composite materials have evolved since the 1950s, so have the methods and practices used to manufacture and cut these materials. Automated cutting systems that can manage data efficiently and are compatible with computer- aided design (CAD) systems help to reduce labor requirements and work-in-progress (WIP) costs, reduce waste of costly materials, and increase the quality of composite parts.

This article briefly reviews the history of prepreg and ply cutting technologies as well as outlines the options available for creating the necessary data and for nesting, cutting, and kitting the plies. The article also discusses the ways these steps influence the workflow for various applications.

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

History of Composites Ply Cutting

Manufacturers first used fiberglass-reinforced plastics and epoxy resins during the 1950s to produce boat hulls and fishing poles. Makers of boats employed straight knives, scissors, or hand-held motorized rotary blades to cut dry, woven and nonwoven fiberglass (Fig. 1). Once cut, the fiberglass was then laid up by hand and “painted” with resin.

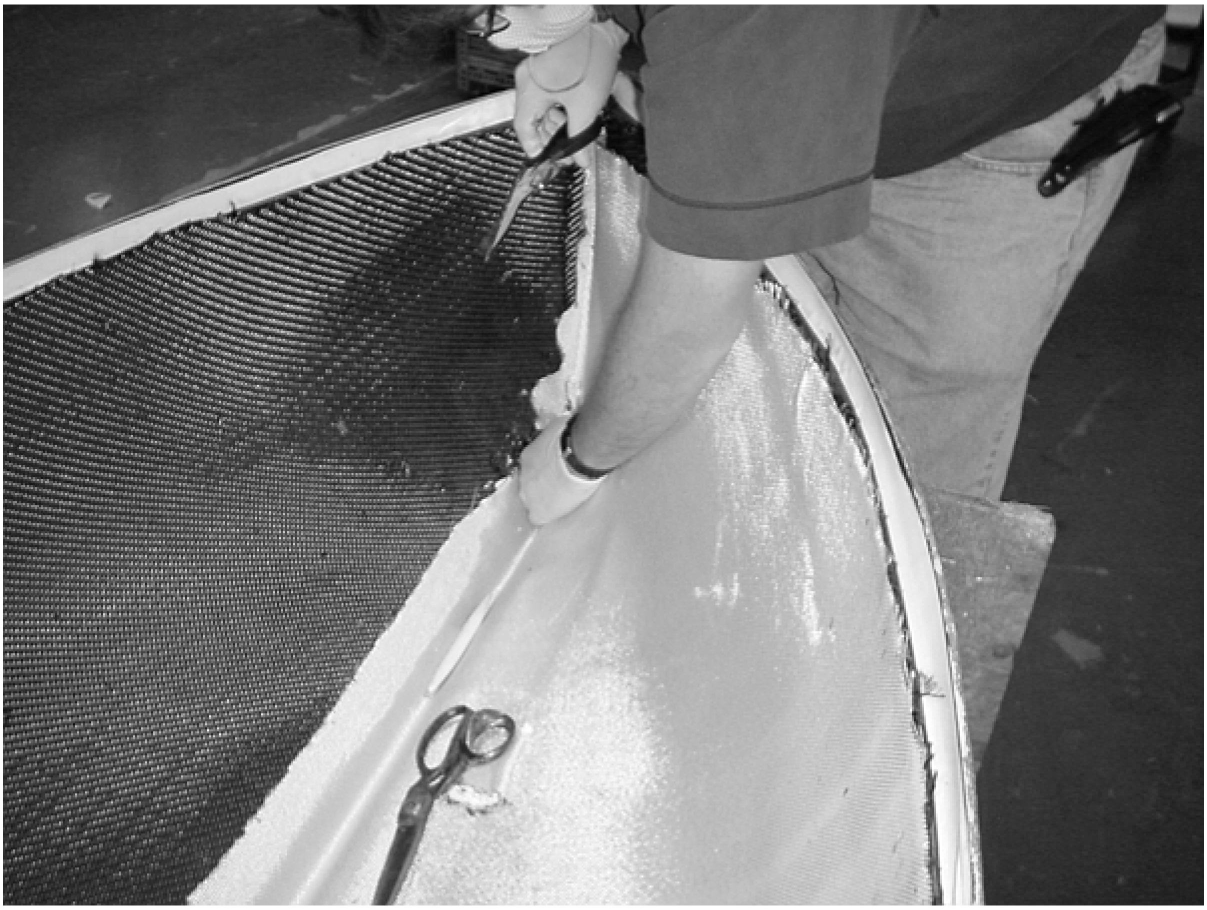

Fig. 1 Hand cutting of fabric

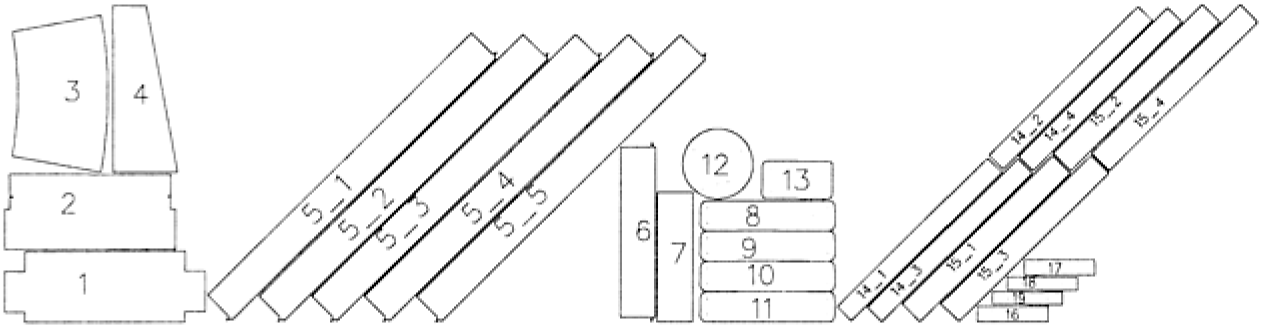
The 1970s gave birth to "advanced" composites, led by the development or refinement of materials such as carbon and aramid fibers and advanced matrix (resin) materials and spurred by the demand for lightweight, high-performance military aircraft. Manufacturers were required to cut these materials very accurately, according to the orientation of their innate fibers (Fig. 2). Once again, they turned to hand-held straightedge knives—using them to trace around aluminum templates placed on the composite material (Fig. 3). The process was slow, inaccurate, ergonomically incorrect, and inherently wasteful.

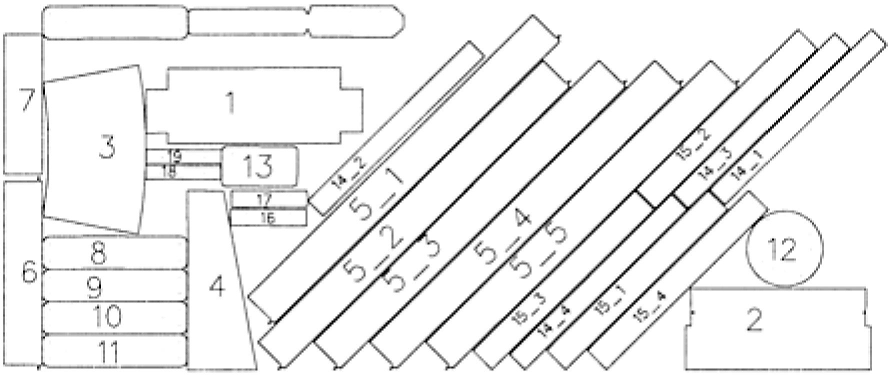
Fig. 2 Examples of cut shapes

Fig. 3 Hand marking of plies

Not only was it necessary for hand cutters to cut each ply according to the specific orientation of the fiber, but to complicate the process even further, they were required to lay each ply in the correct order in the tool. Thus, hand cutters began to cut the materials in the order in which they would later be laminated (Fig. 4).



Nesting in kit order



Nesting for material efficiency

Fig. 4 Nesting

The first tools available to the industry that automated the nesting process were developed by Hughes Aircraft. (“Marking,”“marker making,” and “nesting” are terms used to refer to the process of efficiently marking ply shapes on material to maximize material use.)

During this time, automation providers introduced tools for fast and efficient nesting and cutting of apparel fabric, which, at that time, cost $1 to $3 per yard. How much could these tools save manufacturers in an industry where material costs were as high as $300 per yard? The answer is hundreds of thousands of dollars.

The first automated nested and cutting systems for composites manufacture were sold to large aerospace companies at a cost per installation of approximately $750,000; the costs were funded in part by government contracts. Shortly thereafter, manufacturers introduced ultrasonic cutting systems, which delivered cleaner cuts and higher tolerances at a cost of $1 to $2 million per installation.

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Creating the Data

In a large composites manufacturing facility, cutting is merely one component in the overall process. Cutting personnel receive the material to cut and the data to define the cutting. After cutting, the pieces are usually labeled and removed. Efficiencies can be improved by improving the nesting, labeling, and unloading processes.

In order for composite parts to be manufactured successfully, they must mesh precisely when the final item is assembled. The composite part is usually designed using a CAD system. Computer-aided design data usually encompasses:

- A three-dimensional definition of the lay-up tool or a surface of the finished part
- A flat pattern for cutting that will result in the ply being the correct shape when laid on a curved tool (see Fig. 2 in the article "Manual Prepreg Lay-Up" in this Section)
- Rules or instructions indicating the precise location of each ply on the tool as the part is being assembled

If any of these three conditions is not precisely managed, finished parts will be flawed. Software packages, such as FiberSim (Vistagy Inc.), model the behavior of the material as it is draped on the tool. The bending and draping behavior is taken into account when the flat patterns are defined for cutting. Using such modeling approaches can result in plies that are matched to the lay-up sequence and meet tight tolerances (e.g., 0.40 mm, or 0.015 in.).

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Nesting the Pieces

Material is one of the most costly components in composites manufacturing. Advanced composite material is expensive to produce. In addition, strict environmental regulations make the disposal of many epoxy resins as costly as the production of the actual material.

Advanced nesting of the entire table, rather than individual kits placed end to end, has yielded an 18% improvement in material use (Ref 1). Such improvements in use have significantly reduced the amount of raw material required and the amount of scrap material yielded (Fig. 4).

Overhead laser projectors can also improve material use by providing a preview of pieces to be cut. It is often helpful to view the cutting patterns while positioning material on the table, because, many times, a variance of only a few inches can mean the difference between complete and incomplete kits.

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Kitting

Kitting is the process of assembling cut plies in the order in which they will be placed on tools to form laminates. When dealing with simple kits, operators can recognize and extract plies from the cutting table in the correct order. As kits become more complicated, operators must use maps to determine the order in which plies

should be collected. Full table nesting presents one major problem—unloading cut parts becomes a very complicated and time-consuming task.

Technology has once again addressed this problem. Today, laser projectors guide operators in the proper order of removal of cut pieces. A single laser projector that meets U.S. Food and Drug Administration Center for Devices and Radiological Health (CDRH) class II laser safety regulations can cover an entire 15 m (48 ft) table. A hands-free remote control on the projector automatically advances the display to the next ply when the correct ply has been removed. This feature helps ensure that pieces are removed in the correct order for kitting (Ref 2).

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Cutting

There are several options available to cut plies. When aerospace firms implemented automated cutting in the 1980s, reciprocating blade, multiply, “static” (meaning non-conveyorized cutting surfaces), and ultrasonic cutting systems were the only available technologies.

Manufacturers created work orders to meet their lengthy production schedules. For example, they typically cut and kit materials a month in advance to accommodate their production requirements. The steps in the process were:

1. Pull materials from the freezer.
2. Spread several layers of material on cutting surface.
3. Cut prenested plies in kit order.
4. Remove cut plies for off-line kitting and bagging.
5. Return kits to freezer.
6. Retrieve kits when ready to lay-up.

Because the technology was developed to cut many layers slowly, the equipment was only cost-effective when cutting multiple layers. However, this process increased WIP costs and included many “non-value-added” steps. It also did little to maximize material use. Parts from existing kits were often “borrowed” to complete orders, thereby leaving kits incomplete. Cut materials often went unused and were discarded when their shelf life was depleted.

This process violated many of today's current manufacturing concepts, such as just-in-time (JIT), cellular, and lean manufacturing principles. Existing automated companies were forced to change the way they cut and kit.

Simpler, less expensive, and faster single-ply static cutting systems were introduced in the 1990s. These new systems enabled manufacturers to cut material on demand, more accurately, with less waste, and with improved edge quality. This new cutting method streamlined the entire process. Table 1 compares the characteristics of different cutting methods.

Table 1 Characteristics of prepreg and ply cutting methods

Method	**Capital cost**	**Advantages**	**Disadvantages**	Data required
Hand cutting using templates	Low	Uncomplicated, low maintenance	Slow and inaccurate Ergonomically undesirable Requires the creation, maintenance, and storage of templates	**Patterns reverse-engineered off of tooling**
Automated reciprocating blade	Moderate to high	Multiple-ply cutting for higher volumes, dry aramids	Typically not suitable for lean, just-in-time (JIT), or cellular manufacturing Not suitable for low volumes Involves higher consumable costs and maintenance	**Computer numerically controlled (CNC) data**
Automated ultrasonic	Moderate to high	See above	Maintenance and consumables cost not justifiable for single-ply cutting.	**CNC data**
Drag knife/wheel cutter	Moderate	Best option for modern, lean, JIT, and cellular manufacturing	…	**…**
Dies	**Moderate**	**Suitable for multiply cutting; accurate.**	**Lacks flexibility** **Requires the creation, maintenance, and storage of templates.**	**Typically CNC data**

Today, many composites fabricators can process work orders on a shift-by-shift basis, cutting what they need when they need it. This is what the process may look like today:

1. Generate daily work orders.
2. Pull material from the freezer, as needed.
3. Create efficient nests to meet daily work orders.
4. Cut material quickly.
5. Remove material from the table in the order it is to be kitted, and deliver it to the lay-up personnel.

This process satisfies most needs. However, there are some applications that require different approaches. For higher-volume applications, for example, interior floor and wall panels for major commercial airline companies, multiple-ply cutting is required to meet the high volumes.

In some cases, up to twenty layers of prepreg or woven carbon or up to 75 mm (3 in.) of honeycomb core are cut on a conveyorized reciprocating blade cutter and kitted off-line. The kits are then delivered directly to the crush core panel presses for fabrication in a JIT or lean manufacturing environment.

In other cases, cutting personnel may deliver parts to several lay-up areas. It may, therefore, be necessary to cut multiple plies of material, kit them off-line, and store them in freezers. In such cases, a conveyorized, or single-ply cutter, may be appropriate.

Fundamental differences exist between conveyorized and static cutting systems that should be considered when evaluating cutting systems.

Fundamentals of static single-ply cutting (Fig. 5) include:

- Allows manufacturers to label part numbers on each ply efficiently
- Material is either manually or automatically pulled onto the table.
- Pieces are picked off the table and assembled into kit order.
- Allows greater flexibility when changing materials often
- In most cases, is the best solution for JIT, lean, and cellular manufacturing
- Is a lower-cost technology
- Is available in a variety of lengths to satisfy requirements and floor constraints
- Delivers the best edge quality

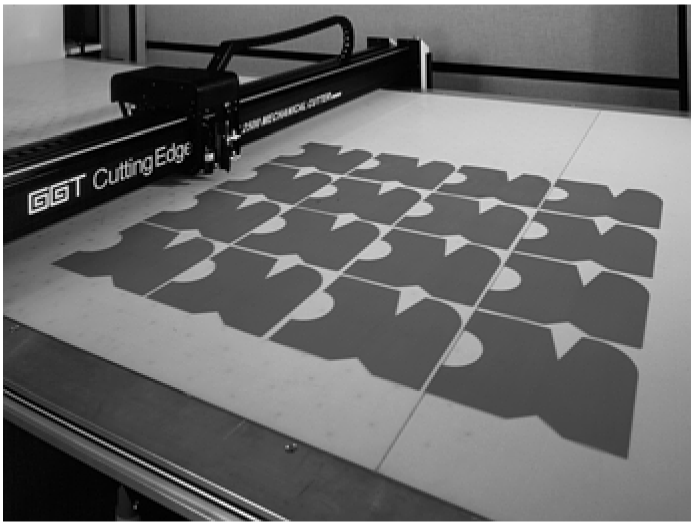

Fig. 5 Static single-ply cutting

Fundamentals of conveyorized single-ply cutting (Fig. 6) include:

- Allows manufacturers to label part numbers on each ply efficiently
- Reduces material handling, because material is automatically fed onto the table
- Material changes are more time-consuming than with static cutters.
- Parts are removed from the table in the order in which they were cut.
- If nesting plies for efficiency, a separate kitting station may be required. This means additional labor costs.
- Can accomplish higher production rates in higher-volume requirements with fewer product mixes
- If plies are nested in kit order, parts can be kitted as they are removed; however, material efficiencies will drop.
- Maximizes floor space
- Delivers best edge quality

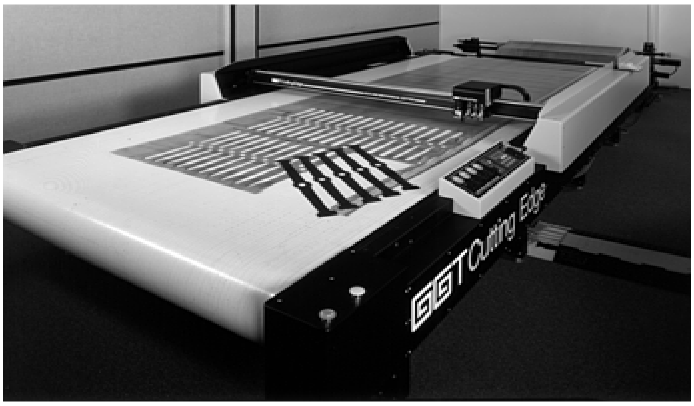

Fig. 6 Conveyorized single-ply cutting

Fundamentals of conveyorized multiple-ply cutting (Fig. 7) include:

- Piece identification requires an additional step.
- Off-line kitting is, for the most part, mandatory.
- Efficient only if cutting multiple plies
- Suited for high-volume cutting
- May require additional floor space to spread materials

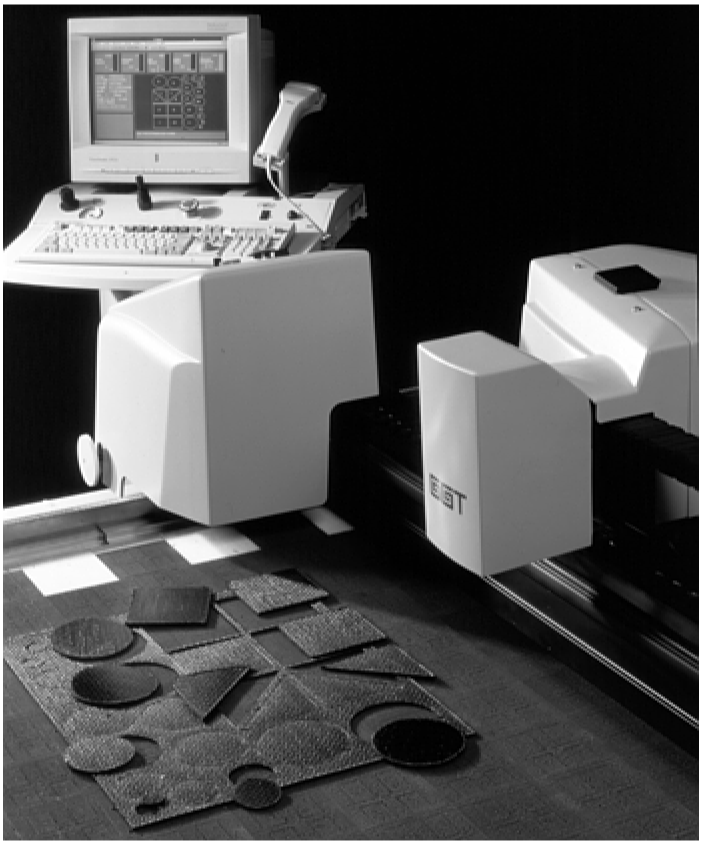

Fig. 7 Conveyorized multiple-ply cutting

Prepreg and Ply Cutting

Joe Lautner, Gerber Technology Inc.

Labeling

There are four primary ways to label cut plies when using an automated cutter (alphanumeric characters and bar coding are options):

- Inkjet part numbers directly on the plastic backing film
- Inkjet-printed, pressure-sensitive labels automatically applied to the cut plies
- Cutter-mounted pen
- Inkjet pressure-sensitive labels manually placed after cutting. (The laser projector system supports a wireless labeler worn on the belt of the cutter operator. When the correct piece is removed from the cutter, this device prints a label for the operator to adhere to the cut part.)

The labeling process typically uses existing label data and requires no new data generation. Labeling usually occurs on the cutter. Occasionally, if the cut pieces are smaller than the labels, an automatic labeler may cause small pieces to stick together. These challenges are easily addressed by an automation solution.
The laser projection system can also guide the sorting of partial kits by pointing to locations on sorting tables, located near the cutters, for partial kits unloaded from the cutter. This also speeds the cutter unloading process (Ref 1).

Manual Prepreg Lay-Up

Andrew Mills, Composites Manufacturing Research Centre, Cranfield University, United Kingdom

Introduction

WHEN THE FIRST PRODUCTION of carbon fiber occurred in the late 1960s, it was realized that very lightweight layers of nonwoven tape would be required to fabricate thin shell and blade components, the first targets for the new lightweight material. Without weaving, the fibers could not be handled once taken off a reel. Another limitation was that the long-established technology of wetting woven fabrics with liquid resins layer by layer was not feasible for thin- layer, lightweight structures, since at the optimal fiber proportion (60% by volume), distribution of the resin had to be accurately controlled. Another complication for the glass fabric, wet lay- up technology was its inability to provide laminated components with tightly packed, accurately aligned fibers. The “runniness” of liquid wet lay-up resins cannot hold fibers where placed by laminator tools.

To provide a stable material with combined resin in layers of typically 0.13 mm (0.005 in.) thickness, prepreg technology was developed by the 3M Company in the United States at the request of Rolls Royce Engines in the United Kingdom, which had started to produce carbon fiber in-house. Automation of fiber and resin combination provided material with near- straight fibers and consistent resin content in a form that had a tackiness suited to laying up multiple layers of material in complex-shape tools.

By 2000, a vast range of prepregs with different fiber types, fabrics, tape styles, resin types, and thicknesses became available, enabling the manufacture of most lightweight structures by hand lay-up. Prepreg hand lay-up has been an exceptionally successful technology.

The process requires very low investment but is a labor-cost-intensive approach. It is best suited to components with either annual production-materials consumption of less than approximately 1 tonne (2200 lb) or curvature that prevents any form of automated lay-up. It utilizes the extreme dexterity of human hands in positioning and conforming prepreg to double-curvature surfaces and tool details such as flanges, ribs, holes, and blades.

Prepreg lamination has become established as a respected craft of the modern age. Because of its versatility and reliability, almost all performance vehicles, racing cars, boats, planes, and spacecraft applications of composites depend on the prepreg hand lay-up process. Today, despite many research attempts, the hand lay-up of prepreg is the most cost-effective, highest quality approach to the manufacture of many large or small components.

Manual Prepreg Lay-Up

Andrew Mills, Composites Manufacturing Research Centre, Cranfield University, United Kingdom

Technique Characteristics and Applications

Prepreg Form. The two most common prepreg forms are unidirectional tape and woven fabric. Different lay-up techniques are required for each form.

For manufacturing-cost reasons, woven-fabric prepregs are used wherever possible despite the considerably lower laminate stiffness and strength achieved with these prepregs. The lower stiffness and strength result from crimp in the fiber tows as the weft yarns cross the warps. This bends the tows during fabric manufacture, and processing cannot recover their straightness. Also, at each yarn crossover, a fiber-free space is created that becomes filled with resin; hence the fiber volume fraction of woven laminates varies from 50% for heavy (24K and above) to 58% for near-unidirectional woven fabrics having 90 to 98% of fiber in the weft direction. For unidirectional prepreg with a multidirectional lay-up, the fiber volume fraction ranges from 58 to 63%. Consequently, woven prepreg laminates are both less stiff and strong and are heavier with the higher resin content than unidirectional tape laminates. Woven laminates also provide much greater damage tolerance than

unidirectional laminates since the latter have low resistance to delamination crack growth during and after impact.
The lay-up attributes of woven prepregs are:

- Thicker (therefore fewer) layers and faster lay-up rate
- Much higher curvature conformability and hence lower susceptibility to wrinkling
- Greater material width of 1.25 or 1.7 m (4.1 or 5.6 ft) compared to 0.3 or 0.6 m (1 or 2 ft) for tape prepreg. (Tape prepreg is narrow since it has low conformability, and materials waste is high for wide tape.)
- Lay-up rates are therefore approximately 3 to 5 times higher than for unidirectional tape.
- No requirement to butt strip edges since fabrics are wider than the parts
- Less-precise ply orientation is required since the lay-up is less optimized; lay-up can therefore be faster.

Manufacturing disadvantages of woven prepregs are:

- Higher proportion of waste from the wider material
- Higher cost of low-thickness fabric prepreg since the weaving process preceding prepregging is an added cost. Thicker woven prepreg with a fiber areal weight (FAW) of 370 g/m^2 has become standard since the weaving cost is around half that of the conventional 285 g/ m^2 fabric. These thick prepregs confer reduced stiffness to the resultant components.

As a result of the manufacturing-cost benefits of woven prepregs, they are used predominantly for hand lay-up, apart from very lightweight- niche applications. Unidirectional tape lay-up is better suited to automated tape layers that can rapidly cut and deposit material, provided the lay-up is flat enough (see the article “Automated Tape Laying” in this Volume). Recently, thicker unidirectional tape prepreg has been qualified for aircraft use so as to increase laminating rate of thick structures. However, the resulting restriction on thickness tailoring prevents the use of thick prepreg in many structures.
The other lay-up characteristics are resin tack and conformability of fabric style. These both determine the difficulty of manipulation of prepreg into tool recesses. For parts with shape complexity, a highly drapable, high-tack resin is preferred to produce a fully consolidated lay-up. For flat or single curvature parts, a less drapable fabric such as plain weave with a low tack (stiff) resin is better suited.
Placement Tolerance. Since hand lay-up is a craft skill using floppy materials, the placement tolerance cannot be specified very closely. The acceptable tolerance differs for woven and tape materials. For tapes, which are much stiffer and applied in strips of typically between 150 and 600 mm (6 and 24 in.), a positional tolerance of ±1 mm (±0.04 in.) and a straightness tolerance of ±2° can be realistically achieved. For woven prepreg, tolerances of ±2 mm (±0.08 in.) for position and ±3° for straightness are realistically achievable.
Application Suitability. A great range of unidirectional and woven prepreg types have been developed to suit diverse applications. The original prepregs were developed for very highly optimized components in aerospace engines, and similar styles of very thin (0.125 mm, or 0.005 in., ply) prepregs are in use today in large volumes. The fighter aircraft and racing car markets use tape and woven prepregs made from very high-cost narrow tow fiber that provides laminate moduli up to 240 GPa (35×10^6 psi) for tape and up to 130 GPa (19×10^6 psi) for woven fabrics. Resins to suit these high- performance fibers have complex formulations tailored either for toughness or temperature resistance but have similar lay-up attributes to long established low-cost resins. These thin materials naturally have a low hand-deposition rate, but the labor cost represents a small proportion of the overall manufacturing cost. For low-volume production of thin structures, the manufacturing cost is dominated by mold tooling and assembly costs.
Over the past ten years there has been a rapid growth in the use of standard high-strength carbon tapes and fabrics. For performance cars, commercial aircraft, and sporting goods use, two standard prepregs have been established: thick unidirectional tape with a fiber weight of 270 g/ m^2 and five-harness satin woven fabric with a fiber weight of 370 g/m^2. The use of prepreg thickness above these levels is not normally considered to be worthwhile, since the lay-up sequences needed to achieve balanced and therefore unwarped laminates result in a low level of thickness optimization.
Non-weight-critical applications such as wind turbines and lower cost sporting goods generally use glass fiber prepreg at as high a thickness as can be readily handled. For this reason thick unidirectional prepregs of up to

500 g/m^2 FAW and woven (and now multiaxial) fabric prepregs of up to 1000 g/m^2 FAW are being produced. The resin-content and void-level specifications are looser for such materials, which, combined with the high fiber weight, enable prepreg manufacture at up to 16 kg/min. The prepreg production cost is therefore very much lower than that for traditional thin prepregs.
Prepreg hand lay-up is well suited to all applications for structures where a stiffness of greater than around 15 GPa (2.2 × 10^6 psi) is required. Below this stiffness, components can be manufactured with far lower labor cost by low fiber volume fraction processes such as chopped fiber, spray up and wet lay-up with heavy (>1 mm, or 0.04 in., thick) fabrics.
The process is also uneconomic for simple- shape components of greater that several millimeters thick where more than one component per week is required. For components that have these factors, automated lay-up becomes attractive. However in lower economies, hand lay-up is still preferred for large, thick simple parts.

Manual Prepreg Lay-Up

Andrew Mills, Composites Manufacturing Research Centre, Cranfield University, United Kingdom

Technique Description

The process of lay-up definition through to bagging for resin-curing comprises the following five stages: lay-up definition, ply-kit cutting, lay- up, debulking, and preparation for curing.
Lay-Up Definition. The lay-up of a component is defined by the:

- Overall shape produced by the mold tool curvature
- Thickness in terms of the number of layers over the surface
- Ply outlines (drop offs) if the thickness is varying
- Orientation to suit the load paths

For most lightweight components, the lay-up instructions will be produced from a finite-element-analysis model of the component. The model will have the simulated design limit load introduced to the lay-up. The thickness and ply orientations are then modified until all regions of the component are shown to have less than maximum allowable strain in each ply. For structures with complex shape and/or loading, the specified lay-up is generally quasi-isotropic, meaning that there is an equivalent number of 0, 90, 45, and 135° plies. This is also preferred since it removes any complication of resin shrinkage symmetry. A so-called balanced lay- up will have a balanced or symmetric proportion of fibers at each angle about a midplane. This is critical for unidirectional tape materials but also important for satin and twill-weave fabrics; plain-weave fabrics are immune to lay-up imbalance but have lower drapability and stiffness than the former types.
The next step is to decide the size and shape of each prepreg piece. To minimize the number of pieces, software tools such as FiberSIM (VISTAGY Inc., Waltham, MA) were developed. These are used to assess the tool shape where prepreg pieces are to be positioned and, using data on the material drapability (ability to be sheared to conform to double curvature), indicate whether prepreg pieces are likely to wrinkle. After one or more iterations, a kit of pieces and their orientations are defined (Fig. 1 and 2).

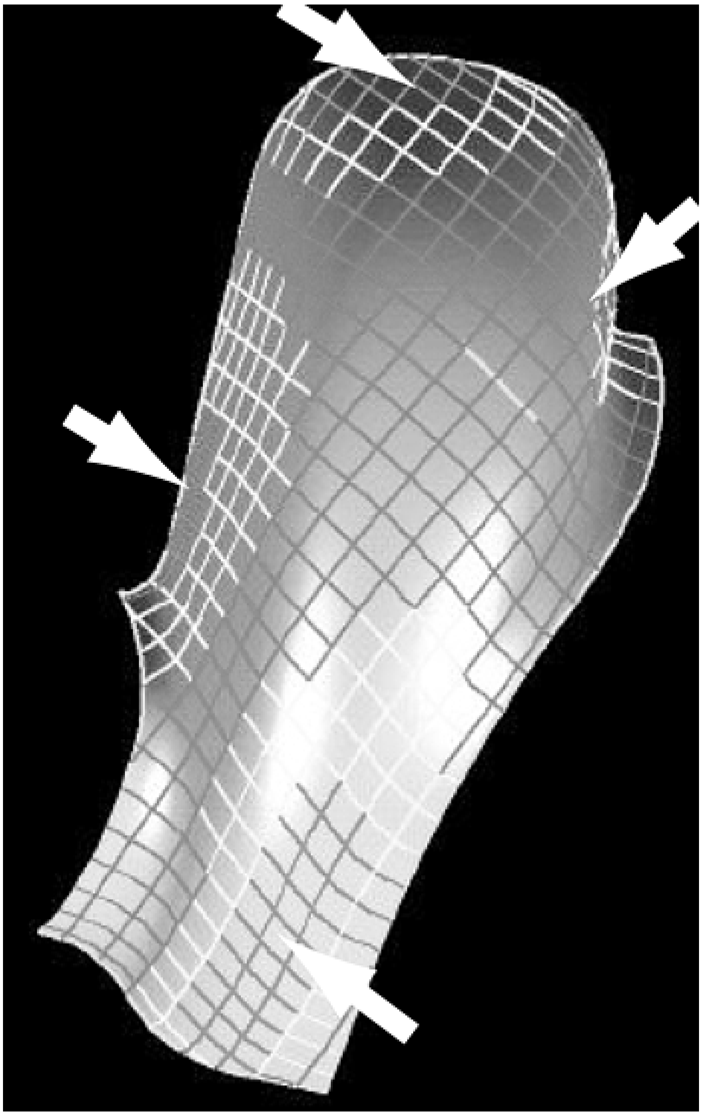

Fig. 1 FiberSIM model of woven-ply draping into fairing tool. Red zones (indicated by arrows) are areas of predicted fiber wrinkling. Courtesy of VISTAGY Inc.

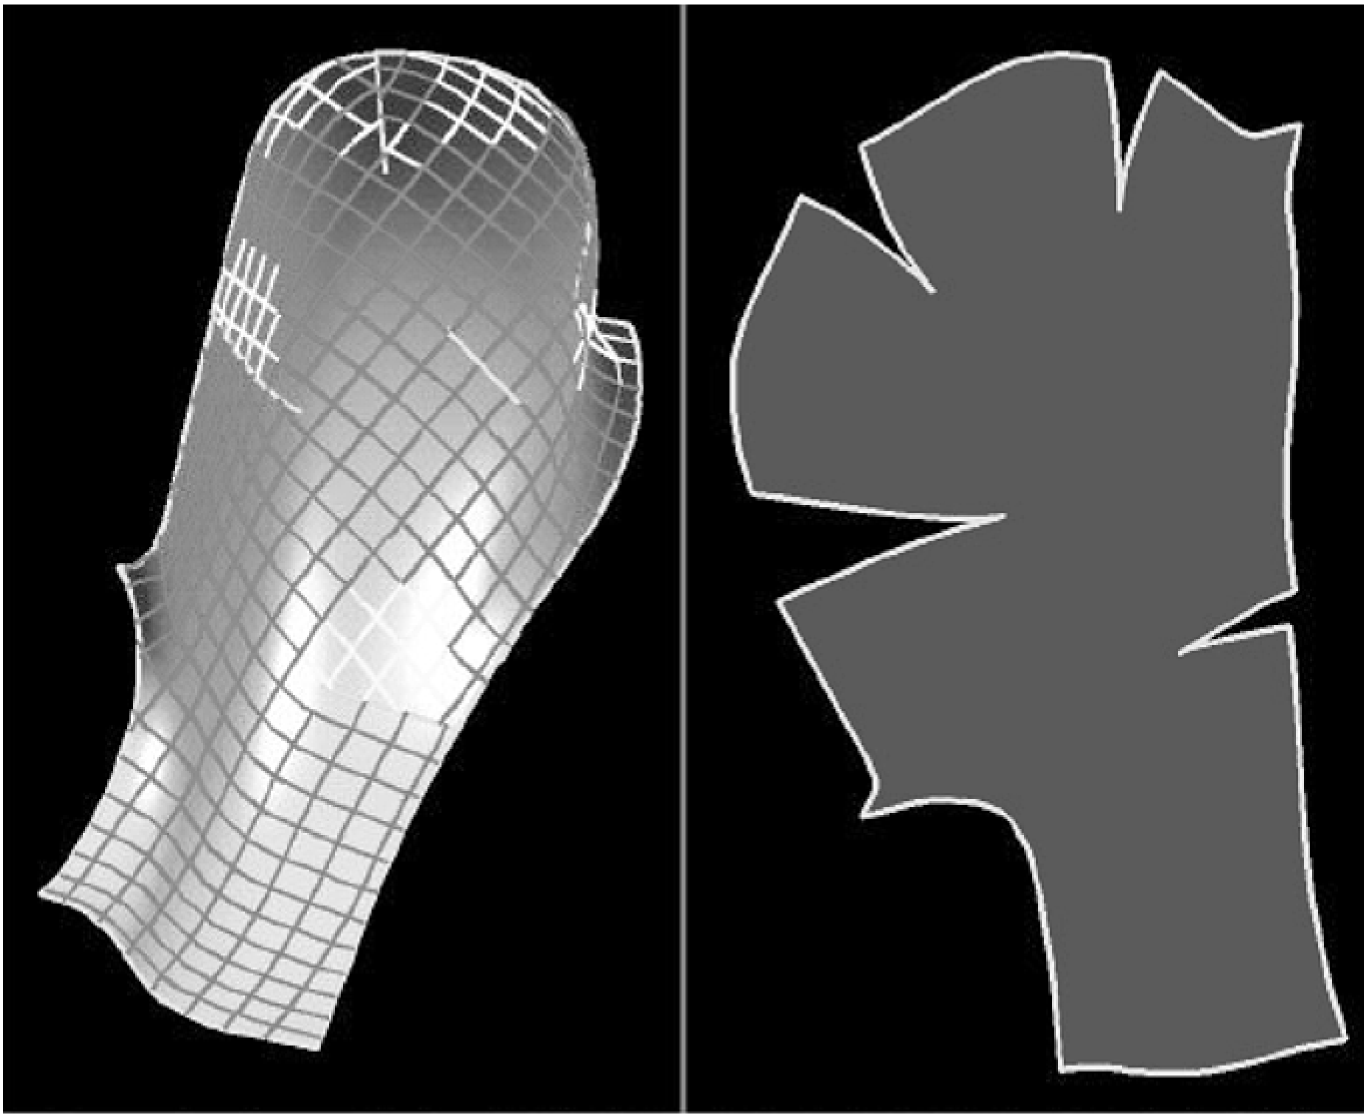

Fig. 2 FiberSIM model of woven ply draping into fairing tool after applied ply cuts. The shape on the right is the predicted flattened ply shape to be cut. Courtesy of VISTAGY Inc.

Ply-Kit Cutting. The target for the cutting operation is to minimize waste as much as possible. Purchase cost and disposal cost is extremely high, even for low-glass prepregs. Off- cuts can represent a hidden cost, which can result in the manufacturing process being unjustifiable.

Software applications such as FiberSIM have been developed to minimize cutting waste from the prepreg roll. The software is used to match the total kit of plies to the material-roll width and to define the cutter paths.

Users of large quantities of prepreg use an automated device that cuts the material and, in some models, stamps a bar code or number on it to identify the piece from CAD data. Ultrasonic machines (Fig. 3) using a vibrating knife are able to leave the lower surface backing film uncut, which reduces lay-up time during laminating. Manually, the pieces are stacked in order for lay-up. These kits may be sealed and stored in a freezer if a delay is incurred before use.

Fig. 3 Ultrasonic prepreg ply cutting machine. Courtesy of GFM (United Kingdom)

Lay-Up. The difficult part of the process is applying the reinforcement, any stiffening cores, and attachment inserts to the mold tool so as to confer the inherent stiffness or strength of the fibers to the molded component.

The kit of prepreg pieces is transferred to the mold tool by laminators, who use their fingers and spreading tools to force the tacky, stiff material into the corners of the tool and then smooth it over the flat or gently curving areas. For complex-shape parts such as racing car chassis, the backing film is peeled away progressively to prevent too much of the surface of the pieces from adhering too soon. Hot air blowers are sometimes used locally to soften the prepreg such that it can be conformed into tight recesses. Even with a fully precut kit, the laminator has to trim plies with a blade at the component edges since, for double curvature components, each layer of prepreg is unique in terms of how the plies shear (Fig. 4) (Ref 1). Sandwich structures, which include tapered edge rigid foam or honeycomb core pieces and any attachment inserts, can be placed directly into the lay-up, or placed into the lay-up with uncured film adhesive; in both instances the sandwich structures are cocured with both inner and outer skin. For accurate location of the core and attachment point inserts, the lay-up is cured three times; once for the outer (tool face) skin, once to bond the core and inserts with film adhesives, and once for the inner (bag face) skin.

Listed are some essential stages or features of the lay-up process to achieve acceptable quality moldings:

- The mold tool must be suitably treated with a release agent to prevent bonding during cure. A solvent or (now increasingly for health and safety reasons) a water-based formulation is wiped onto the tool with a cloth. One coating is applied to each molding and three or more layers to a new or repaired tool.
- The prepreg must be neither too tacky to be “unrepositionable” (since complex-shape pieces need to be applied in stages) nor too dry such that it will not adhere to the tool or the lay-up. The tack level is dependent on the resin formulation itself, its out-life (the resin becomes harder with time at room temperature), and the lay-up room temperature.
- No bridging of prepreg can occur across tool corners such that during cure, the bagging materials fully compress the prepreg to the complete surface of the tool with no air pockets or resin filled corners.
- No air pockets can be trapped between layers since these may remain throughout the lay-up and cure resulting in cracking between layers.
- No wrinkling or folds can be introduced since the stiffness and strength of the component is dependent on the fibers being as straight as possible along the main load paths. Wrinkles will also act as stress concentrations and may cause failure below design-limit strain.
- Nothing can be allowed to contaminate the lay-up such as backing films, grease, insects, and litter. Any inclusion may prevent bonding, cause wrinkling, or produce gas during cure. It is exceptionally easy to leave pieces of thin polythene-backing film between layers. They are frequently brightly colored to help avoid this. Many inclusions are undetectable by nondestructive examination and may become partly bonded. Evidence of an inclusion can possibly only be detected through catastrophic disbonding in service. Such mistakes may be expensive, particularly with aircraft primary structure or space programs.

Ply Orientation and Position. In spite of the tacky nature of the prepreg and the complexity of many tool shapes, a laminator has to maintain the ply orientation and edge position. The criticality of this depends on the maximum working strain of the component, the area of structure, and the tooling approach used. Fortunately, there is usually an obvious inverse correlation between shape complexity and normal working strain. Highly loaded parts or areas of components are usually close to being flat and straight. The most complicated parts do

not normally work at very high strain. The tooling approach is important because some critical components, such as wing skins, match ply edge positions (ply drops) to steps in tooling. This ensures that there is no resin-rich bead or possible void at ply edges. To allow the laminator to reach an acceptable deposition rate, two visual techniques are used to show where the prepreg piece edges should be positioned: foil templates and laser projection.

Before the introduction of laser projection, for components with critical lay-up, ply-drop positions, the laminator needed to apply a foil template over the tool and then over each applied layer and then mark the next ply-edge positions using a noncontaminating marker pen. The laminator starts lamination by laying each ply following the marked most critical edge and working outward to the component edge, trimming any excess.

Laser projection is a clever, yet essential and most effective innovation that greatly reduces lay-up time and improves quality. Instead of a laminator following a drawn outline, a laser and mirror device causes very rapid precession of a laser point around the ply outline, which produces a static, bright red line. The line is produced by a suspended laser projector connected to a personal computer, which converts ply outline data with data on the tool curvature to provide the true ply edge (Fig. 5).

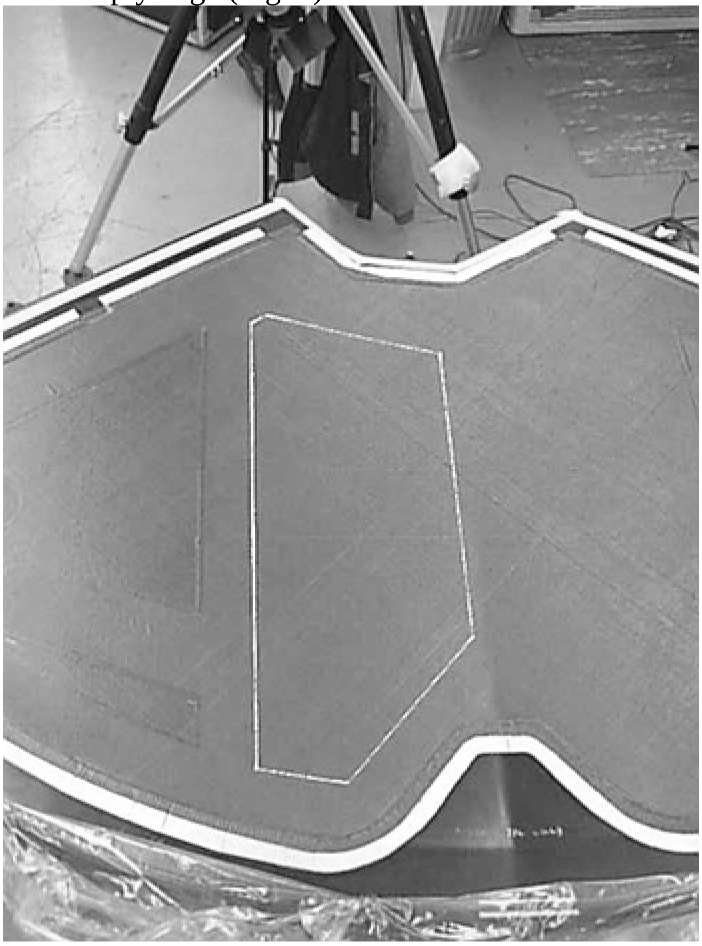

Fig. 5 Laser ply outline projection system in use on aircraft wing and fuselage fairing tool. Courtesy of Assembly Guidance Systems

Debulking. An unfortunate result of the nature of high-quality prepreg is the inevitability of air entrapment between layers. Even after visible air pockets have been forced out, very thin pockets of air can remain. If these are not removed before the curing process, the resulting laminates can have entrapped air bubbles. If the concentration of bubbles or voids is high enough, the laminate is vulnerable to matrix cracking and delamination.

A process known as debulking is used to remove entrapped air. A reusable nylon, natural rubber, or silicone-rubber membrane is sealed around the tool periphery over the lay-up with a fabric breather cloth placed in between and a vacuum applied to the lay-up. The lay-up becomes compressed and, during a period of around 30 min, the layers are squeezed more tightly together and air removed. This process is carried out between every 0.5 and 2 mm (0.02 and 0.08 in.) of lay-up thickness. Although this step detracts from process efficiency, the laminator can use the interruption to organize documentation and materials.

The debulking process has a secondary benefit resulting from the additional compaction. After the debulking stage, the lay-up is consolidated to a thickness very close to that of the finished laminate. Consequently, when the fully laminated component is cured in an oven or autoclave, the outer plies should remain unwrinkled. Without debulking stages, the outer plies tend to wrinkle as the lay-up underneath compresses (Fig. 6).

Fig. 6 Debulking of racing car monococque lay-up. Courtesy of Nigel Macknight, Motorbooks International

Preparation for Curing. When the lay-up is complete and checked, it needs to be sealed such that it can be compressed and cured by the specified pressure and temperature cycle. This varies from vacuum only (oven) cure with 120 °C (250 °F) temperature applied for 1 or 2 h for non- weight-critical parts to autoclave cure with typically 5 bar (500 kPa) pressure with a carefully determined temperature-profile application lasting for 5 h or longer for critical parts such as airframe structure. Prepregs for vacuum (oven) cure have a slightly higher resin content than for high- (autoclave-) pressure cure; the laminate fiber volume fraction for woven-prepreg oven-cured laminates is approximately 54%.

For applications that can tolerate the high cost of the consumable materials, four layers of material are applied to the lay-up:

- *Peel ply (woven polyester fabric, sometimes with a corona-discharge electrical treatment to ease removal):* to provide a uniform surface that protects the surface during subsequent operations prior to bonding
- *Release film with small holes ("pin pricked" thin film):* to allow air and volatiles to escape from the lay-up upper surface. Release films with perforations encourage resin removal (bleeding), whereas types without holes prevent bleeding.
- *Breather cloth (polyester fiber wadding):* to carry air and volatiles to be expelled through a vacuum pump
- *Vacuum bag (nylon film) with tacky rubber sealant gasket:* to seal the lay-up from the oven or autoclave hot air

This is a most difficult and costly process for both labor and materials. The total consumable cost varies from around \$15/m^2 to \$60/m^2, depending on the temperature and pressure applied. The vacuum-bag application is particularly difficult since for double curvature parts or those with raised details or tooling flanges, the bag needs to be folded with sealant tucks applied. Bag failures are common with less experienced operators. Consequently, where tooling budgets allow, custom silicone rubber bags are manufactured. These bags are made from 3 to 5 mm (0.12 to 0.20 in.) thick tough rubber that is bonded to a frame; the rubber can be stretched over the component surface by the applied vacuum. Their cost is in the order of \$145/m^2 to \$715/m^2 of tool surface, depending on the size and complexity. To reduce cure preparation time and the risk of puncture, very tough and “high elongation” consumable bagging films have recently been introduced.

Although preparation for cure appears to be a very complex and costly process, it improved with the introduction of nil-bleed prepregs in the 1980s. Prior to these, specific volumes of excess resin would be bled out of the lay-up into glass fabrics. These had to be applied in one or several layers between the peel-ply and release-film layers. Prepregs are now reliably produced with a highly controlled resin content of typically 34 ± 1% by weight. Figure 7 (Ref 2) shows a cured, demolded, and trimmed Formula 1 car chassis, upper half. Figure 8 shows the completed car of which all of the structure apart from the engine and gearbox is composite, predominantly manufactured using 120 °C (250 °F) curing epoxy- resin and woven intermediate-modulus (IM) fiber prepreg.

Component Properties

Over the history of composite structures, prepreg hand lay-up has been used to mold a great diversity of parts. Extremes of sewage tanks to satellite solar array supports and truck leaf springs to Formula 1 engine air inlet trumpets and fuel injector tubes are examples.

These diverse applications have had materials specifically tailored to provide extremes of performance. For instance aramid fibers in conjunction with resins with low-fiber adhesion can provide laminates that are impenetrable to low- velocity bullets. Space satellite structures are optimized for extreme low weight and just enough robustness to reliably survive launch vibrations; such structures can have laminate stiffnesses of up to 280 GPa (41×10^6 psi), more than double that of standard carbon fiber unidirectional laminates. One limitation with current polymer prepreg matrix resins is a maximum service temperature of around 270 °C (520 °F). Non-polymer-matrix materials are not amenable to prepreg hand lay-up since they are not tacky.

The prepreg hand lay-up process can use all types of reinforcement fiber in tape or fabric form. Fibers range in stiffness from E-glass, providing laminates with tensile moduli up to 42 GPa (6×10^6 psi), to ultrahigh-modulus pitch- based carbon, providing laminates with tensile moduli up to 490 GPa (71×10^6 psi) (Fig. 9). Any resin can be used that is capable of being formulated to provide a high viscosity such that the prepreg has tacky

surfaces. The most common matrix resins are epoxies as a result of their strength, fiber adhesion strength, and slow curing, which provides a freezer out life (i.e., lay- up period) of up to many weeks. Their upper service-temperature-limit is around 150 °C (300 °F) in a hot, wet environment and hence for higher service temperatures, bismaleimide resins with a limit of around 200 °C (390 °F) and then polyimides with a limit of around 270 °C (520 °F) were developed (Ref 3) (see the articles "Bismaleimide Resins" and "Polyimide Resins" in this Volume). Figure 9 shows the range of laminate stiffnesses provided by a wide range of prepreg reinforcement types.

Design Guidelines

Materials and process selection for lightweight composite materials is primarily driven by how much an industry will pay for weight reduction of components and how many parts will be made. For one-off structures and those with production levels of one or a few per month, the cost of the prepreg is usually greatly outweighed by the design, project engineering, and tooling cost.

Structures for which there is little incentive for weight reduction are rarely manufactured from prepreg, since wet lay techniques use much lower-cost composite materials.

Hand lay-up of prepregs is applied to a very wide field of industries and applications. At the industrial end with higher volume production in the order of five to ten parts per day, a thick prepreg, often using a multiaxial stitched (multilayer, multiangular, nonwoven) fabric with a lower-cost, faster-cure resin, will be used. The maximum service-strain levels will be low, and, hence, bubbles and the occasional wrinkle can be tolerated. This also allows the prepregs to be manufactured fast, having wider resin content tolerance bands. A good example of this is E- glass fiber/epoxy resin wind turbine blades. The thick (typically 600 g/m^2) stitched multiaxial fabric in a very tacky resin is able to conform to the blade curvature and to the root section where it joins the hub.

For low-volume, high-performance applications such as rocket launchers with skin features for attachment points, the lay-ups are complex and are provided by unidirectional-tape prepreg of very low thickness (typically 125 g/m^2 FAW). The fiber choice is high-modulus grade, and the resin is formulated to resist higher temperatures than epoxies can sustain. The bismaleimide carbon prepregs are up to 200 times the cost of the glass-epoxy wind-turbine materials.

Table 1 gives a comparison of prepreg types and their manufacturing attributes, costs, and laminate-damage resistance. Figure 10 indicates the level of curvature conformability that can be provided by prepreg reinforcement forms and its relationship with prepreg width and thickness.

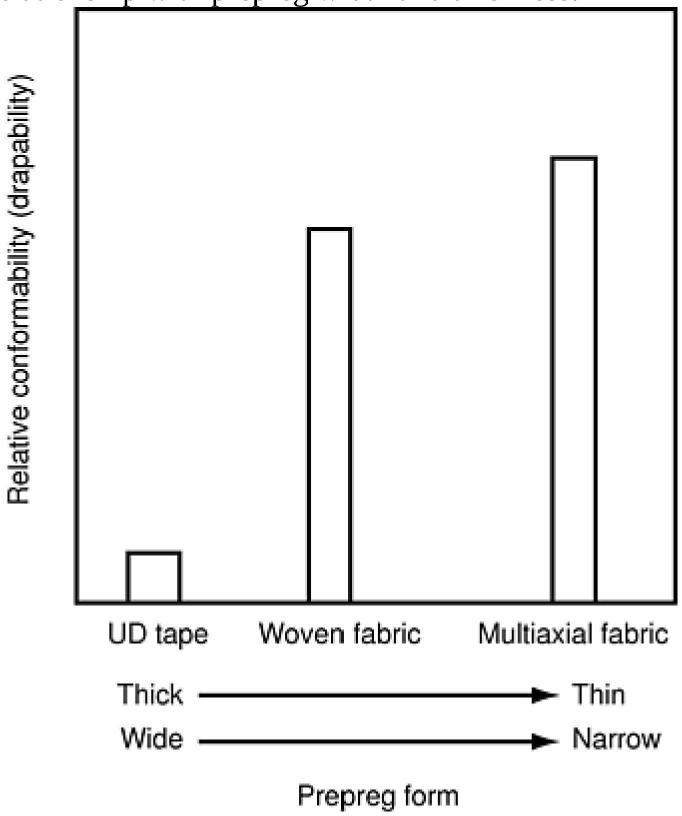

Fig. 10 Relationship between prepreg form and conformability to component curvature

Table 1 Prepreg types and lay-up characteristics

Fiber type	Form[(a)]	Resin type	Cure temperature		Typical thickness		Width		Maximum lay-up rate		Approximate cost		Damage resistance
			°C	°F	mm	in.	m	ft	kg/h	lb/h	$/kg	$/lb	
E-glass	UD	Epoxy	120	250	0.25	0.010	0.6	2.0	2	1	30	14	Medium
	Woven	Epoxy	120	250	0.37	0.015	1.7	5.6	10	5	25	11	Very high

(a) UD, unidirectional tape with multi-angular lay-up. Multiaxial, fabric with 2 to 7 layers of tows at varying angles knitted into a drapable fabric (also called noncrimp fabric).

Andrew Mills, Composites Manufacturing Research Centre, Cranfield University, United Kingdom

Outlook

Despite many impressive research projects and facility investment in the United States and Europe, which have investigated and implemented production of molding processes considered to have the potential to offer cost reduction compared to prepreg hand lay-up, prepreg lay- up is not being replaced for low-volume applications except for low-surface-area parts with extreme lay-up complexity. Very successful examples where resin injection molding of dry preformed fabrics have been developed for propeller-blade molding by Dowty aerospace propellers in England; for sine wave spars and engine-intake ducts for fighter aircraft by Dow–UT (now GKN Westland Aerospace) in the United States and for regional aircraft control surfaces by Bombardier Shorts in Northern Ireland. These applications make use of the higher drapability of dry fabrics compared to prepreg and the use of matched metal tools to provide net-shape parts, which do not require shimming during assembly. The process-engineering simplicity of prepreg lay-up and cure using a vacuum bag and/ or pressure is undeniably preferable to liquid molding processes. The downside of freezer storage and high prepreg cost if procuring small quantity continues to be overcome by the ability to make components simply and reliably.

For applications with low curvature, such as aircraft-wing and tailplane panels, prepreg tape laying by large machine tools will continue to replace hand lay-up. For applications with highly weight optimized, closed sections that can be rotated, such as small aircraft and helicopter fuselages, the fiber placement process as developed by Alliant Techsystems, Cincinnati Milacron, and Boeing will become further established (see the article “Fiber Placement” in this Volume).

There are two apparent trends for prepreg manufacture to further reduce the cost of hand lay-up:

- Scale up of production with low-cost carbon fiber to enter new markets such as low volume production cars, trains, larger wind-turbine blades, and infrastructure repair. Companies such as Zoltech and Hexcel are installing wider, faster prepreg lines.
- Introduction of thick multiaxial fabric prepregging is being made to capitalize on the stiffness of these laminates coupled with the very low manufacturing cost of the fabric.

Fiber Placement

Don O. Evans, Cincinnati Machine

Introduction

FIBER PLACEMENT is a unique process combining the differential tow payout capability of filament winding and the compaction and cut-restart capabilities of automated tape laying. During the fiber placement process, individual prepreg fibers, called tows, are pulled off spools and fed through a fiber delivery system into a fiber placement head (Fig. 1). In the placement head they are collimated into a single fiber band and laminated onto a work surface, which can be mounted between a headstock and tailstock.

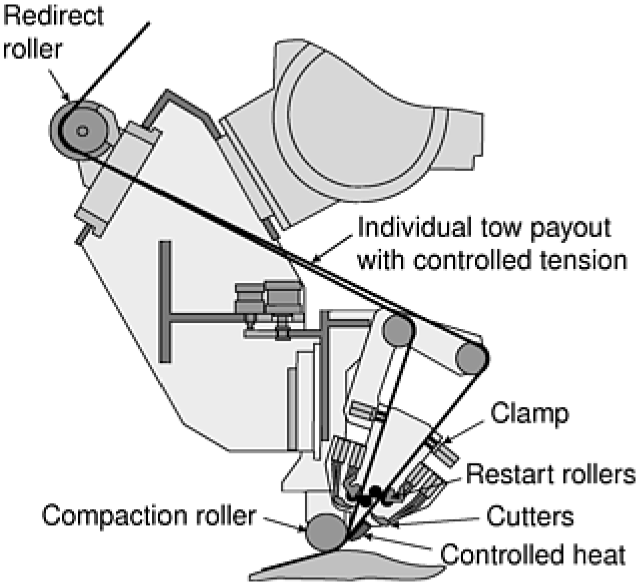

Fig. 1 Fiber placement head

When starting a fiber band or course, the individual tows are fed through the head and compacted onto a surface. As the course is being laid down, the processing head can cut or restart any of the individual tows. This permits the width of the fiber band to be increased or decreased in increments equal to one tow width. Adjusting the width of the fiber band eliminates excessive gaps or overlaps between adjacent courses. At the end of the course, the remaining tows are cut to match the shape of the ply boundary. The head is then positioned to the beginning of the next course.

During the placement of a course, each tow is dispensed at its own speed, allowing each tow to independently conform to the surface of the part. Because of this, the fibers are not restricted to geodesic paths. They can be steered to meet specified design goals.

A rolling compaction device, combined with heat for tack enhancement, laminates the tows onto the lay-up surface. This action of pressing tows onto the work surface (or a previously laid ply) adheres the tows to the lay-up surface and removes trapped air, minimizing the need for vacuum debulking. It also allows the fiber to be laid onto concave surfaces.

Figure 2 is a diagram of a fiber placement system. This system has seven axes of motion and is computer numeric controlled. The machine consists of three position axes (carriage, tilt, crossfeed), three orientation axes (yaw, pitch, roll), and an axis to rotate the work mandrel. All of these axes are necessary to make sure the processing head is normal to the surface as the machine is laminating tows. The machine also has up to 32 programmable bidirectional electronic tensioners, which are mounted in an air-conditioned creel. These tensioners provide individual tow payout and maintain a precise tension. The fiber placement head is mounted on the end of the wrist. The head precisely dispenses, cuts, clamps, and restarts individual prepreg tows.

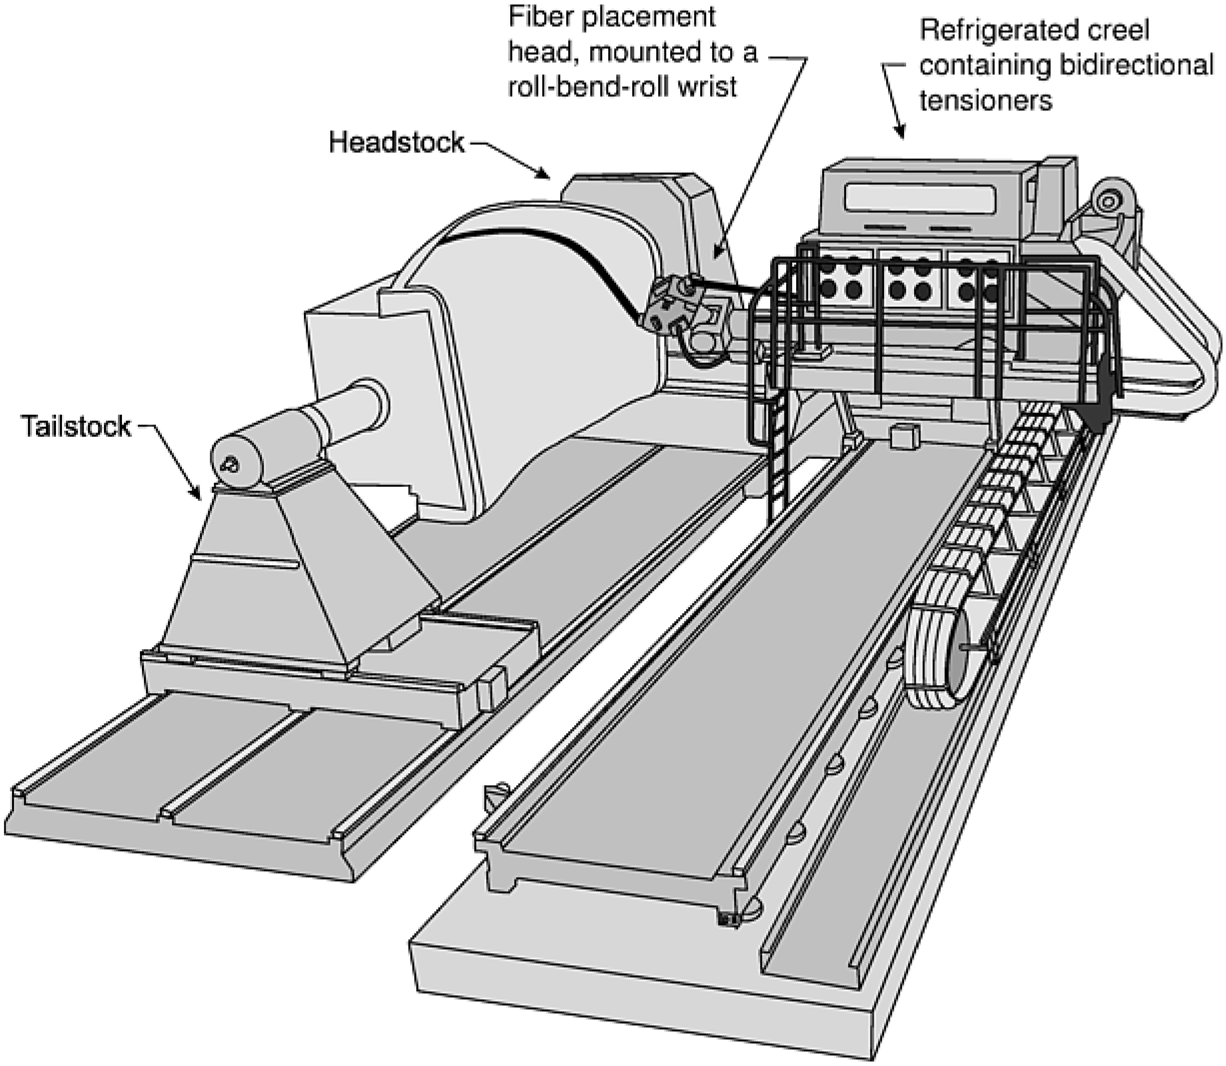

Fig. 2 Fiber placement system

Fiber Placement

Don O. Evans, Cincinnati Machine

Applications

Fiber placement was developed during the mid-to-late 1980s. In 1990 the first production fiber placement machine was delivered to an aerospace company. The first company to implement fiber placement on a production aircraft was Boeing Helicopters. A U.S. government- funded program was conducted by Boeing and Hercules to develop the design and process for fiber placing the aft fuselage for the Bell/Boeing V-22 Osprey. This part was designed to take advantage of the unique capabilities of fiber placement. The first four prototype V-22 aft fuselages were made from nine hand-laid sections. Switching to single-fiber-placed monolithic structure cut the number of fasteners by 34%, and cut the trim and assembly labor by 53%. Through the combination of design optimization and fiber placement, Boeing also reduced the material scrap by 90%. Several other production V-22 parts are being fiber placed by the Bell/Boeing team. These components include the fuselage side skins, sponsons, drag angle, main landing gear doors, fuel boom, and the rotor blade grip (Ref 1).

Another military aircraft that is taking advantage of the unique capabilities of the fiber placements is the F/A-18 E/F Super Hornet. The U.S. Navy funded a program to further advance fiber placement by implementing it on a

F/A-18 E/F fuselage skin (Fig. 3). The program implemented at Northrop Grumman realized a labor savings of 38% when compared to hand lay-up. Northrop Grumman is also using fiber placement for inlet duct skins, side skins, and covers for the F/A-18 E/F.

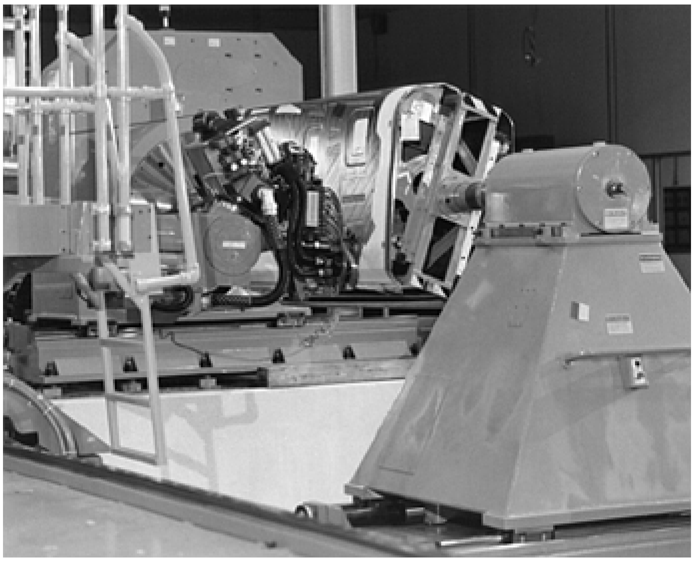

Fig. 3 Fiber placement of the Northrop Grumman F/A- 18 E/F fuselage skin

Fiber placement is also being used in commercial aircraft. Raytheon Aircraft in Wichita, Kansas, is using fiber placement to fabricate fuselage sections for the Premier I and Hawker Horizon business jets (Fig. 4). The fuselage is a honeycomb sandwich construction. Graphite facesheets inclose a Nomex (DuPont) honeycomb core for a total thickness of 20.6 mm (0.81 in.). This design creates a fuselage shell free of frames and stiffeners. The shells are also free of rivets and skin joints. Because the shells do not contain frames, there is more usable space for passengers or cargo.

Fig. 4 Raytheon Premier I fuselage manufactured by fiber placement

By using the fiber placement process to fabricate the fuselages, Raytheon has realized weight savings, material savings, reduced part count, reduced tool count, reduced shop flow time, and increased part quality. The Premier I fuselage consists of only two cured parts. The forward shell extends from the radome bulkhead to the aft pressure bulkhead and is 8 m (26 ft) long. It includes the baggage area, cockpit, and cabin areas. The aft shell extends from the aft pressure bulkhead to the tailcone, and is about 5 m (16 ft) long. The Premier I shells weigh less than 273 kg (600 lb), whereas an equivalent metal aircraft would weigh at least 454 kg (1000 lb). This is a 40% weight savings. If the same two composite fuselage sections were made in a comparable metal design, they would contain more than 3000 pieces. It would be made up of stringers, stiffeners, bulkheads, clips, and external skins. This reduction in part count significantly reduces part fabrication time and the number of tools required to make and assemble the parts (Ref 2).

Material scrap for hand lay-up can be as high as 30 to 50%. Fiber placement has a typical material scrap of 2 to 7%. On a 273 kg (600 lb) fuselage, this material savings becomes very significant.

On the Premier I fuselage, quality assurance (QA) review found that the machine is very repeatable and maintains a tighter tolerance than the hand lay-up process. Because of this, QA personnel closely scrutinize the first production part to make sure that it meets all of the design requirements. If the part program builds a part that meets all of the design requirements, it is considered “bought off.” As long as the part program is not changed, QA personnel needs to do only periodic inspections, instead of checking every ply as it is laid.

Materials

A fiber placement machine can dispense prepregged fibers that are commonly used by the aerospace industry, such as carbon, aramid, glass, and quartz. These fibers need to be fully impregnated with a resin and formed into tows or slit tape. The width of tow or slit tape used by fiber placement range from 3.2 to 4.6 mm (0.125 to 0.182 in.). A width of 3.2 mm (0.125 in.) is most common today. Tows are typically wound onto a 7.6 cm (3 in.) diameter by 28 cm (11 in.) long core in a helical pattern. A typical length for a 2.3 kg (5 lb) spool of prepregged IM7-12K tow, 3.2 mm (0.125 in.) wide, is 3350 m (11,000 ft).

Slit tape is fabricated by running a 7.6 cm (3 in.) wide tape through a slitter, creating smaller widths of slit tape. These narrow slit tapes are then wound onto a number of cores to form spools. When the slit tape is wound onto the core, a backing film, which is wider than the slit tape, must be added. If the backing film is not used, the slit tape cannot be removed from the spool, because of stringers that will occur during the despooling operation. A stringer occurs when the edge of the slit tape separates and stays on the spool while the rest of the slit tape is despooled. This will cause the slit tape to eventually break. During part fabrication, this backing film is removed before the fiber reaches the fiber placement head.

The tow width of the material is very important in controlling the gap between the prepregged tows. For example, if the fiber placement head is designed to lay down tows that are 3.2 ± 0.38 mm (0.125 ± 0.015 in.) wide, the tows will be compacted onto the surface in 3.2 mm (0.125 in.) spacings. If the tow is exactly 3.2 mm (0.125 in.) wide, there will be no gap between the tows. If the tows are 2.5 mm (0.100 in.) wide, there will be a 0.63 mm (0.025 in.) wide gap between the tows. If the tows are 3.8 mm (0.150 in.) wide, there will be a 0.63 mm (0.025 in.) overlap.

The ideal fiber placement material has no tack at 21 °C (70 °F) and high tack at 27 to 32 °C (80 to 90 °F). Low tack is needed when the material is being pulled off the spool and guided through a fiber delivery system and head, but high tack is needed when it is being compacted onto the surface.

Materials that have a low tack can be despooled with a fiber tension of 0.23 kg (0.5 lb) or less. These low tensions are achieved because the resin does not stick to the spool or the components of the fiber delivery system. This lower fiber tension is needed while fiber placing concave areas. A higher tension will cause the fiber to bridge over concave areas. Materials with low tack levels also have less tendency to deform or rope while being pulled through the fiber delivery system. They also transfer less resin to the components of the fiber delivery system and head. This reduces the number of times that these components need to be cleaned because of a resin buildup. Resin buildup in the head can cause it to malfunction.

Don O. Evans, Cincinnati Machine

Part Design Considerations

Fiber placement has the capability of reducing composite material and labor cost. To take advantage of these cost savings, the designer must take into consideration the unique capabilities and limitations of fiber placement. Some of the items that the designer must consider are ply shapes, tow steering, dropping and adding tows, and surface geometry. By optimizing ply shapes, the designer can eliminate the need to hand lay a piece of the ply that cannot be laid by the machine. The designer can also take advantage of the ability of fiber placement to steer tows so they can follow applied stresses, but the tows must not be steered less than 635 mm (25 in.) or they will buckle. The designer needs to take into consideration where the tows are added and dropped, making sure there are not too many gaps and overlaps in a small area. The surface geometry must be such that there are no head collisions and that the concave radii are not too small for the compaction roller to fit into.

When generating ply shapes, the designer must consider the shortest tow length the machine can lay down. This length is the distance from the start of the lay-down point to where the tow is cut in the head. This is called the minimum cut length. It varies from 63.5 to 152 mm (2.5 to 6 in.), depending on the head size and configuration. If the area that is to be filled with tows is less than the minimum course length, the machine cannot lay tow in these locations. These areas could be laid in by hand, or the ply shapes could be adjusted to overcome this limitation. Three techniques can be used to eliminate areas of missing tows (Ref 3):

- In the problem areas, the exterior ply boundaries can be extended past the required part shape, such as tabs on the corner of 45° plies. These extended areas are later removed.
- Curved interior plies can be reshaped to match the fiber angles.
- Some of the holes can be distributed to full- coverage plies having the same fiber angles.

Designers specify the fiber angles that are required to meet mechanical property requirements. Steering of the fibers is required to maintain these angles on a complex shaped tool. A typical fiber placement machine using 3.2 mm (0.125 in.) wide materials can steer a fiber band along a 63.5 cm (25 in.) radius without buckling the individual tows. The buckling occurs because the fibers on the outside steering radius are in tension and the fibers on the inside steering radius are in compression. When steering a radius smaller than 63.5 cm (25 in.), the tows will begin to buckle if laid on a flat or a convex surface, or "Venetian blind" if laid on a concave surface. Venetian blinding occurs when the fibers on the inside steering radius of the individual tows are adhered to the surface and the fibers on the outside steering radius are in the air.

The designer needs to pay special attention to two surface geometry issues when designing a part that is to be manufactured by fiber placement. The first is concave surfaces, and the second is areas with small radii of curvature. When considering a part with a concave surface area, the designer must make sure the fiber placement head can fit into the concave area without hitting the surface of the part. There are some techniques that can be used to overcome some of these limitations. To help the head fit into a concave area, the off-line software has a feature known as collision avoidance. The part and head geometry are programmed into the software. The software constantly checks to see if the two are colliding. If they come close to colliding, the software will rock the head off the surface normal away from the collision. There are limits to how much the head can be rocked off the surface normal. If the head hits on both the front and back sides, the software cannot avoid the collision, and the area should be redesigned. Rocking the head to the front or back slightly affects the effective applied compaction force and the minimum cut length. Rocking the head sideways also affects the effective applied compaction force and requires extra compactor compliance.

Fiber Placement

Don O. Evans, Cincinnati Machine

Outlook

Because of the unique capabilities of fiber placement, many aerospace companies are using it to fabricate a variety of composite parts. In a relative short period of time, this approach has been developed into a widely accepted automated manufacturing process for affordable composite aerospace components. In the aerospace community, it is typically very difficult to obtain approval to change how a part is fabricated once the part has been qualified to be flight worthy. To change the part design or how it is fabricated requires the part to be requalified. This can be an expensive effort and makes it difficult to justify the change. The key to avoiding this requalification cost is to design the parts for fabrication by fiber placement from the beginning. As new aircraft and aerospace programs are introduced, fiber placement will be used to fabricate many more composite parts to gain the benefits of reduced cost, improved quality, and improved performance.

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Introduction

AUTOMATED TAPE LAYING is a mature process and is currently being used in both commercial and military aircraft applications. This article provides a brief history of the process and describes the use of

commercially available flat and contour tape-laying equipment. The materials section describes feedstock materials suitable for automatic tape layer (ATL)-grade composite materials.

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

History

Advanced composites were introduced in unidirectional tape form in the early 1960s. Originally performed by hand, the lay-up process was labor intensive, and inconsistency with hand lay- up caused quality problems with the cured laminates. In the mid-1960s, there was a big push for automation by the aircraft industry. Early machines were home-built by aerospace companies and/or job shops under the direction of materials suppliers. Machine configurations ranged from hand-assisted tabletop prototypes to the first full computer numerically controlled (CNC) gantry- style tape layer, which was developed under U.S. Air Force contract by General Dynamics and the Conrac Corporation. This machine was used to make composite parts for the F-16 with 75 mm (3 in.) wide tape. During the late 1970s and early 1980s, machine tool builders produced the first commercially available flat and contour CNC tape-laying machines, which made aircraft parts for military programs such as the B-1 and B-2 (stealth) bombers (Fig. 1). Tape widths ranged from 75 to 150 mm (3–6 in.) on contoured surfaces and up to 300 mm (12 in.) on flat surfaces (Ref 1 and 2). In the late 1980s, the use of automated tape laying began to focus on commercial aircraft applications. Throughout the 1990s, the equipment, programming, lay-up techniques, and ATL-grade composite materials were further developed to make the tape-laying process more productive, reliable, and user friendly. As of 2001, there are approximately 40 to 45 commercially produced tape-laying machines in the field (Fig. 2).

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Process Overview

Unidirectional graphite epoxy tape is supplied in roll form on backing paper and typically comes in 75, 150, and 300 mm (3, 6, and 12 in.) widths. Contour applications use 75 and 150 mm (3 and 6 in.) widths, while flat applications use 150 and 300 mm (6 and 12 in.) widths. The roll of material is loaded into the tape-laying head (Fig. 3). The tape head is mounted on a 4-axis gantry for flat applications or a 5-axis gantry for contour applications (Fig. 4). The gantry positions the tape head over and onto flat or contour tools for lay-up. A typical part consists of many plies of tape laid up at various ply angles. A "ply" consists of one layer of tape courses at a given angle (Fig. 5). Plies are laid or stacked on top of each other to create a laminate. For flat laminates (commonly called charges, blankets, or panels), once the lay-up process is completed, the laminates are typically removed from the lay- up bed and transferred to a CNC ply cutter where parts are cut out of the laminate. The cut pieces or part kits are stacked and hot drape-formed into structural parts, such as stringers, ribs, C-channels, I-beams, and so on, or stacked onto a contour skin tool to form a contour skin panel. The formed structural parts or skin panels are cured either as a separate structural part or skin panel, or assembled together and co-cured/co-bonded as a contoured skin panel with structural stiffeners (Fig. 6). Laminates that are laid as a contour part usually remain on the contour tool (Fig. 2). The contour tool and the laminate are transferred to the autoclave for curing or to an assembly area where they are mated with structural parts prior to curing.

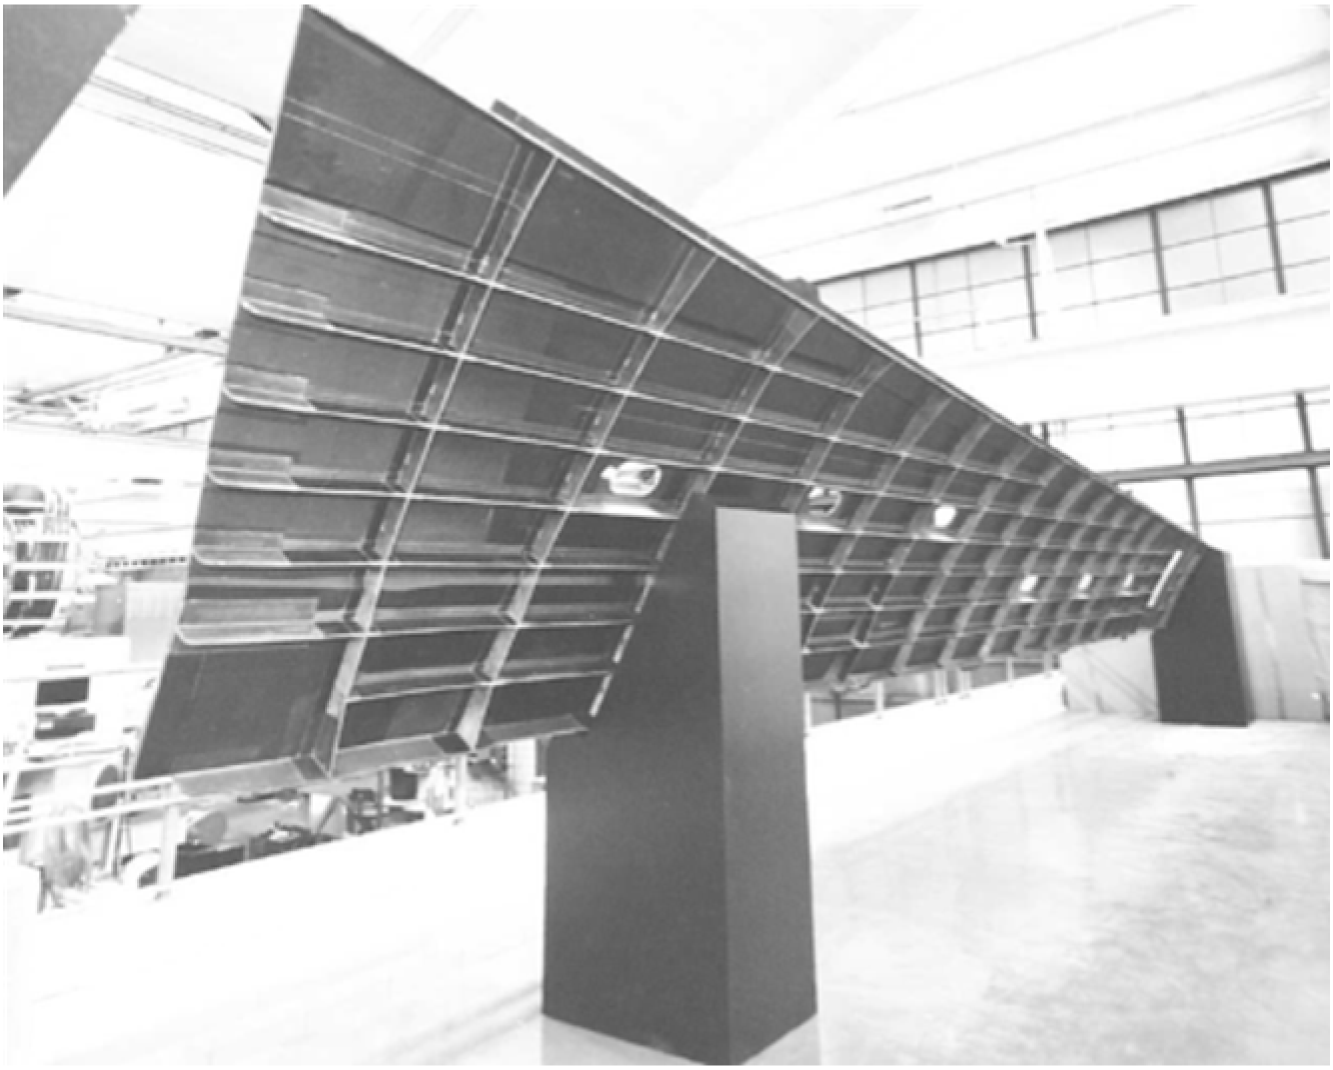

Fig. 6 Airbus A330/340 HTP contour lower skin with stringers, rib shear ties, and spar caps integrated

Advantages. Tape layers compact plies of graphite/epoxy tape with exceptional consistency and greatly reduce fabrication costs compared to hand lay-up. Users of tape-laying equipment have claimed reductions in personnel hours of up to 70 to 85% for flat charges versus hand lay-up, and lay-up rates as high as 1000 kg/week (2200 lb/week). See Fig. 7 for typical lay-up versus scrap rates for flat panels made from 150 and 300 mm (6 and 12 in.) tape widths. Lay-up rates for contour skin panels vary depending on contour complexity, accuracy required, part thickness, and width of tape used. Flat-to-medium contoured parts are well suited for tape laying. The bigger the part and plies, the more productive tape layers are.

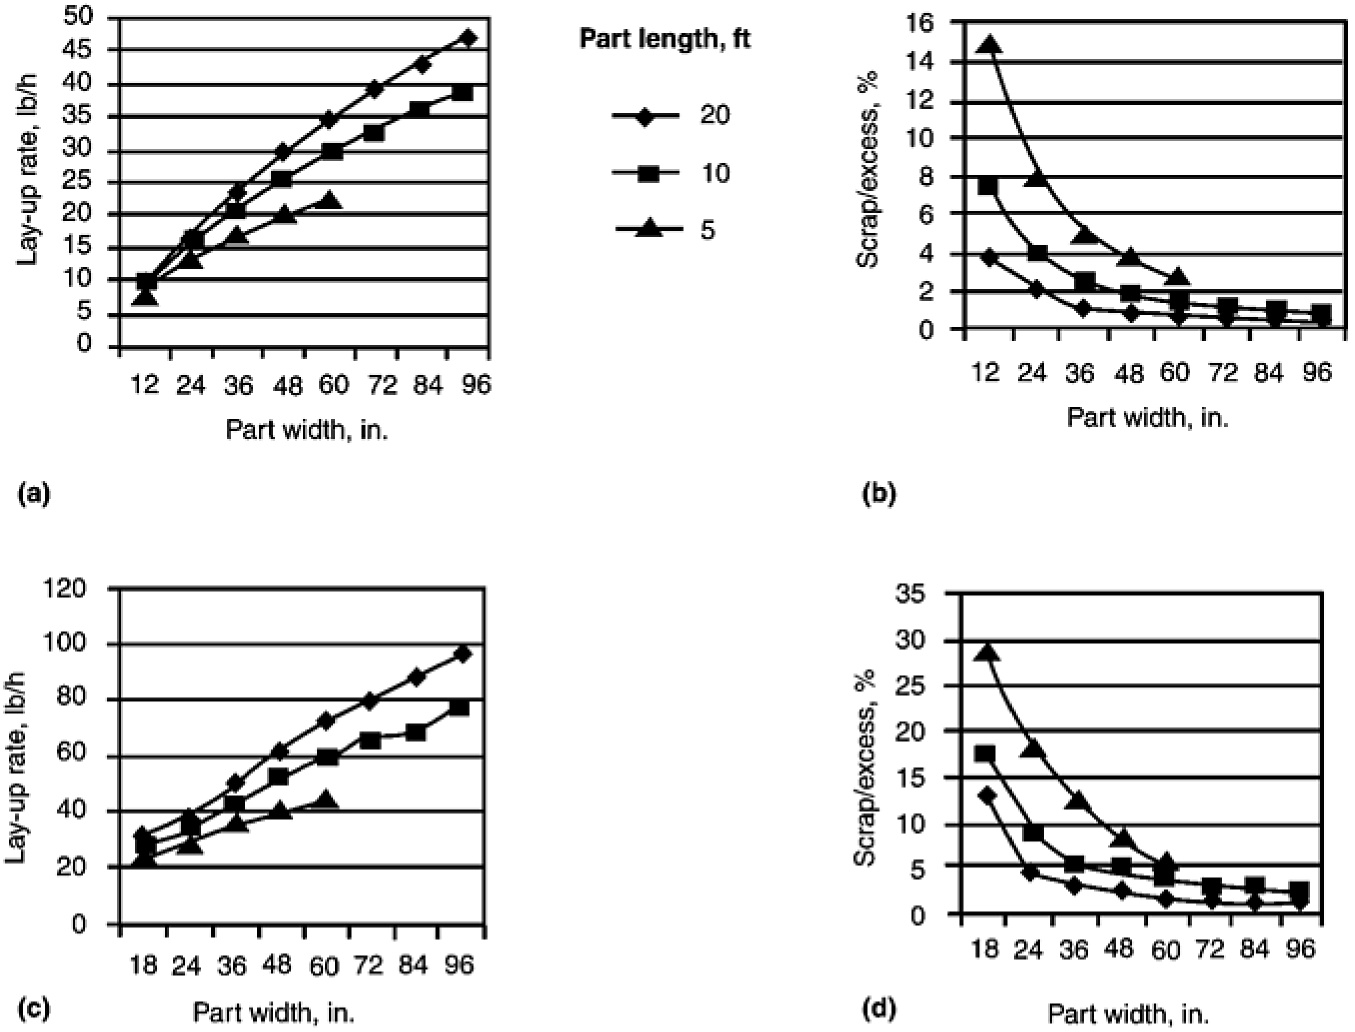

Fig. 7 Estimated flat lay-up and scrap rates for 150 and 300 mm (6 and 12 in.) tape widths. (a) Lay-up rate for 150 mm (6 in.) tape. (b) Scrap rate for 150 mm (6 in.) tape. (c) Lay-up rate for 300 mm (12 in.) tape. (d) Scrap rate for 300 mm (12 in.) tape

Another advantage is that tape layers have ±190° of head rotation; therefore, fiber angles are not limited—any ply angle can be laid up. Cut angles range from 0° to 85°. Tape slitting is used on nonfull width courses.

Disadvantages. Highly contoured parts are not suited for tape laying because the tape tends to buckle and bridge at plane transitions. Also, backing paper breakage can occur. Small plies also lower the productivity of the tape layer.

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Description of Equipment

Tape Layer. The ten-axis gantry-type tape- laying machine shown in Fig. 4 is designed to lay composite tape materials on flat and contoured surfaces. All ten axis movements (five on the gantry and five on the tape head) are CNC to enable the tape to be laid on the contour of a mold surface automatically.

The high-rail gantry-type machine is constructed with *x*-axis ways in 3.7 m (12 ft) increments. This allows the use of multiple gantries on a common set of ways and permits lamination operations on different workpieces simultaneously. Another advantage of the gantry-type machine is the capability of loading and unloading workpieces on one end while continuing to laminate on the other end.

The *x*-axis gantry travels on two parallel sets of hardened-steel guide ways that are elevated and supported by two parallel sets of fixed uprights spaced in 3.7 m (12 ft) increments. The *y*- axis cross saddle and *z*-axis vertical slide assembly, which provide the transverse and vertical movement of the tape-laying head, are mounted to the gantry cross rail. The cross saddle travels on two parallel sets of guide ways mounted to the gantry cross rail. The *z*-axis vertical slide is located in the center of the cross saddle and travels perpendicularly to the cross saddle on a pair of ways mounted to the vertical slide. The *c*-axis supports and rotates the *a*-axis saddle and tape head and is assembled in the vertical slide. The *a*-axis saddle travels on radial ways mounted to a plate attached to the *c*-axis. Movement of the *a*-axis provides the tape-layer head tilt motion. The tape head is bolted to the *a*-axis saddle (Fig. 3).

Tape Head. A spool of tape is loaded on the supply reel located on the top front of the tape head (Fig. 3). Tape is fed past the tape position feedback device, over the upper tape guide chute, and past the cutters. It continues through the lower tape guides, under the segmented compaction shoe, and onto a backing paper take-up reel located on the rear of the tape head. The movement of composite tape through the tape head is called the *u*-axis. Both the supply reel and take-up reel motors control the tape.

The two linear cutter axes *v* and *q* are identical in construction and are mounted on the front of the head between the supply reel and the segmented compaction shoe. They slide in a direction perpendicular to the tape path. The two rotary cutter axes *d* and *e* orient the stylus cutters to the tape. These two axes are similar in construction. The *d*-axis is mounted on the *v*-axis and the *e*-axis is mounted on the *q*-axis. The *v*- *d*- and *q*-*e*-axes perform the motions to cut the desired angle on the tape. The *d*- and *e*-axes normally position simultaneously with *x*- and/or *y*- axis positioning for the next cut at start of course. Cutting is through the composite tape, but not through the backing paper.

The segmented compaction shoe is designed to lay composite tape over contoured surfaces such as pockets (Fig. 9), pad-ups, and overall skin contour while maintaining a fairly even compaction force distribution across the width of the shoe. A tail compaction roller accompanies the tape shoe. This roller is required when the end of the tape is cut diagonally into a long strip (tail) to suit the edge of the ply. A programmable tape-compaction system allows variable tape-compaction pressures to be applied during tape laying. Pressures are changed by the part program or by operator input.

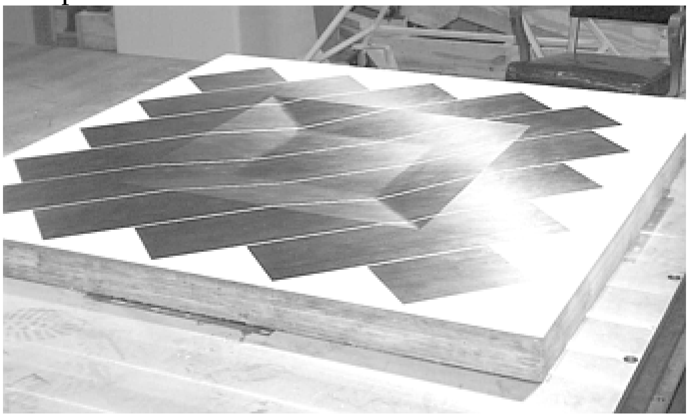

Fig. 9 Contour pocket test tool for automated tape lay- up

The tape head is equipped with an optical tape-flaw-detection system that signals the machine control to stop laying tape when a flaw marker on the tape has been detected. The tape head also contains a tape-heating system (Fig. 3). For bismaleimide and other dry resin systems that lack appropriate tack for tape-to-tape adhesion, the tape-heating system warms the prepreg to increase tack levels just ahead of the lay-down shoe/roller (Ref 4). Heated tape temperatures range from 26 to 43 °C (80–110 °F).

Control. The CNC is a multiblock buffered- contouring system, which is specifically designed for tape-laying applications. It contains no spindle or tooling functions that are associated with general purpose CNCs (since these are not needed by tape-laying machinery), but has additional functions and flexibility to accommodate different composite tape-laying heads. All operator controls, along with the monitor, are enclosed in a control console, which is located outside the work zone. In addition to the console, a hand-held pendant is provided allowing the operator to control various machine functions from within the working envelope.

Off-Line Programming System. The design and programming system (Fig. 10) aids the user in preparing input data for CNC composite tape- laying machines. Creating the part programs requires special programming techniques because the tape must follow the "natural path" determined by the contour of the tool. Also,

individual courses of tape must be positioned to ensure the user's design criteria, including gap and fiber-orientation specifications, are achieved.

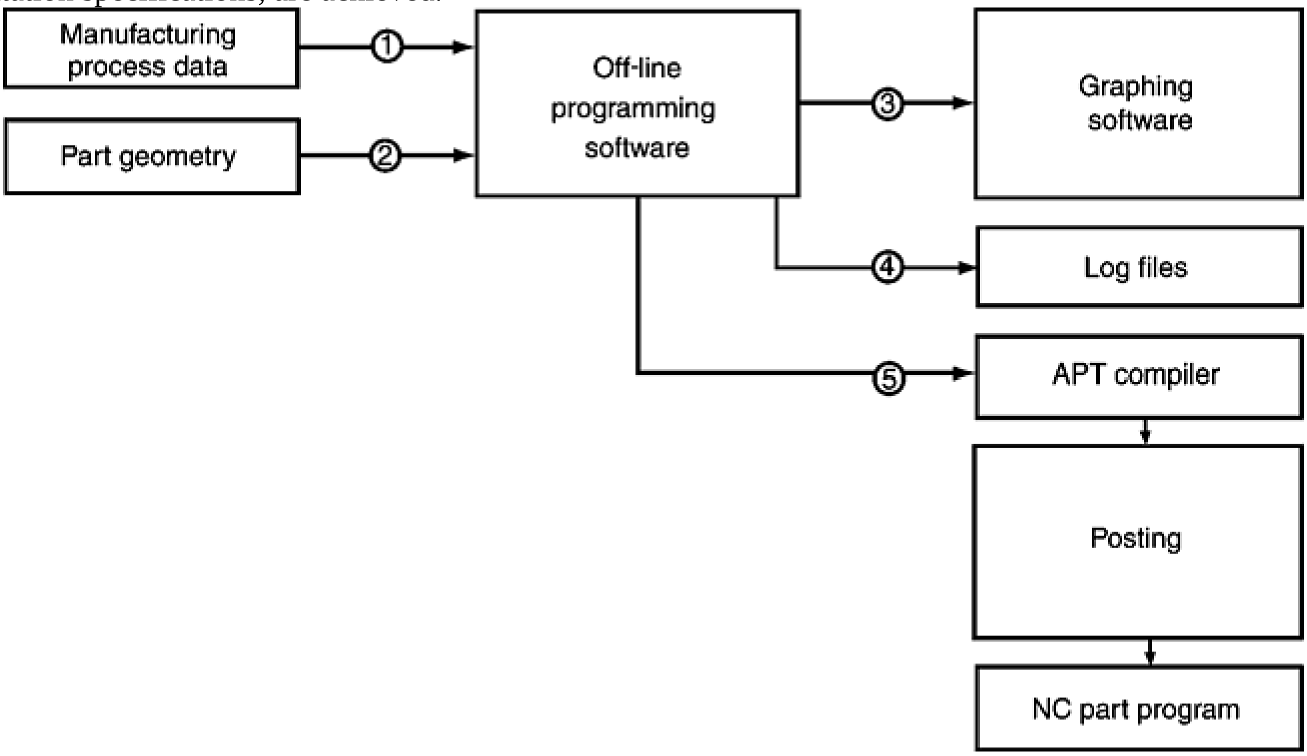

Fig. 10 Programming system block diagram for an automated tape layer. (1) Manufacturing process data include specifications such as tape width, tape thickness, fiber orientation, and gap tolerances. (2) Part geometry consists of numerical descriptions of the contoured surface and boundaries. (3) Graphics data, generated by the software, can be visually displayed with graphing software. (4) Log files are generated by the software and contain exception listings and the ply summary report. (5) APT source code is generated by the software for processing by an APT compiler. NC, numerical control

The user defines the surface of the tool, ply boundaries, design parameters, and machine processing parameters. Using these file inputs, a batch program creates an automatically programmed tool (APT) source code along with graphics data, log files, and a restart file. The results may be analyzed graphically. The APT source program may be processed by an APT compiler and postprocessor to create the numerically controlled part program for the tape layer.

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Tape Laying Process Description

According to the part program, the proper codes and axis position commands are executed to place the tape head onto the mold surface. After touchdown, tape is laid on the mold surface in the manner desired through the use of CNC programmed movements of the machine *x-, y-, z-,c-, a-, d-, e-, q-, v-,* and *u*-axes.
As the tape is laid on the mold surface, the head is suspended above the tool, with the compaction force being applied by the compaction shoes/roller to the lay-up surface. This reduces tape wandering when traversing over breaks and through valleys (Fig. 8). Compaction force is programmable and is entered from the operator's console. The tape-compaction force across the full width for 150 mm (6 in.) wide tape ranges from 27 to 133 kgf (60–293 lbf), and the total- compaction force across the full width for 300 mm (12 in.) wide tape ranges from 27 to 273 kgf (60–601 lbf). These compaction ranges are used during normal tape lay-up mode.
Prior to the end of each tape course, the tape is cut to suit the angle at the edge of the ply. Cuts are made with either the tape head stopped for a zero-degree cut or with the tape head moving for an angled cut. This operation is performed by four programmed CNC drives (*q-, v-, d-,* and *e-* axes) that control movement of two cutters. The speed of each linear cutter axis is programmed to be in relationship to the tape speed to establish the angle of the cut. The other two drives provide for rotation of the two cutters about their shaft axis (*d* and *e*). This programmed cutter rotation assures the cutter always will be aligned along the direction of the cut. Cuts are made by cutting through the composite material but without cutting through the backing paper.
After the tape cut has been made, the last portion of the tape is laid either with the compaction roller (if on an angled cut) or with the segmented shoe (if on a zero-degree cut). The head then lifts from the mold surface and moves to the start of the next course of tape to be laid. Tape courses can be laid unidirectional or bidirectional. Typically, bidirectional is faster because it takes less time to rotate the tape head 180° and move to the next course than it takes to leave the tape head in the same orientation and move back to the start of the next course. For course lengths that are shorter than 1 m (40 in.), unidirectional and bidirectional lay-up take approximately the same amount of time moving between tape courses. This process repeats to create the finished ply. Plies are laid on top of each other to create the finished laminate.

Automated Tape Laying

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Typical Material Types and Forms

In general, feedstock materials (tape) suitable for automated tape laying consist of unidirectional carbon fiber or glass impregnated with thermoset resin, supplied in roll form on a backing paper carrier material, on 255 mm (10 in.) inside-diameter cores, and with edges of impregnated fibers flush with backing paper.
Backing Paper and Resin Impregnation. Rolls of composite material for hand lay-up and automated tape lay-up have different requirements. The durability and release coatings of the backing paper carrier material are very important and make ATL-grade supply rolls successful for automated lay-up over material supply rolls for hand lay-up. For example, if the backing paper is not durable enough, problems with backing paper breakage will occur. When the backing paper breaks, the tape head will need to be rethreaded. Improper release coatings will affect how freely the tape will move through the tape head guide chutes and compaction devices. Also, improper release coatings will also affect how well the composite tape is maintained or stays on the backing paper in addition to how well the tape comes off the backing paper during compaction of the tape to the lay-up surface. If the impregnated composite tape separates from the backing paper prior to the cutting, guiding, and compaction devices, poor tape placement on the lay-up tool will occur. If the impregnated composite tape does not come off or separate from the backing paper during compaction, tape placement will also be affected.
Material tack is also a key factor for successful automated tape lay-up. The distribution of the resin through the fibers (“wet-through” or “wet- out”) affects how well the tape will adhere to the lay-up tool and to itself when laminating subsequent plies. Prepreg with too little resin on the surface of the fibers will not adhere well to itself or to the lay-up surface and will require tape heating to increase material tack for lamination. Bismaleimides and other toughened epoxy resins also require tape heating to increase material tack for lamination because these resin systems tend to have very low tack. Good wet-out also aids in holding the fibers

together during compaction. Prepreg with too much resin on the surface of the tape and too little resin in the center of the tape tends to pull apart or separate during compaction. For example, half of the composite tape may adhere to the lay-up surface while the other half stays on the backing paper. In other words, the tape tears apart.

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Design Guidelines

Automated tape laying is among a variety of processing techniques that are used to fabricate composite parts. To best use the tape laying process, part geometry and the method that is used (flat or contour tape laying) must be considered. Depending on part complexity, size, and shape, tape-laid parts are usually flat-to-medium contour and fall into part categories mentioned earlier. Highly contoured aircraft parts such as fuselages, inlet ducts, nose cones, nozzles, sponsons, rotor blade grips, and so on are better suited for fiber placement than tape laying. When considering automated tape lay-up to manufacture a part, the following part features should closely match machine capabilities:

- Ply shapes/fiber angles should fall within the cutter angles available.
- Contour and mold clearance required must be relative to the tape head shape.
- Pad-ups/stiffeners or ramp angles must be accommodated, and the machine must be able to conform to the surface without tape buckling or bridging.
- Composite material formulation and form must be suitable for the part and the process.
- Process requirements such as tape heating need to be considered.
- The width of tape used should be selected to maximize lay-up rates while keeping scrap to a minimum when creating ply shapes.
- Adequate material choices must be available to meet the design requirements of the part.

In areas where the process required does not match the machine's capabilities, manual intervention will be necessary. To reduce manual intervention, it is best to consider the composite materials available, the equipment processing capabilities, and part flow through the plant at the start of a new program.
Consideration must also be given to the lay- up surface or tool. The choice of mold or table surface materials used for bismaleimide (BMI) tape lay-ups, which typically require tape heating, is important. For instance, on the tape-dispensing head itself, special materials are used to help maintain tape temperature once the tape is heated. These same considerations must also be applied to the mold surface. Materials that act as a heat sink must be avoided for BMI tape lay- up. Other typical lay-up surfaces include Invar (iron-nickel alloy) contour tools and aluminum flat tables with vacuum. Tape is laid up directly on the tool surface or on plastic films (Mylar, Tedlar, E.I. DuPont de Nemours and Co., Inc., Wilmington, DE; nylon; etc.) for flat lay-ups held in place with vacuum. Another film used for flat lay-ups is glass/polyphenylene ether (PPE) that is taped down to aluminum tables. The part is laid up and then removed from the glass/PPE film, which remains on the aluminum table.

Michael N. Grimshaw, Cincinnati Machine, A UNOVA Company

Outlook

The tape-laying process has played an important role in advancing the use of composites for both commercial and military aircraft applications. Tape laying will continue to be a highly productive and cost-effective solution as more parts are converted from aluminum to composite and as new programs consider composites for added strength, light weight, and fabrication economy. Some examples of future applications could include composite wings for commercial aircraft, windmill blades, structural parts for civil applications, and structural parts for the automotive and other transportation industries.

Curing

Introduction

CURING is the irreversible change in the physical properties of a thermosetting resin brought about by a chemical reaction, condensation, ring closure, or addition. Cure may be accomplished by the addition of curing or cross- linking agents, with or without the addition of heat and pressure.

Curing of resins can also be accomplished using ultraviolet radiation and electron beams, but these methods are used for very specific applications and are not commonly used for composite manufacturing.

Preparation for Curing

Processing materials must be added to a composite ply lay-up before autoclave curing. These materials control the resin content of the cured part and ensure proper application of autoclave pressure to the lay-up.
In selecting materials for use in preparing a laminate for curing, cure temperatures and pressures must be considered, as well as compatibility of the processing materials with the matrix system.

Material Types and Functions

The materials usually used in preparing a lay- up for autoclave curing are peel ply (optional), separator, bleeder, barrier, breather, dam (depending on laminate thickness and tooling), and vacuum bag. The materials shown in Fig. 1 and 2 represent complex lay-ups. A generality may be made concerning these materials: Each should be prevented from becoming a possible source of contamination to the composite laminate. Contamination can result in poor adhesion in subsequent bonding or painting operations; also, volatile contaminants can enter the laminate prior to gelation, resulting in porosity and consequent poor matrix-dominant properties. The materials must also be compatible with the maximum cure temperature and pressures required for the matrix system being cured. Each material is discussed subsequently. Maximum use temperatures can be determined by consultation with suppliers.

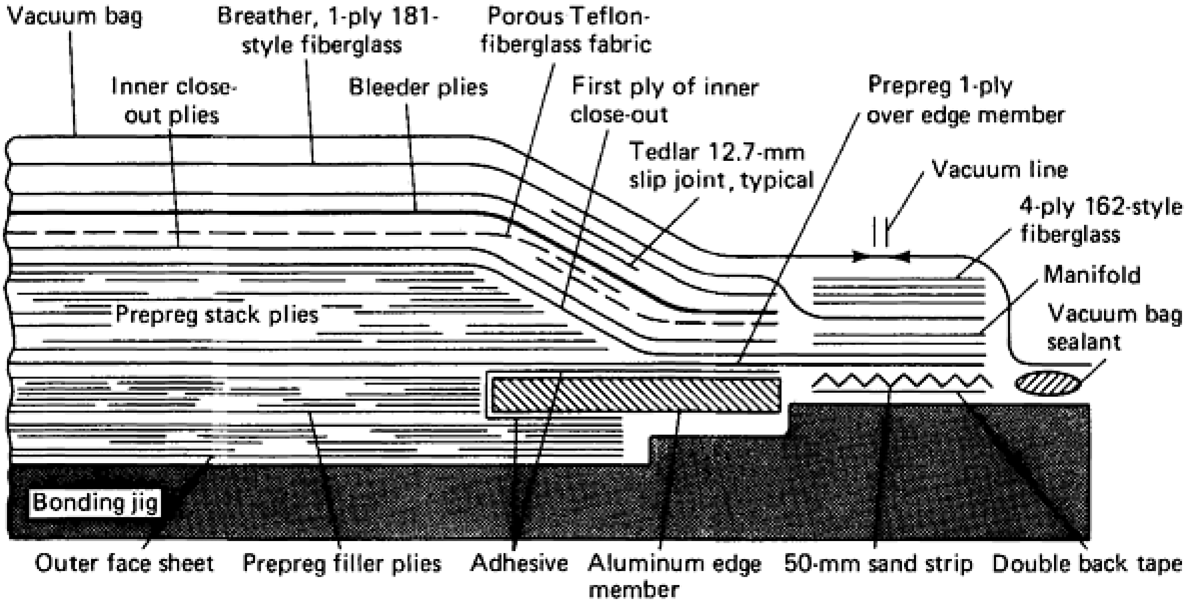

Fig. 1 Complex lay-up, including metal closeout

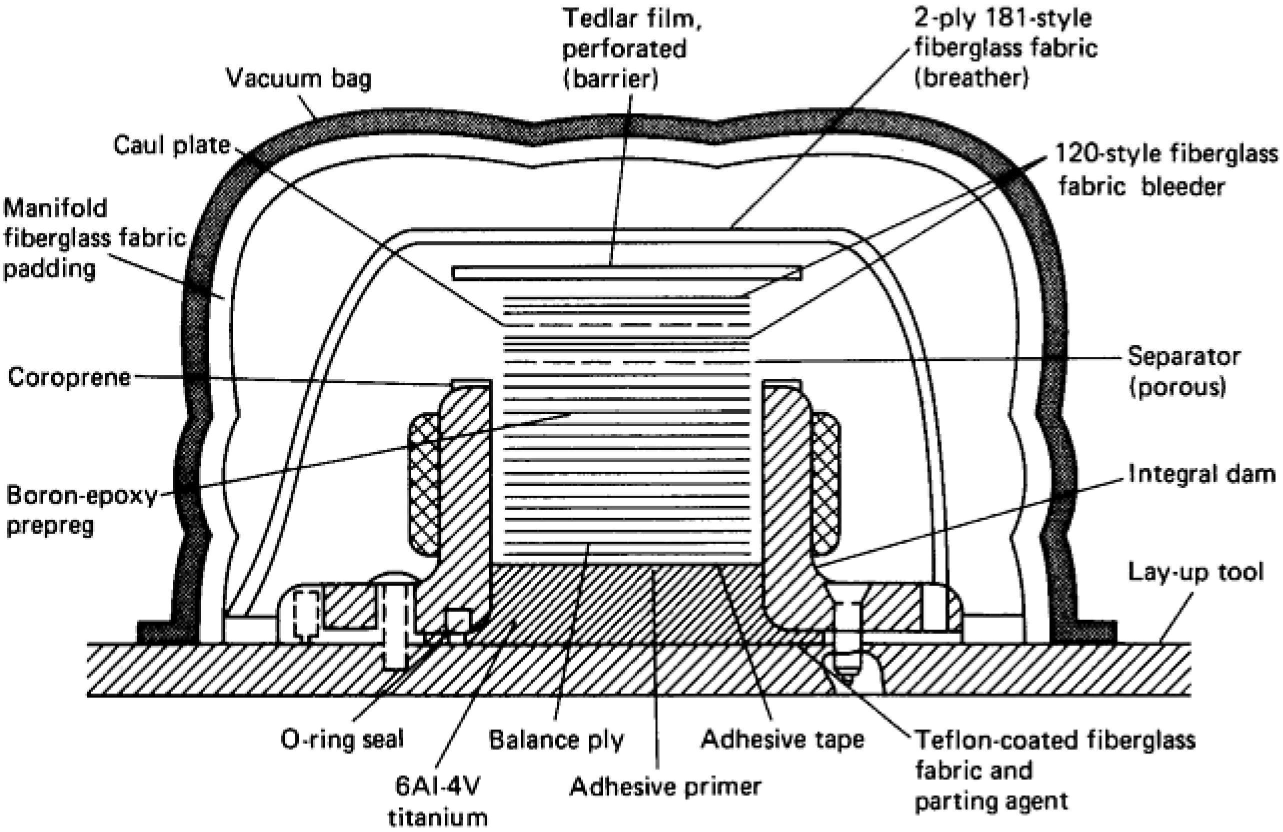

Fig. 2 Complex lay-up showing tool with integral dam. Shown before application of vacuum for clarity. After vacuum is applied, the vacuum bag and fiberglass padding conform to the shape of the tool/lay-up assembly. Note: Lay- up to be co-cured to titanium strap

The peel ply, if used, is placed immediately on top of or under the composite laminate. It is removed just before bonding or painting operations so that a clean, bondable surface is available. It is usually a woven fabric and may be either nylon, polyester, or fiberglass. The fabric is treated with a release agent that must not transfer to the laminate; otherwise, subsequent bonding or painting operations may not be satisfactory. Nylon will not release from phenolics and is not satisfactory for high-temperature curing matrices, such as polyimides or bismaleimides, because its upper use temperature is about 177 °C (350 °F). Nylon can be used if the initial cure temperature is low and if it is removed before postcure. A peel ply can also be used between the mold and a thick laminate to accept entrapped volatiles, thereby preventing porosity in the external composite plies.

A separator (release material) is placed on top of or under the laminate and peel ply (if peel ply is used). It allows volatiles and air to escape from the laminate and excess resin to be bled from the laminate into the bleeder plies during cure. It will also give the cured part a smooth surface, except for porous Teflon (E.I. DuPont de Nemours and Co., Inc.), which gives a slightly textured surface. After cure, the release material must be easily freed from the cured laminate without causing damage. Most separator materials are porous or perforated and contain fluorocarbon polymers. The size and spacing of perforations or the porosity of the material determines the amount of resin flow from the surface of the laminate, thereby lowering resin content (increasing the fiber volume) of the cured part. If no resin removal during cure is desired, totally unperforated separator film should be used. A prepreg with high flow will not be retarded by porous Teflon, which acts as a minibleeder ply and soaks up a small amount of resin.

Bleeder. The purpose of the bleeder material is to absorb excess resin from the lay-up during cure, thereby producing the desired fiber volume. Fiberglass fabric or other absorbent materials or fabrics are used for this purpose. The amount of bleeder used is a function of its absorbency, the fiber volume desired in the part, and the resin content of the prepreg material used in the lay-up. In advanced composites, essentially all excess resin is bled from the surface of the laminate, with edge bleeding being minimized by properly damming the lay-up edges. Personnel should establish tables giving plies of bleeder per ply of lay-up for each prepreg material. These tables are often set up for a particular bleeder material, and then equivalencies are given for other

materials. For instance, 1 ply of 181-style fiberglass is considered equivalent to 2.5 plies of 120-style fiberglass fabric. To determine the correct number of plies to use:

1. Determine resin content of prepreg from receiving inspection data or vendor certification data.
2. Obtain bleeder/prepreg ratio from the table for the given resin content.
3. Multiply number of plies in the lay-up by the bleeder/ply ratio.
4. Round off to the nearest low whole number; this is the number of plies of fiberglass fabric to be used as a bleeder.

For example, to determine the number of plies of 120-style fiberglass fabric required for a 24- ply laminate in which the graphite/epoxy has a resin content of 35.7%:

1. Round off 35.7% to 35%.
2. According to a user table, ratio of bleeder/ply of graphite/epoxy for 35% is 0.27.
3. $24 \times 0.27 = 6.48$
4. Round off to 6; this is the number of bleeder plies.

If the user is willing to tolerate a lower fiber volume with lower cured mechanical properties, bleeding may be eliminated. However, a significant weight increase may occur if the prepreg used in the no-bleed process contains more resin than remains in a cured part subjected to bleeding. An alternative is to obtain a prepreg with an existing fiber volume close to that of the desired final part. Either method eliminates the cost of the bleeder.

Barrier. A nonadhering material, called the barrier, or barrier film, is commonly placed between the bleeder plies and breather plies. In the case of epoxy resins, it is frequently an unperforated film, or barrier film so resin removal from the part can be controlled. For resins that produce volatile by-products during cure, a film with small perforations and large spacing is used to prevent the breather material from becoming clogged with resin and unable to perform its function. Often, a low-cost material such as Tedlar (DuPont) film is used instead of nonporous Teflon, because of the expense of the latter. Thermocouples are installed at the edge of the part between the barrier film and breather plies to monitor part temperature. They also provide the information needed to allow control of the heating medium operation in computer-controlled autoclaves.

The breather is a material placed on top of the barrier film to allow uniform application of vacuum pressure over the lay-up and removal of entrapped air or volatiles during cure. It may be drapable, loosely woven fabric, or felt. Care must be exercised in using coarse, open-weave fabrics, because if bridging of the vacuum bag occurs beyond the elongation properties of the bag material, bag failure will occur, which could result in loss of the part. Some lay-ups use an edge breather consisting of a single fiberglass tow laid along the edges of the composite and draped over the dams.

A dam is sometimes located peripherally to minimize edge bleeding. It may be an integral part of the tool or built in position using materials such as rubber neoprene cork pressure-sensitive tape, silicone rubber, or Teflon or metal bars. Dam height should be approximately the same as the lay-up thickness, including release and bleeder plies, to prevent rounding off of the part edge by the action of the vacuum bag.

The vacuum bag is used to contain any vacuum pressure applied to the lay-up before and during cure and to transmit external autoclave pressure to the part. It prevents any gaseous pressurizing medium used in the autoclave (air or inert gas) from permeating the part and causing porosity and poor or unacceptable part quality. Commonly, an expendable material such as nylon is used for this purpose. Because of the physical and chemical properties of the bag, nylon-6 cannot be used above 160 °C (325 °F), and nylon-6,6 cannot be used above 205 to 215 °C (400 to 420 °F). Neither of these materials is compatible with phenolic resins or certain other matrices. Kapton (DuPont) can be used with polyimides and other materials requiring high-temperature cures. For long runs and highly contoured parts, semipermanent bags may be used. Such bags are commonly made of molded-to- shape rubber. To provide a seal between bag and tool, the bag is commonly secured to the tool with a tape material (bag sealant) that adheres to both the tool and the bag.

The application of the vacuum bag is extremely critical. Bag perforation by the sharp edges of the tool and leakage due to improper sealing at the tool edges may result in a porous part. The complex contours of most aircraft parts often require folds in the bag to take up excess bag material. If these folds are not properly made, or if large wrinkles are left in the bag, undesirable wrinkles may develop in the cured part. Thus, this operation is probably the most critical single step to part quality and must be performed carefully by skilled mechanics.

Autoclave Cure Systems

An autoclave system allows a complex chemical reaction to occur inside a pressure vessel according to a specified time, temperature, and pressure profile in order to process a variety of materials. The evolution of materials and processes has taken autoclave operating conditions from 120 °C (250 °F) and 275 kPa (40 psi) to well over 760 °C (1400 °F) and 69,000 kPa (10,000 psi). The materials processed in autoclaves include metal bonding adhesives, reinforced epoxy laminates, thermoplastic laminates, and metal-ceramic-, and carbon-matrix materials. Although the autoclave system is tailored to specific process requirements, the basic design and subsystems described here are standard for most autoclaves.

The major elements of an autoclave system are a vessel to contain pressure, sources to heat the gas stream and circulate it uniformly within the vessel, a subsystem to pressurize the gas stream, a subsystem to apply vacuum to parts covered by a vacuum bag, a subsystem to control operating parameters, and a subsystem to load the molds into the autoclave.

Pressure Vessel

The pressure vessel shell provides the means to retain pressure inside the work space. The pressure vessel typically is fabricated from carbon steel and lined with galvanized or stainless steel. Plates up to 150 mm (6 in.) thick are rolled to shape and joined by arc welding. The dome- shaped heads or ends are fabricated from similar material and either press-formed or spun.

The most critical portion of the vessel is the closure, or breech lock. A silicone or fluorocarbon rubber material is normally used in this area to allow good sealing without requiring metal- to-metal contact at the door face. The door is usually hinged or carried to one side by a crane.

It is mandatory to design, fabricate, and test all pressure vessels to national and industry-recognized standards. These include material specifications and design stress levels allowable in the vessel.

The autoclave owner must have an approved organization modify or maintain the pressure vessel; any improperly made modification or repair may compromise the integrity of the vessel and subsequent safety. If properly maintained and inspected, the life of a pressure vessel should exceed 50 years.

Internal Structure. The vessel, upon completion and subsequent testing, is prepared for installation of the internal structure, which provides insulation, duct work, and support for all components to be mounted in the autoclave.

The insulation is used to reduce energy costs and keep the exterior at a safe temperature by preventing heat transfer to the vessel. It is typically a ceramic wool material, in sheet or blanket form, and should not be in direct contact with the autoclave atmosphere. The insulation is covered with sheet metal, normally 16- and 18-gage aluminized steel or stainless steel, which is attached in such a way as to allow thermal expansion and protect the insulation from the gas stream in the autoclave.

The duct provides a channel for the gas to be circulated in the autoclave. Provisions for tracks for carts to bring the molds into the autoclave are made.

Gas Stream Heating and Circulation Sources

Currently, several heating methods are available for autoclave systems. The most common method for large autoclaves is indirect gas firing, in which products of combustion from an external chamber are passed through an internal, stainless alloy coil. This system is reliable and can be controlled to allow thermal cycling. The gas-fired systems usually provide substantial operating savings over electrical systems, and are used in autoclaves with maximum operating temperatures of 450 to 540 °C (850 to 1000 °F).

Steam heating can be used for autoclaves operating in the 150 to 175 °C (300 to 350 °F) range. The superheated steam is passed through a coil in the autoclave to heat circulating gas.

Most small autoclaves (under 2 m, or 6 ft in diameter) are electrically heated. Electric heating elements are mounted in the circulating gas stream and configured not to radiate onto the workload in the autoclave. An advantage is the ease of temperature control.
Gas circulation within the autoclave is essential to provide mass flow for temperature uniformity and heat transfer to the part load. This is accomplished with a blower mounted in the rear of the autoclave. The gas is drawn into the blower through the cooling coil and heater, then returned down the length of the autoclave through the annular duct to the door, where it is then directed through the work space. In the modern autoclave system, the fan motor is mounted in a pressurized housing.
The air circulation should be from 1 to 3 m/s (250 to 500 ft/min) in the work space. Circulation any higher than 3 m/s (500 ft/min) may cause problems with the vacuum bags over the parts if they are not properly attached. Variable- speed fan systems are available for improved part heating performance.

Gas Stream Pressurizing Systems

Three pressurization gases are typically used for autoclaves: air, nitrogen, and carbon dioxide. Proportional inlet and vent valves allow autoclave pressures to be controlled and varied precisely. It is important that this very hot gas being introduced into the pressure vessel not impinge on the part load, because the gas stream could cause part damage due to thermal or mechanical shock.
Air is relatively inexpensive when supplied in the 690 to 1030 kPa (100 to 150 psi) range and is acceptable for most 120 °C (250 °F) cures. The main disadvantage of air is that it sustains combustion and thus, may be hazardous at temperatures above 150 °C (300 °F). Nitrogen is the gas most commonly used in autoclaves. The liquid nitrogen is stored in cryogenic form and then vaporized at approximately 1400 to 1550 kPa (200 to 225 psi). Higher-pressure tanks and systems are available. Nitrogen suppresses combustion and diffuses well into the air when the autoclave is opened. However, nitrogen costs can be significant if many autoclaves in a plant are using nitrogen and if the autoclaves are large and operating at high pressure. Carbon dioxide is the second most commonly used gas. It is stored as refrigerated liquid at approximately 2050 kPa (300 psi). Its primary disadvantages are high density, hazards to personnel, and physical flow- related problems. When using any nonlife-sustaining gas, care should be taken not to enter any vessel without ensuring that adequate oxygen is present.

Vacuum Systems

Most parts processed in autoclaves are covered with a vacuum bag, which is used primarily for compaction of laminates and to provide for removal of volatiles. The bag allows the part to be subjected to differential pressure in the autoclave without being directly exposed to the autoclave atmosphere. The vacuum bag is also used to apply varying levels of vacuum to the part.
New production methods have brought increasing complexity to autoclave vacuum systems. Originally, the vacuum systems consisted of a three-way valve that allowed application of vacuum to the part bag or venting of the bag to the atmosphere after pressure application. This proved to be adequate for simple laminates and metal bonding, but as the resin systems became more sensitive and quality control became more stringent, advanced vacuum systems were developed (Fig. 3).

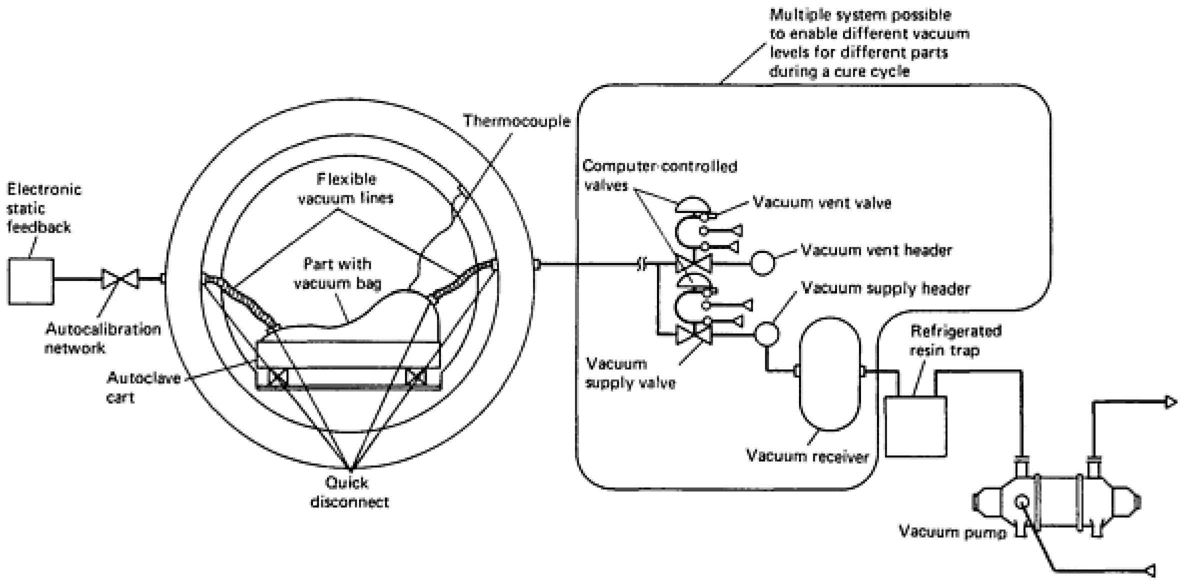

Fig. 3 Advanced vacuum system

The purpose of these systems is to provide fully computer-controlled manipulation and monitoring of part pressure, not just supply pressure. The ability to provide pressure on the part under the bag by means of vacuum has reduced void content by keeping the dissolved volatiles and water in solution in the resin system itself.

Loading Systems

Loading systems are probably the most perplexing aspect of production confronting the autoclave user. Because of the circular configuration of the vessel and the relatively small size of the components, carts must be designed to distribute parts horizontally and vertically in the autoclave. Other considerations are:

- The loaded parts should be accessible to enable repair of bag leaks.
- All vacuum source and vacuum sensor lines must be connected to the part when loaded on the cart, and vacuum must be maintained as the parts are introduced into the autoclave.
- The cart must be easily rolled or transported into the autoclave.

Designing a cart system to meet all the desired criteria is a challenge. The essential loading-system requirements must be determined, because including one feature will often preclude the inclusion of another. Typically, carts of various configurations are used, based on mold size and shape.

Modified Autoclaves for Specialized Applications

The development of thermoplastic-matrix composites has necessitated the design of specialized equipment for use within autoclaves to form thermoplastic materials. This need has been met with retrofittable processing fixtures that enable the processing of high-temperature materials in existing low-temperature autoclaves. Often, electrically heated molds are used. Autoclaves should be manufactured to incorporate design features that make transitions to new materials relatively simple.

The polyimides and related resin-matrix systems have created a new set of problems in the design of autoclave systems. Primarily, the vacuum control systems have had to be reengineered to accept the large amount of volatiles (resin solvent) released during cure. Also, additional computer interaction is required to process these materials properly.

Metal-matrix composites require systems operating from 480 to 700 °C (900 to 1300 °F) at 6900 to 69,000 kPa (1000 to 10,000 psi) to diffusion bond the matrix into a homogeneous mass. Because of the high-pressure requirement, autoclave systems for curing these composites are usually smaller than others.

Modified autoclaves are being used for processing carbon-carbon composites, both for impregnation and carbonization. These complex autoclaves operate at temperatures up to 815 °C (1500 °F).

Phenolic parts have been processed as exit cones and throats for rocket motors in hydroclaves for many years. A hydroclave is similar to an autoclave, except that it is water flooded and pressurized. Hydroclaves are typically run at 6900 kPa (1000 psi) and 150 to 175 °C (300 to 350 °F).
The vacuum pressure chamber (Fig. 4) is a dedicated flexible process center designed for field repair and remanufacturing of composite parts. Future advances will necessitate more dedicated equipment that is directed to specific applications, yet is functionally similar to the autoclave.

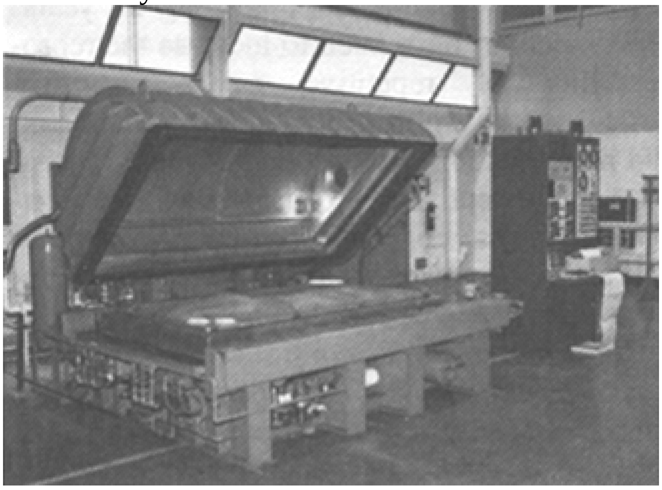

Fig. 4 Vacuum pressure chamber. Courtesy of Naval Air Rework Facility, San Diego

Safety and Installation

It is usually standard to have redundant safety features on any autoclave because of the potential seriousness of any malfunction. Overpressure conditions are usually prevented by three different methods: a separate overpressure sensor and shutdown control, rupture disks designed to rupture at pressures above the operating pressure of the autoclave, and pop-off safety valves with the same function. A standard-production autoclave has all three. Vessels are usually proof tested to high margins of safety, but the danger posed by the possibility of a burst vessel cannot be overemphasized.
Overtemperature protection is not as critical an issue from an injury standpoint, but overtemperature conditions could damage the interior systems of the autoclave; therefore, overtemperature controls are usually provided. The vessel shell, because of the internal insulation, may not be rated to the maximum operating temperature of the autoclave. The external surface of the autoclave should not exceed 60 °C (140 °F), except at penetrations.

Curing

Control Systems

Recent developments in sensors and computer technology have greatly increased the ability to monitor and control cure cycles (see the article "Cure Monitoring and Control" in this Volume).
The cure cycle is controlled by feedback from thermocouples, transducers, and advanced dielectric and ultrasonic sensors. The software is growing in complexity, with features varying between suppliers of computer systems.
Autoclave curing of composites attempts to induce specific chemical reactions within polymers that result in predictable engineering properties. Accordingly, control of the curing process should be based on chemical engineering and fluid dynamic principles. This article describes a computerized approach to the simultaneous control of materials reaction behavior and consolidation dynamics, using an autoclave as the reaction vessel.
The primary objectives of computer control of the autoclave process are to improve cured-product quality and reduce fabrication costs by providing:

- Process optimization
- Reduced process inconsistencies and product rejections
- Accurate, real-time quality assurance with rapid error detection and correction
- Verification of process reaction behavior kinetics
- Nondestructive verification of cured properties
- Accurate, permanent process documentation
- Flexibility in adapting to new or modified processes

Aircraft structures are designed on the basis of allowables, which in turn are based on the testing of coupons cured by a specified procedure, which includes time, temperature, heat-up rate, pressure, and vacuum. In production, the parts are cured on tools that vary in geometry, materials, and mass and therefore can result in different thermal cycles. This variance can affect the quality and performance of the laminate. The product characteristics can differ from those in the engineering allowables database.

The computer is programmed to cure the parts according to an algorithm based on the specifications. If any parts cannot be cured properly because of the mass of the tool, the computer identifies them from its calculation and records the discrepancy in its memory. Thus, parts are cured properly and efficiently, and a proper quality control record is maintained.

Control Dynamics

Composite cure control begins with a basic understanding of the reaction process relationships. The primary regulating parameter for these reactions is temperature. More accurately, the thermal history of a material determines its kinetics, viscoelasticity, morphology, phase precipitation, cross-link density, glass transition properties, and polymer network structure. These are the factors that affect both the process behavior (flow consolidation consistency) and the structural-engineering properties evolved from the cured prepreg.

In addition, each material has different thermal reaction sensitivity characteristics, based on its composition, which define the most tolerant and effective thermal-cure profile. It is the total thermal-cure history that governs the consistency, uniformity, and quality of the chemical curing process, as illustrated in Fig. 5, which shows that a shift of 6 to 9 °C (10 to 15 °F) in temperature can affect the viscosity state a material exhibits during cure. This information, when combined with kinetic data, defines the thermal-control requirements of the process (heat rates, allowable thermal gradients across the entire load, and optimal pressurization time).

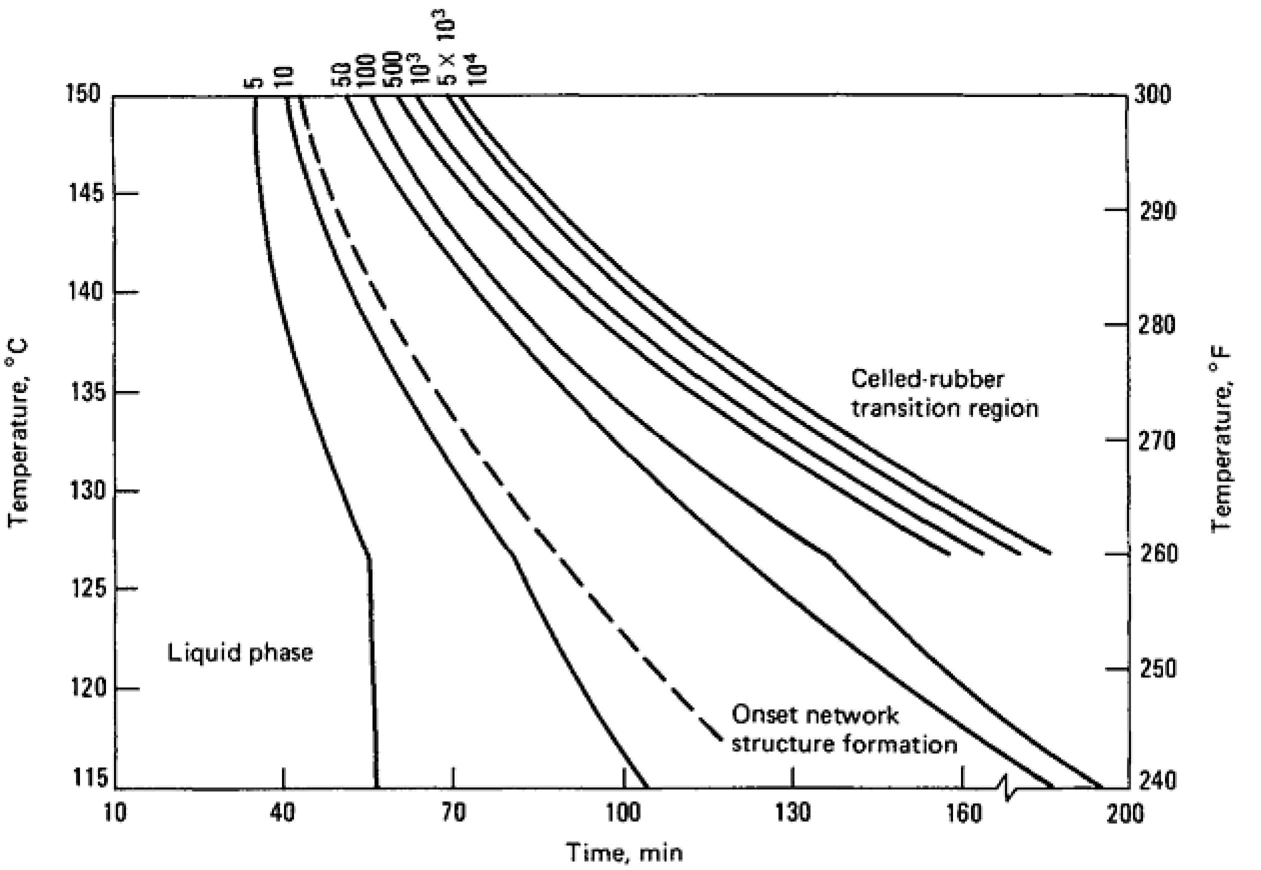

Fig. 5 Effect of temperature and time on material viscosity during cure

The chemistry data are also used to define heat transfer, fluid, and gas transport requirements for the specific part configuration being built. Resin viscosity and kinetics interact with gas diffusion processes and fluid hydrostatic pressure through the time-temperature cure cycle. The laminate quality depends on how well these interactions are controlled to favor void reduction rather than generation.

The autoclave vessel dynamics must also be recognized. The vessel represents a chamber in which air or inert gas is circulated. The vessel can heat or cool this air stream and increase the chamber pressure. Initially, the main reason for the use of autoclaves in composite manufacturing was to achieve uniform pressurization around complex shapes to consolidate the material. Although autoclaves accomplish their function well, autoclave air streams moving across part tooling surfaces create nonuniform air flow disturbance patterns inside the vessel. As a result, heat transfer dynamics to the part become variable and, when coupled with tooling mass variations, part thermal conformance to process requirements is not met. The challenge is to develop logic that recognizes the thermal- variation effects and can control interactively to maintain part conformance.

Temperature Control Logic. The approach to temperature control logic for chemically reactive material uses multiple thermocouple sensors to provide sufficient information for accurate computation of the critical characteristics of the load. The critical parameters that the system must compute are heat rate transfer and part temperature gradients. The heat rate transfer characteristics of the load determine the efficiency of the translation of the power level of the vessel into part temperatures. It is important to realize that this parameter is not constant during a run or repeatable between autoclave runs. It depends on tooling-mass differentials, autoclave loading geometry (air stream deflection and turbulence), vessel temperature, and vessel pressure. Variation in thermal transfer characteristics of the load results in temperature gradients in the parts and variant reaction behavior. The general chemical rule of thumb is that the reaction rates double for every 10 °C (18 °F). The computer calculates the maximum, average, and minimum load heat transfer characteristics dynamically during the process. This information is coupled with vessel temperatures that will optimize uniformity and process rates.

Part temperature gradients result from variable heat transfer characteristics and must be controlled to achieve uniform properties in the composite structure. The composite laminate undergoes the transitions from liquid to gel to glass (vitrification) as a function of the effect of temperature on kinetic behavior. Thus, allowing

significant temperature gradients to exist at these transition functions can cause laminate cure stresses, nonuniform laminate consolidation, and trapped volatiles, all of which degrade performance properties.
The initial objectives are to collect sufficient information to characterize the thermal dynamics of the load in real-time and to control the temperature gradient distributions in the part (and, ultimately, the consistency of reaction cure behavior).
Pressure and Vacuum Control Logic. Vacuum, actually a subset of pressure, refers to the level of pressure in the part bag envelope. Pressure control follows a logic that is similar to that of temperature. This allows for diffusion control of volatiles, which can reduce the potential for laminate porosity. The process specification defines the vessel and bag pressurization requirements, based on cycle times and part temperature. The resultant control output signals are sent to the vessel and bag manifold regulating circuits, respectively.
Other real-time controls include monitoring resin viscosity, resin chemical characteristics, and ply thickness.

Other Process Cures

Room-temperature curing is the most advantageous in terms of energy savings and portability. Efforts continue to produce room-temperature cure resin systems with improved physical characteristics.
Oven curing is much like the autoclave method. Vacuum bagging is used for consolidation and the removal of trapped gasses. The pressure is limited to the difference to atmospheric pressure. Shrink-wrap tapes can be used to apply additional pressure to the composite. This is practical when the geometry is simple, such as a cylindrical composite sleeve being shrunk on a metal shaft.
Hot presses are used for bulk molding compounds and prepregs. The pressure, temperature, and cycle time are readily controlled. The metal tooling is heated internally. Good dimensional tolerances can be achieved.
Resin transfer molding may be used with room-temperature cure resins or may be cured at elevated temperatures.
Pultrusion uses a heated die to create shapes with constant cross sections. The geometry of the die and the pull rate determine the cure time. Cure time, temperature control, and material consistency is critical, because the material must be fully cured just as it exits the die.

Thermoplastic Composites

Thermoplastics are not cured, but they are heated to a sufficient temperature to be molded into the desired shape with vacuum and/or pressure. The processes of thermoforming reinforced thermoplastics does share some of the same challenges of temperature, pressure, vacuum control, and material consistency.

Resin Transfer Molding and Structural Reaction Injection Molding

C.D. Rudd, University of Nottingham

Introduction

RESIN TRANSFER MOLDING (RTM) and structural reaction injection molding (SRIM) belong to a family, sometimes denoted liquid composite molding. The common feature is the injection of a liquid polymer through a stationary fiber bed (Fig. 1). Impregnation relies on a pressure gradient, and the way that this is created, together with the nature of the tooling, defines the process. Several variants can be identified in addition to the two main processes given in the title. Many of these rely on subtly different applications of vacuum to drive the resin flow and are covered elsewhere in this Volume. This article reviews mainly those techniques that use hard tooling and positive (superatmospheric) pressures to produce structures.

Technique Characteristics

Main Features and Drivers. One of the principal advantages of liquid molding is the absence of a single, defined process. The tooling and process can be configured to suit the economics of the application. For one-off molding and large structures single-sided tooling with vacuum- driven impregnation is normal, while for high volumes reactive processing combined with matched steel molds and robotic assembly of fiber preforms provide the highest throughputs. This flexibility permits economic processing across a broad range of production volumes, although the principal range of interest is up to 35,000 and 100,000 units per year for RTM and SRIM, respectively.

Liquid molding competes with most of the open-mold and closed-mold alternatives. The significant advantages and disadvantages are listed in Table 1. The major shifts toward this family of process can be attributed to three important factors:

- New or threatened legislation concerning volatile organic compound (VOC) emissions. This is manifested largely in new applications for vacuum infusion for low-volume fabricators.
- Cost-reduction drives in the aerospace industry. Here the shift is away from high-cost prepregs toward lower-cost fabrics and epoxy resins using RTM, resin-film infusion (RFI), and vacuum infusion.
- Niche-market vehicles in the automotive industry. Low- and intermediate-volume vehicle bodies are uneconomic to manufacture in stamped metal. Below 35,000 units/yr attractive savings in investment costs are possible by using liquid molding instead of sheet molding compounds (SMCs).

Table 1 Advantages and disadvantages of liquid composite molding versus competitive processes

Advantages of liquid molding	Disadvantages of liquid molding
Versus open mold/wet laminating	
Reduction/elimination of VOC emissions Improved uniformity, quality assurance Two cosmetic faces Reduced labor costs	**Higher investment costs–tooling and equipment**
Versus prepreg processing/vacuum bag and autoclave	
Reduced materials costs Reduced labor costs Thick sections possible–easier debulking Direct control of thickness and fiber volume fraction Flexible use of reinforcement, resins Fewer shelf life issues	**Higher tooling costs** **In-house resin formulation** **Greater quality assurance responsibility (molder)**
Versus compression molding/SMC, BMC	
Reduced tooling costs **Fewer shelf life issues** **Use of structural performs**	**Longer cycle times** **In-house resin formulation** **Greater quality assurance responsibility (molder)** **Greater floorspace requirement**

Process Capabilities and Economics. Process throughput is largely a function of investment. Figure 2 shows a typical cycle breakdown for a large component. Aside from handling operations that benefit from investment in automation, the two main factors are injection and heating/curing times. Simple gravity or vacuum- driven

injection systems may be useful for low- volume or prototyping work, but most industrial operators rely on positive-pressure systems that operate between 2 and 10 bar. Typical filling rates are 1 to 3 L/min (0.26–0.79 gal/min), although exact values depend on the gating strategy, fiber fraction, and the nature of the injection system. SRIM metering systems may double these outputs. Heating and curing times vary with part thickness and resin formulation. Urethane-based SRIM resins may be sufficiently rigid for demolding within 40 s of mold fill, while thick sections or epoxy laminates may require several hours in the mold. Process times are generally competitive with SMC for small parts, where 3 min seems a reasonable target, while larger items (>1 m^2, or 10.8 ft^2) require 20 min or more.

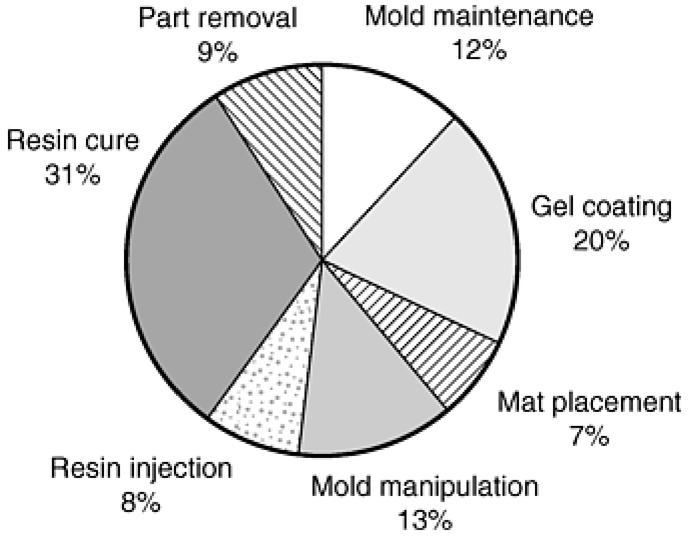

Fig. 2 RTM cycle time breakdown for typical industrial part

Flexibility in the use of materials is one of the key attributes of liquid molding. Industrial applications involve a variety of reinforcement styles, although the main split is between the aerospace sector, using more or less exclusively fabrics, and the automotive industry, where random reinforcements are used for appearance and semistructural items. However, as vehicle manufacturers and their suppliers make further inroads toward fully structural composite bodies some convergence is likely. Whichever route is followed, a wide range of reinforcements styles can be incorporated, including the relatively narrow range of fabrics used in prepregging, as well as less conventional braids, three-dimensional weaves, for example. Fiber architecture imposes the main limit on achievable volume fraction of fiber (V_f); 65 vol% is feasible for flat panels (although 60% is a more realistic target), while for (continuous) random reinforcements 35 vol% represents a practical ceiling.

Cost reduction provides the rationale for the majority of new applications. Automotive manufacturers seek reductions in tooling costs, and this provides an operating window that competes with the lower band of SMC applications (typically up to 35,000 units). Conversely, aerospace operators look to offset the higher investment costs associated with RTM by lower-cost materials, since the manufacture of an intermediate prepreg is eliminated. One cost-saving feature that is common to both sectors is component integration, whereby several moldings or stampings can be combined with a substantial reduction in tooling investment. A simple example is the manufacture of a one-shot sandwich panel in RTM (Fig. 3) that replaces separately molded skins and a secondary bonding operation. Clearly, the same approach can be extended to much more complex structures as demonstrated by several studies from the automotive sector.

Applications

Automotive. Many of the prominent applications of liquid molding have been automotive. Lotus (U.K.) introduced vacuum-assisted resin injection (VARI) for the 1974 Elite, which continued for the 1990 Elan. The Dodge Viper (U.S.A.) is another example of a low-volume, high-performance vehicle with RTM body panels and SRIM bumper beams; similar is Aston Martin's DB7 (UK), with the hood, fenders, and deck-lid in RTM. The latter manufacturer extended its use of composites in the 2001 Vanquish with A pillars, front-crash structure, and transmission tunnel in RTM. Other low-volume applications of note include GM's Corvette (USA) and Alpha Romeo Spider (Italy) convertible hard tops, Ford Aeromax 120 (USA) and Mack (USA) truck hoods, Iveco (Europe) Eurocargo truck cab roofs, and BMW Z-1 (Germany) body panels.

In addition to mainstream passenger vehicle and truck parts, resin transfer molding has made successful inroads into low-volume niche vehicles for defense applications including the manufacture of all-terrain-vehicle bodies. Djurner and Palmqvist (Ref 1) describe one example of an all-terrain-vehicle body designed to withstand the high loads imposed during helicopter lift. Large panels were made using unsaturated polyester and acrylic resins with preformed continuous filament random mat (CFRM) reinforcement.

The Renault Espace (France) provides what is probably the most notable example at medium volumes. Matra produced the RTM body panels and closures for this vehicle, which were installed onto a galvanized steel space frame. The Espace became a victim of its own success when sales demand outpaced production capability, and body manufacture switched to SMC.

One of the first commercial applications for SRIM was a bumper beam for the 1989 Chevrolet Corvette. New application areas under investigation include underhood parts, for example, radiator supports, lamp housings, and oil pans. Other emerging application areas include structural cross-members, truck beds, and floor pans.

The most successful high-volume applications have been the manufacture of foam-cored spoilers by Sotira (France) using RTM and variants on that process for a variety of European vehicles. The process reached maturity for nonstructural parts with the introduction of RTM rear spoilers for the 1995 Ford Fiesta at projected

annual volumes of up to 250,000 vehicles/yr. Front bumper beams for the General Motors' all-purpose vehicles (Lumina, Silhouette, and Trans Sport) have also been produced at annual volumes in excess of 115,000. Further potential high-volume applications include semistructural seating components such as the BMW (Germany) 300 series seat back.

Aerospace. Early examples of aerospace applications include the manufacture of radomes. These are generally produced in monolithic or syntactic cored laminates using a woven or knitted sock preform. A typical example is that of the (U.K.) Royal Air Force (RAF) Tornado fighter with an overall length of approximately 2 m and major diameter of 1.6 m. One of the best documented aerospace applications has been blading for aircraft and hovercraft propellers (Ref 2), using a complex preforming process that includes fabric, mat, foam injection, and braiding. Several successful airframe parts were produced for the (USA) F-22 and F117-A fighter aircraft. These replace, for example, hand-laminated sine-wave spars at a reported cost saving of more than $25,000 per aircraft. Other applications include engine inlet glands and fuselage frames, both of which are fracture critical, having equivalent or improved structural properties compared with prepregs and demonstrably lower void levels. Aeroengine applications have grown also. Boeing's blocker door replaced a 40-piece aluminum assembly with a six-piece carbon/epoxy fabrication manufactured in matched metal molds. Similarly, inlet and fan exit casings, thrust reversers, and cascades have also been produced by Dow-UT. Each of these parts is flight critical and has been certified by the Federal Aviation Administration (FAA), generally replacing titanium alternatives.

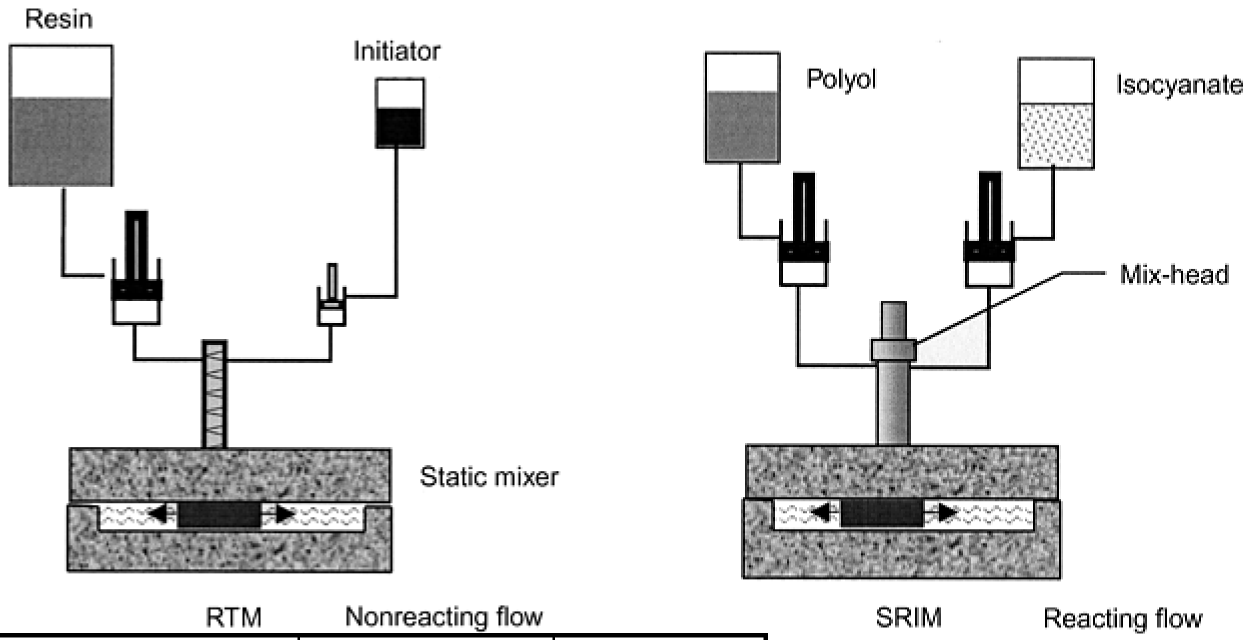
Resin Transfer Molding and Structural Reaction Injection Molding

C.D. Rudd, University of Nottingham

Technique Description

The basic approach consists of loading the mold cavity with the required level of reinforcement, closing to a predetermined cavity height, and injecting a liquid resin at positive pressure. The reinforcement (preform) may contain inserts of rigid foam or other materials, while the polymer phase is (usually) introduced as a thermosetting resin. As indicated earlier, there are many variants on this simple approach, which have been developed to speed production, to reduce tooling costs, or to improve properties. The more important variants are discussed briefly in the sections that follow.

Structural reaction injection molding (Fig. 4) relies on polyurethane chemistry. The high reactivity of the material, once mixed, demands rapid dispensing and close metering. The key to SRIM is the rapid delivery of low-viscosity reactants on a metered basis through (usually) an impingement mix head into a heated mold. Delivery is via a piston or lance system. The delivery rates are controlled to modify process times or polymer properties. The separate storage tanks are usually heated and agitated, while the reactants are recirculated to the mix head and back to the tanks periodically in order to maintain the entire system at uniform temperature. Many materials are moisture sensitive, which requires the reactants to be stored under a blanket of dry nitrogen. Although the reactants are stable in isolation, polymerization is extremely rapid once mixed. Thus it is necessary to clear the mixing device of any material following a molding shot. Self-cleaning impingement mix heads are now common.



Capability or characteristic	**RTM**	SRIM
Delivery pressure	Moderate	**High**
Mixing	Static	**Impingement**
Materials	Polyester/epoxies	**Urethanes**
Processing speeds	Slow/moderate	**High**
Investment required	**Low**	**High**

Fig. 4 Comparison of RTM and SRIM processes

Most commercial reactive processing facilities involve two streams. Occasionally a third stream will deliver pigments, and so forth. High flow rates mean that the dynamic response of the system needs to be very fast, and the delivery needs to be metered very carefully. For piston or lance-based pumps this is usually monitored using linear displacement transducers. Hydraulic actuation is used exclusively for the dispensing devices. Depending on the materials being processed, the reactant temperatures may be 30 to 200 °C (85–390 °F), although 50 to 90 °C (120–195 °F) is common for urethanes. The tanks and hardware are maintained at the necessary temperature by circulating hot oil or water, while the delivery lines are kept warm by circulating the reactants. For high-viscosity systems, trace heating is used on resin supply lines and fittings. A comprehensive review of RIM processing and processing equipment is provided by Macosko (Ref 3).

Vacuum-assisted resin injection has broad industrial applications. Lotus pioneered its use, although the original process is generally attributed to Hoechst. Vacuum-assisted resin injection molds are usually vented. A partial vacuum is applied to provide mold clamping, reinforcement compaction, and an increase in the forcing-pressure gradient. The reduced internal pressure minimizes mold deflections, which is particularly important when producing large-area moldings in low-cost, lightweight molds. Hayward and Harris (Ref 4) demonstrated a significant increase in laminate mechanical properties, attributed to reduced voidage resulting from the partial vacuum; removing air from within fiber bundles improved wet through and reduced voidage at a microscopic level.

Vacuum Infusion. A logical extension of VARI is to evacuate the mold cavity completely prior to impregnation. This technique has two main applications:

- The manufacture of aerospace composites with low void fractions
- Low-investment manufacture under flexible tooling

In the first case, the vacuum (1–5 mm Hg) is generally augmented by a positive resin supply pressure, while in the second case the resin supply is generally at atmospheric pressure. This process is popularly known as VARTM, RIFT, SCRIMP, and so forth and is covered in detail elsewhere in this Volume.

Vacuum-injection processes have been used for glider ailerons, railroad coachwork, and for a wide range of marine structures. The principle is that a sealed mold cavity, containing a preform, is created between the vacuum bag and a relatively stiff mold. This cavity is then evacuated, which compacts the reinforcement and

removes the residual air. Resin is then introduced to the cavity (usually via a peripheral gallery) and impregnates the reinforcement as it advances toward the central suction point(s). Since the process is carried out at atmospheric pressure, the degree of rigidity required in the tooling is minimal. The mold is generally a gel-coated glass/epoxy laminate with a heating matrix embedded in an epoxy concrete backing. Since the available pressure difference is limited to around 1 bar, resin velocities are lower than those in conventional RTM. Although peripheral gating speeds up the filling phase, fill times can be prohibitive for large parts. Thus, flow-enhancing fabrics are used to increase effective preform permeability. While the creation of easy-flow channels within the preform is generally undesirable due to the difficulty of ensuring complete air removal, the presence of the vacuum means that the danger of air entrapment is greatly reduced. A useful review is given by Williams et al. (Ref 5).

Resin-Film Infusion (RFI). This process lies somewhere between traditional autoclave molding and vacuum infusion. A single molding tool is used in combination with a vacuum bag to drive the impregnation. The resin is introduced as a film or pelletized solid at the same time as the reinforcement. The raw materials are then enclosed as for conventional vacuum bagging, and the resulting assembly is taken through a heat and pressure cycle to reduce the matrix viscosity sufficient for impregnation prior to gel and cure. Materials costs are lower than with prepreg, and through-thickness properties can be improved by stitching or three-dimensional fabrics. The main attraction of RFI is probably for parts of high surface area. Since the flow is through-thickness, the in-plane dimensions are relatively unimportant, whereas in conventional RTM they influence the filling time strongly.

Injection-compression molding involves loading the preform, partially closing the mold cavity (Fig. 5), and injecting a metered resin shot. The degree to which the mold halves are held apart during injection varies in practice, but is generally only a small fraction of the overall cavity height. A small increase in thickness results in a relatively large change in preform permeability; thus the resin can be injected relatively quickly. Since the resin charge is injected into an expanded cavity, it will only impregnate a portion of the final surface area of the part. The final compression stroke, which closes the cavity down to its final design thickness, provides the squeezing action necessary to cause the in-plane flow, which fills the cavity. A proprietary version of the process has been used with a high degree of success in the manufacture of automotive spoilers (Ref 6).

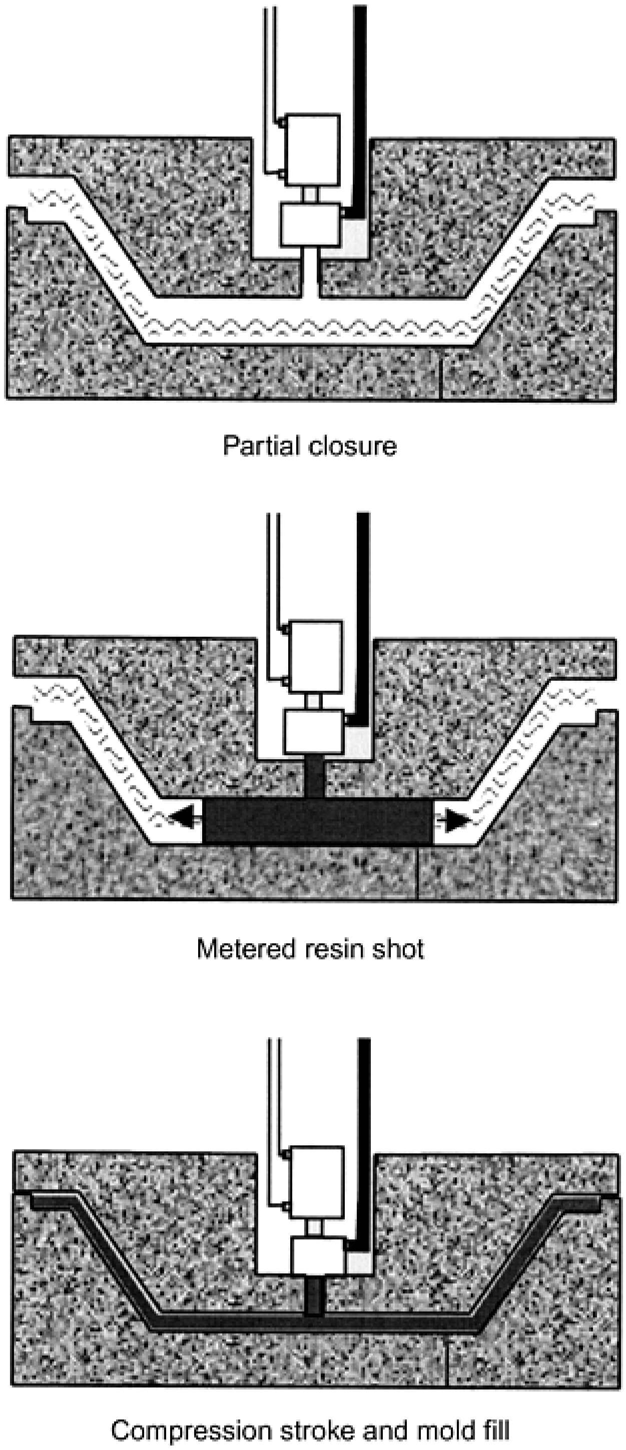


Fig. 5 Injection-compression molding. Initial stand-off enables rapid injection due to increased permeability. The final compression stroke provides rapid fill-out and void collapse.

Resin Transfer Molding and Structural Reaction Injection Molding

C.D. Rudd, University of Nottingham

Material Types and Forms

The materials used in liquid molding do not vary greatly from the conventional mats, fabrics, and resins used in wet laminating or press molding. Where significant differences occur, these generally involving adjustment of either the resin viscosity, gel time, or the reinforcement architecture to provide relatively easy flow during impregnation. This section provides a brief overview of the materials that are commonly used together with some of the processing characteristics that are important to processing speed and part quality.

Reinforcement Materials. Moldings can be made successfully using most conventional forms of mat and fabric reinforcements. The two important exceptions to this rule are chopped- strand mats, which are usually made with high- solubility binders and are therefore susceptible to fiber washing and dense preforms produced exclusively from monofilaments as these have very low permeabilities. Some fabrics are produced specifically for liquid molding. These are termed flow-enhancing fabrics and contain warp-bound tows that create local flow channels in an otherwise low-permeability region.

The major decision that impinges on structural design is the choice of preforming route. This influences the available fiber orientations and volume fractions. Low-volume parts or simple preforms are best assembled by hand in the mold using mats or fabrics. However, this is time consuming and introduces variability. Hand-placed reinforcements tend to be combined with a pinch-off, and this necessitates a postmold trimming operation. Alternatively, net-shape preforms can be produced conveniently by thermoforming the same materials using thermoplastic powder as a binder. Conventional systems use infrared ovens and low-cost stamping presses, which are often actuated pneumatically, since the pressures involved are limited to a few bar. The fiber volume fraction available with CFRM implies a maximum tensile modulus of approximately 10 GPa (1450 ksi) and tensile strength of up to 120 MPa (17 ksi). For higher performance, fabric reinforcements are used, and these include a wide range of woven products and the so-called zero crimp or engineered fabrics. Engineered fabrics offer greater flexibility depending on their method of construction and are produced as multilayer fabrics stitched together with nonstructural yarns. Standard configurations include quasi-unidirectional, 0°/90°, ±45°, and quasi-isotropic (0°/+45°/90°/–45° or–60°/+60°/120°). Custom arrangements can always be procured, although the setup costs tend to be prohibitive for short runs. The construction of both woven and engineered fabrics influences not only the mechanical performance of the part but the ease with which it can be formed into a complex shape (drapeability) and impregnated with liquid resin (permeability). Both of these issues are addressed in subsequent sections.

Large (e.g., marine) structures cannot be formed effectively to produce a handlable preform. These are often dealt with using combination mats or fabrics that are prestitched to reduce labor costs and assembly times. Typical examples include woven/chopped fiber assemblies and random mat skins fastened to a polyester felt to form a lightweight sandwich construction.

Unlike prepregs, liquid molding is relatively flexible in its use of different reinforcement styles. Thus, textile techniques such as braiding or three-dimensional weaving can be used to provide other fiber architectures. Braiding is useful for closed sections (especially tubular components) and provides either biaxial (±φ) reinforcement, which provides good torsional properties, or, when axial or bending loads dominate, 0° reinforcements can be inlaid using a triaxial braid. The principal advantage of three-dimensionally woven structures is for applications demanding high through-thickness or impact properties. Similar effects can be achieved by through-stitching with Kevlar. These techniques are likely to be of future interest for aerospace applications, where a degree of shaping potential, plus the facility to vary the balance of through-thickness and in-plane reinforcements, offers useful flexibility for structural design.

Reinforcement Processing Characteristics. The relationship between compaction pressure and fiber volume fraction is important since this dictates the mold-clamping force for a given laminate thickness (Fig. 6) (Ref 7). Compaction forces may be of the same order as the resin pressure. The transverse compliance is also a function of temperature and saturation arising from the heat-softening characteristics and lubrication effects, respectively. Compliance is relatively easy to measure directly using a mechanical testing machine or, in an industrial environment, a simple arrangement can be set up using a dial gage together with a series of weights.

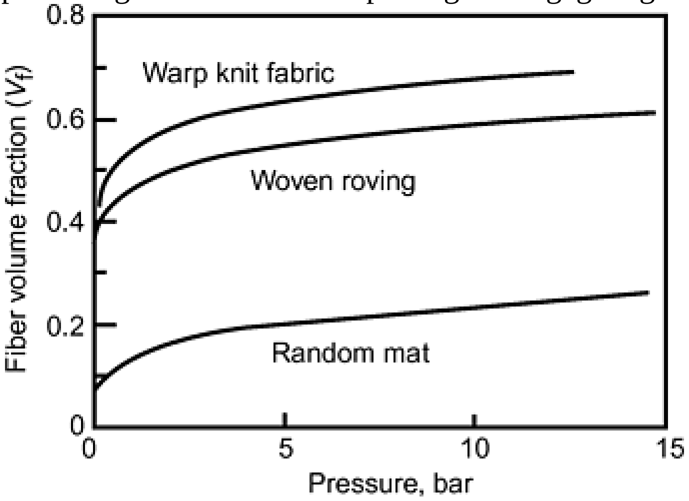

Fig. 6 Typical reinforcement compaction behavior at ambient temperature. Source: Ref 7

Permeability is defined by Darcy's law and describes the ease with which the resin will impregnate the reinforcement. In general, permeability decreases exponentially with increasing fiber volume fraction and will also be higher for random reinforcements than aligned fiber materials (Fig. 7). This effect is tied to both the operating volume fraction and the reinforcement architecture. Reinforcement permeability is related strongly to wetted surface area and, as such, reduces dramatically as the fiber volume fraction is increased. The time necessary to impregnate a given geometry from a constant-pressure resin supply is generally proportional to the porosity (proportion of voidage) divided by the permeability. Conversely, when using a positive-displacement pump the pressure required to impregnate the same geometry will be proportional to the inverse of this relationship. Thus, the reinforcement design is linked closely to the characteristics of the processing equipment and the molding cycle time. Typical relationships between in-plane permeability and reinforcement volume fraction are illustrated in Fig. 7 (Ref 8).

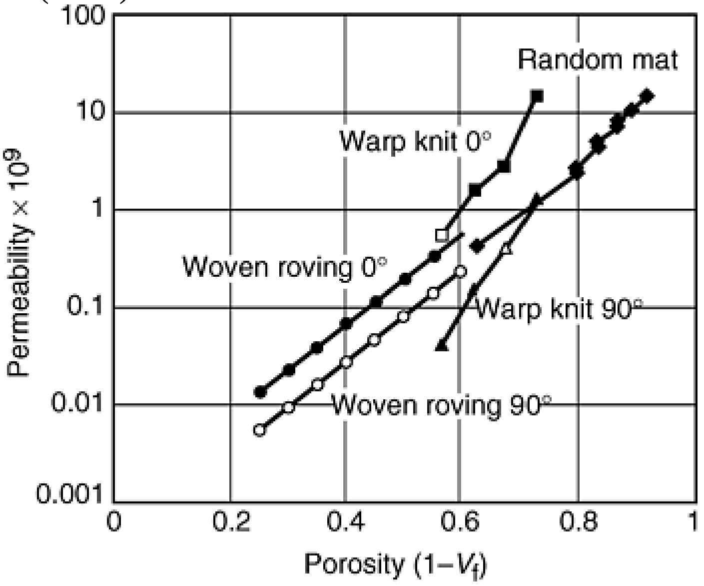

Fig. 7 Typical reinforcement in-plane permeability behavior. Source: Ref 8

Although quoted values of permeability provide a convenient basis for comparing reinforcements, it is worth remembering that this relies on a very approximate description of the impregnation process. The reinforcement structure is generally heterogeneous, which is to say that the pore space is not distributed evenly between the fibers. Large gaps may exist between adjacent yarns, while the spacing between filaments within these yarns is

likely to be orders of magnitude lower. These variations may provoke “flow-fingering” during impregnation and subsequent entrapment of microvoids within the yarns. Such phenomena depend on the architecture of the reinforcement, the resin flow rate (or imposed pressure difference), and the viscosity and surface tension of the resin. Where microvoidage problems arise they can often be reduced (but not necessarily eliminated) by vacuum assistance and by reducing the flow rate to a value that approaches that of capillary action. However, the latter method may be impractically slow. Alternative strategies for void removal include purging with an excess of resin and “burping” or introducing several packing- venting cycles where the cavity pressure is alternatively raised and then vented following mold fill. Other potential sources of microvoids include the entrainment of air in liquid resin during mixing (which can be dealt with via a degassing phase) and the presence of volatiles within the mold cavity.

Where complex curvature exists in the part, it may be desirable to consider the formability of the reinforcement. Random reinforcements can tolerate uniaxial strains of around 30% before fiber straightening limits further stretching. Fabrics deform via a different mechanism due to the presence of the straight, inextensible tows. The dominant mechanism here is in-plane shear, and most materials exhibit nonlinear stress-strain behavior up to the so-called locking angle. Comparative measurements can be made using a simple parallelogram fixture. While the forces themselves are of relatively little interest, it may be useful to know the point at which locking occurs. This is usually taken as the point at which fabric wrinkling becomes evident and occurs at around 30^o. The effective locking angle is a function of the fabric architecture (Fig. 8) (Ref 9) and, for zero crimp fabrics, is controlled by the presence of holding stitches.

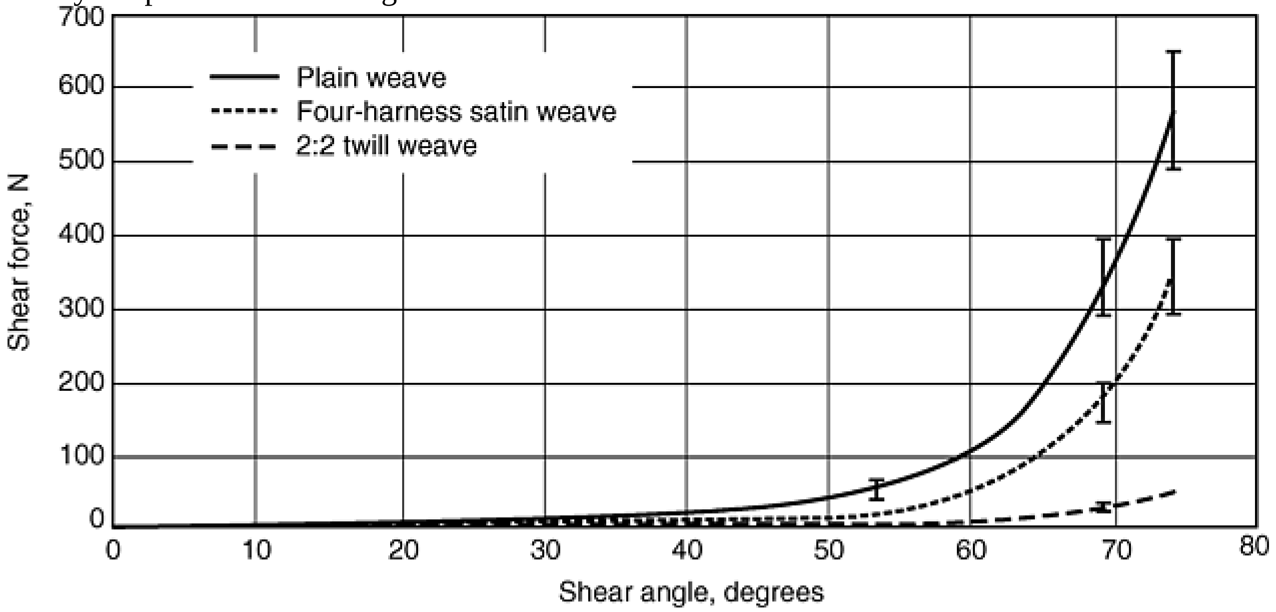

Fig. 8 Typical reinforcement in-plane shear behavior. 800 g/m^2 glass fiber fabrics. Source: Ref 9

Resin Systems. Most of the familiar resin types can be processed by liquid molding including polyesters, acrylics, phenolics, epoxies, and bismaleimides. The controlling factor here is viscosity and an upper limit of 0.8 Pa · s (similar to a heavy motor oil) provides a useful rule of thumb. Where the viscosity exceeds this value, it may be necessary to introduce either resin preheating or a low viscosity, reactive diluent. The latter are used widely for vacuum infusion due to the low-pressure gradients available in that process.

Unsaturated polyesters represent the largest tonnage and are used mainly in nonstructural parts. The low-viscosity requirement generally dictates a higher styrene content than normal laminating resins, although fillers and shrinkage control additives can be used in the usual way. Epoxies fall into three main categories: very- low-viscosity (0.3 Pa · s) formulations for vacuum infusion, which use reactive diluents to reduce fill times, medium-viscosity (0.5 Pa · s) formulations for RTM, and high-performance resins, which require substantial preheat temperatures to achieve the low viscosities necessary for injection. Epoxy formulations for SRIM have also been developed that combine low viscosity (using preheat) with a high reactivity hardener to give rapid fill and fast cure (<5 min), although significant applications have yet to emerge. Aerospace applications requiring higher-temperature performance usually use bismaleimides, and here again the high room-temperature viscosities usually require preheat temperatures in the region of 100 °C (210 °F) for injection.

Structural reaction injection molding relies almost exclusively on polyurethanes (although a number of other polymers can be processed in this way). These differ slightly from conventional RIM systems in that the gel time is extended to take account of the longer fill times that accompany the use of a preform. To provide a compromise between the rapid processing of polyurethanes and the ease of handling of polyesters, several hybrid resins have been developed for RTM. These use styrene monomer with an isocyanate component, together with conventional organic peroxide curing agents.

Although virtually all of the established processes use thermosets, there are several thermoplastics that can be processed via liquid molding. Since the major factor inhibiting impregnation with thermoplastic resins is their high viscosity, one potential solution is to impregnate using monomers and polymerize the thermoplastic in situ. The technology used here is that of RIM, for which–aside from urethanes–polyamide 6 is the best known application. Relatively few studies have been reported for fiber composites, and most of the development has focused on NYRIM, a variant patented by DSM. Related processing for polyamide 12 has been patented by EMS Chemie (Ref 10), which uses anionically polymerized laurolactam to produce either a fiber reinforced part directly or an intermediate, thermoformable prepreg. To overcome pot-life problems, a liquid-activator system was developed containing both activator and catalyst. Both the liquid activator and the molten laurolactam can be stored indefinitely. A somewhat different approach is offered by "cyclics" technology (Ref 11). The concept here is to impregnate the reinforcements with a low-viscosity thermoplastic resin (prepolymer), which subsequently reacts in the presence of heat and a catalyst to increase its molecular weight via conversion of its short molecular chains to a linear structure in a ring-opening polymerization reaction. This technology has been demonstrated in the past for polybutylene terepthalate (PBT) and polycarbonates.

Curing. Unlike SMC compression molding, curing of liquid-molded parts takes place in a generally nonuniform pattern. This is due to the variations in thermal and chemical history of the resin from the injection gate to the vent. These differences are most noticeable in nonisothermal processes (i.e., when cold resin is injected into a heated mold). In most situations, the vent region will cure first and the (cooler) gate last. Drastic measures need to be adopted to correct or reverse this tendency. One possibility is to introduce variable initiator dosing (Ref 12), while another is to use a tapered resin preheating technique (Ref 13). For near-isothermal processes (or where the resin gel time is much longer than the fill time), the mold will generally reach an equilibrium temperature before curing commences, thus the cure progression will be more or less uniform. In-plane curing gradients do not appear to provoke any particular problems. Any arising variations in degree of cure can be dealt with by postcuring the part. Through-thickness problems can be more problematic. The main problem here is with relatively thick laminates that may be subject to overheating or interlaminar cracking during polymerization. The first problem may be addressed simply by adjusting the resin formulation (reducing the initiator concentration or adding inhibitors) to produce a less vigorous reaction. The second problem occurs mainly in curved shells (Ref 14) and is a function of resin shrinkage, fiber orientation, and thickness-to-diameter ratio. This can be resolved in many cases by adding flexibilizers, reducing the proportion of hoop reinforcement or redesign.

Representative Component Properties

In a well-organized process, the properties of RTM parts are determined in the usual way by the fiber reinforcement and the matrix resin (Fig. 9, 10) (Ref 15). The major factor, as in most processes, is the fiber volume fraction window at which a given reinforcement can be processed. A lower band is imposed here by the need to prevent fiber washing. This is achieved largely by imposing a compaction pressure in the mold. The process-specific factors that may also play a role include:

- Fiber volume fraction limitations imposed by the part geometry. These can be determined empirically or estimated with the aid of draping software.
- Fiber realignment arising from the preforming stage. Again, draping software may be useful here.
- Matrix modifications due to absorbed binders, for example. The solubility of any preform binders in the matrix resin may have a significant influence on the final toughness and glass transition temperature. Depending on the relative rates of filling and solution, this may produce a property gradient in the matrix.

Resin Transfer Molding and Structural Reaction Injection Molding

C.D. Rudd, University of Nottingham

Design Guidelines

Although processes vary widely, most rely on low-pressure impregnation. This makes the technology particularly attractive for large-area parts that would require expensive and heavy press tools for use with molding compounds. Other competing low-pressure, low-cost tooling routes include vacuum bag or autoclave molding. However, liquid molding offers two major advantages from a design perspective:

- Components can be made with two accurate, molded faces. Dimensional control is superior, which facilitates any subsequent assembly operations.
- Thick sections (or sandwich panels) are easier to produce since debulking is easier with dry fabrics than prepreg.

Another advantage is the ability to produce relatively complex shapes. The dry mats or fabrics that are used can be formed or tailored fairly conveniently to complex curves and other forms. Geometric forms are generally limited by the same considerations regarding draft angles as conventional pressing operations, although it is possible to produce difficult shapes involving reentrants, for example, by special tooling techniques. These require the use of either flexible tooling based on elastomers, expendable cores such as low-melting-points alloys, water soluble plasters, or bladders. Some of these are subject to patent protection.
While the geometric form is generally unconstrained, it is usually sensible to maintain the thickness as uniform as possible. Change in thickness requires a step change in the number of layers of mat or fabric, and unless the superficial density is very low this may cause rippling in the laminate surface. The reinforcement preparation stage is also complicated, requiring multiple templates or robotic cutting. Step changes in thickness are especially undesirable due to the difficulty of ensuring that the reinforcement butts closely to the corner of the mold. Many attempts to ensure that the reinforcement is located with a high degree of accuracy are frustrated

by reinforcement shifting during either mold closure or resin injection. Some of these problems can be overcome by adopting a separate preforming operation.

Sandwich Structures. Sandwich panels are generally easier to make by liquid molding than by using prepreg techniques. The reinforcement is assembled with any inserts or cores before impregnation in a single shot, with significant reductions in secondary foaming or bonding operations. Many of the successful RTM applications to date involve sandwich laminates, including automotive spoilers and propeller blades.

The decision to produce the structure as an integral molding or to manufacture the skins separately, followed by bonding or postfoaming, depends on the cost and difficulty of producing the foam core. The conventional way involves a separate molding (usually in polyurethane or polyetherimide foam) that is made to the dimensions of the component, minus an allowance for the skin thickness. The core is then enclosed by the reinforcement and impregnated. Failure to maintain the required fiber volume fraction is likely to result in core shifting (Fig. 11).

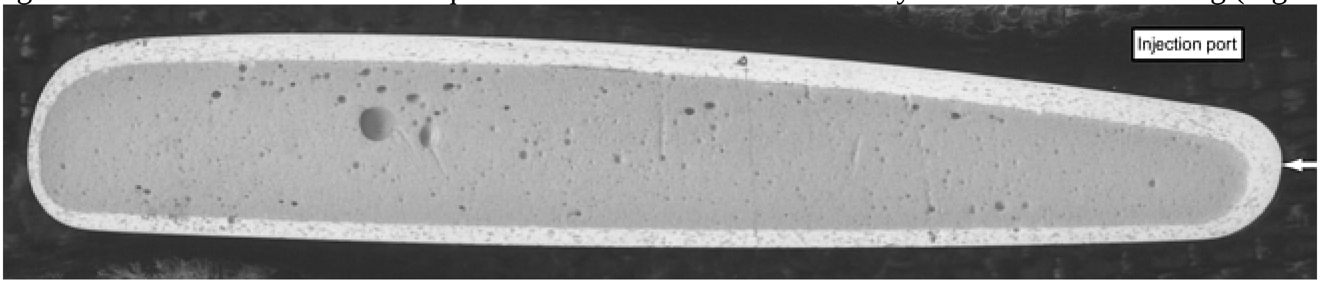

Fig. 11 Cross section through a foam-cored RTM component showing evidence of core shifting. Although specified with uniform skin thickness, the rigid polyurethane core has shifted under fluid pressure to produce approximately 2-to-1 right-to-left and upper-to-lower skin thickness ratios.

Foam cores play an important role in successful processing, and their quality should not be overlooked. Since they help to define the flow cavity, any inaccuracies may compromise molding quality. Undersize cores reduce the reinforcement volume fraction in the skins, causing resin richness and overweight parts. They also reduce the reinforcement compaction pressure. Since this is the only means of core location during resin injection, reduction in the holding force makes the core susceptible to movements under fluid pressure. Consequences include uneven skin thickness, dry patches, and overheating in the thicker areas. Similarly, core-surface imperfections also result in resin-rich areas. These cause high local shrinkage or sink marks in the laminate surface.

The final design consideration concerns the skin-core adhesion. When the core is produced as a separate molding, its glossy skin does not support bonding. There may also be a significant carryover of release agent, which inhibits the development of a useful bond. Delamination may result during postcuring, painting, or in-service loading. Skin abrasion prior to RTM is normal using abrasive paper or by bead blasting. However, either route may reveal surface voids that must be filled prior to resin injection to avoid causing the sink marks described previously.

Hollow Laminates. Hollow structures offer a significant weight and cost saving compared with sandwich panels, but require more imagination to produce by RTM (Fig. 12) (Ref 16). A common technique here is to use an elastomeric bladder (which may be filled with particulates). The bladder is filled, loaded into the mold, and evacuated to rigidize the core. The preform skins are added, and the matrix resin is injected. Following resin cure, the core can be removed after releasing the vacuum. In a further variant, a positive pressure is applied to the bladder after the end of injection and prior to resin cure in order to consolidate the laminate. One potential advantage here is that the core may be formed with indentations in the surface that provide a runner system to aid resin distribution. These channels are destroyed when positive pressure is applied to the bladder, and the excess resin is bled out through the laminate. If particulates are used to stabilize the bladder, these can be extracted after venting. The bladder itself may be sacrificial or reusable.

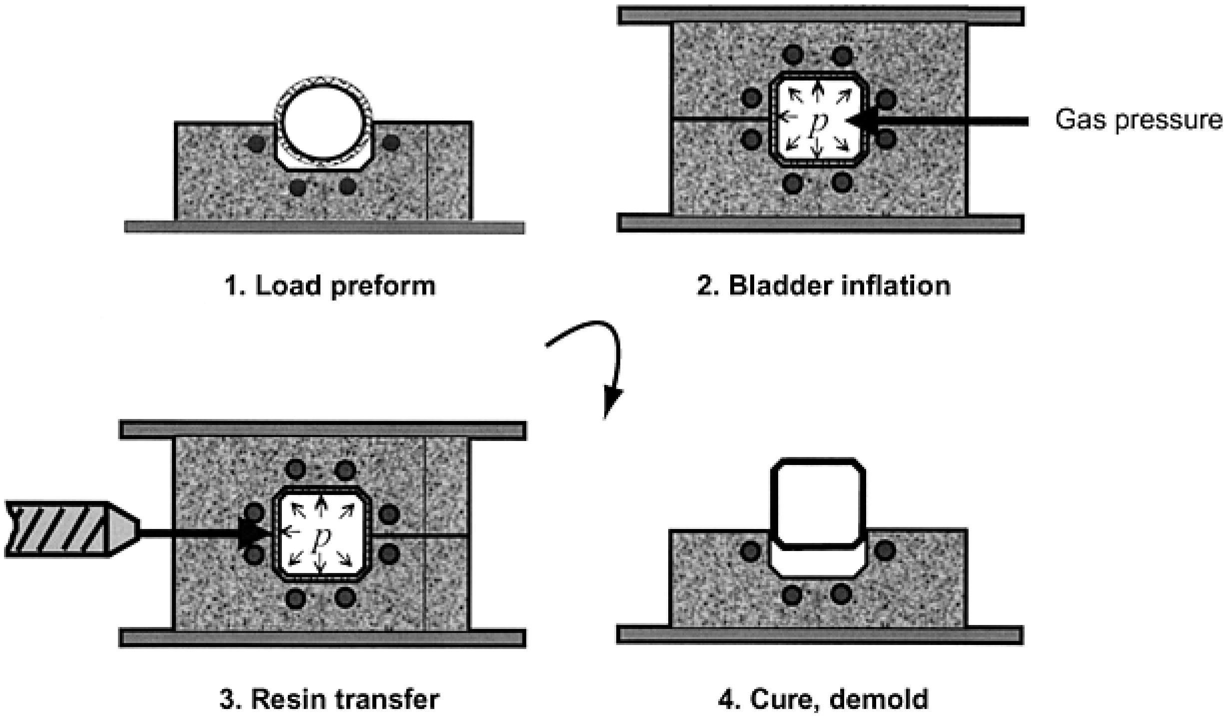

Fig. 12 Bladder inflation molding for hollow RTM structures. Source: Ref 16

Laminate/Preform Design. As with prepregs, the reinforcement dominates laminate stiffness and on-axis properties. When fabrics are used, it is simply necessary to generate design data at the relevant fiber volume fractions. Design calculations may then proceed in the usual way using laminate theory or finite element analysis. Complex shapes may dictate a need to take into account the effects of forming on the reinforcement architecture. This emerging discipline is discussed in detail elsewhere (Ref 17).

Inserts. One of the advantages of liquid molding includes the potential for incorporation of cores and inserts within a single-shot molding. In practice, the designer must decide whether inserts should be included at the preforming stage or fitted after molding. While the former may provide better mechanical integrity, it may be prohibitively expensive, in which case the molding may require subsequent drilling and bonding operations. When molded-in inserts are used, these may be located within the mold body, the preform or foam core. The situation is complicated by the need to ensure a reasonable level of fiber reinforcement around the insert when it is intended to transfer loads in and out of the structure. Bighead or other proprietary fasteners are commonly used in this respect. If inserts are to be used in this way, then the decision needs to be made at a relatively early stage to ensure they are accommodated in the design of the tooling.

Mold Design. The earliest decision that must be made concerns the mold material. This is governed almost entirely by the production volume. Serviceable prototypes for static testing can often be made using soft tooling (e.g., plaster, resin, resin/sand concrete, etc.). Here, the working life of the mold will only extend to a few parts, and the operating pressures and temperatures must be kept close to ambient. Low-volume manufacture (less than 1000 parts) relies heavily on glass reinforced plastic (GRP) tooling, which may be hand-laminated or vacuum- bagged glass fiber-epoxy. Secondary stiffening is usual via plywood or steel box-section, and this is laminated over the rear face of the tool.

Shell tooling (Fig. 13) is often used in medium-volume manufacturing (up to 40,000 parts), and this mimics GRP construction with the composite shell replaced by nickel or a nickel/copper laminate with a steel or aluminum stiffener. The nickel surface may be polished to a high degree and is considerably more durable than GRP. The shells themselves are manufactured traditionally by electroforming, although more recently chemical vapor deposition has gained in popularity.

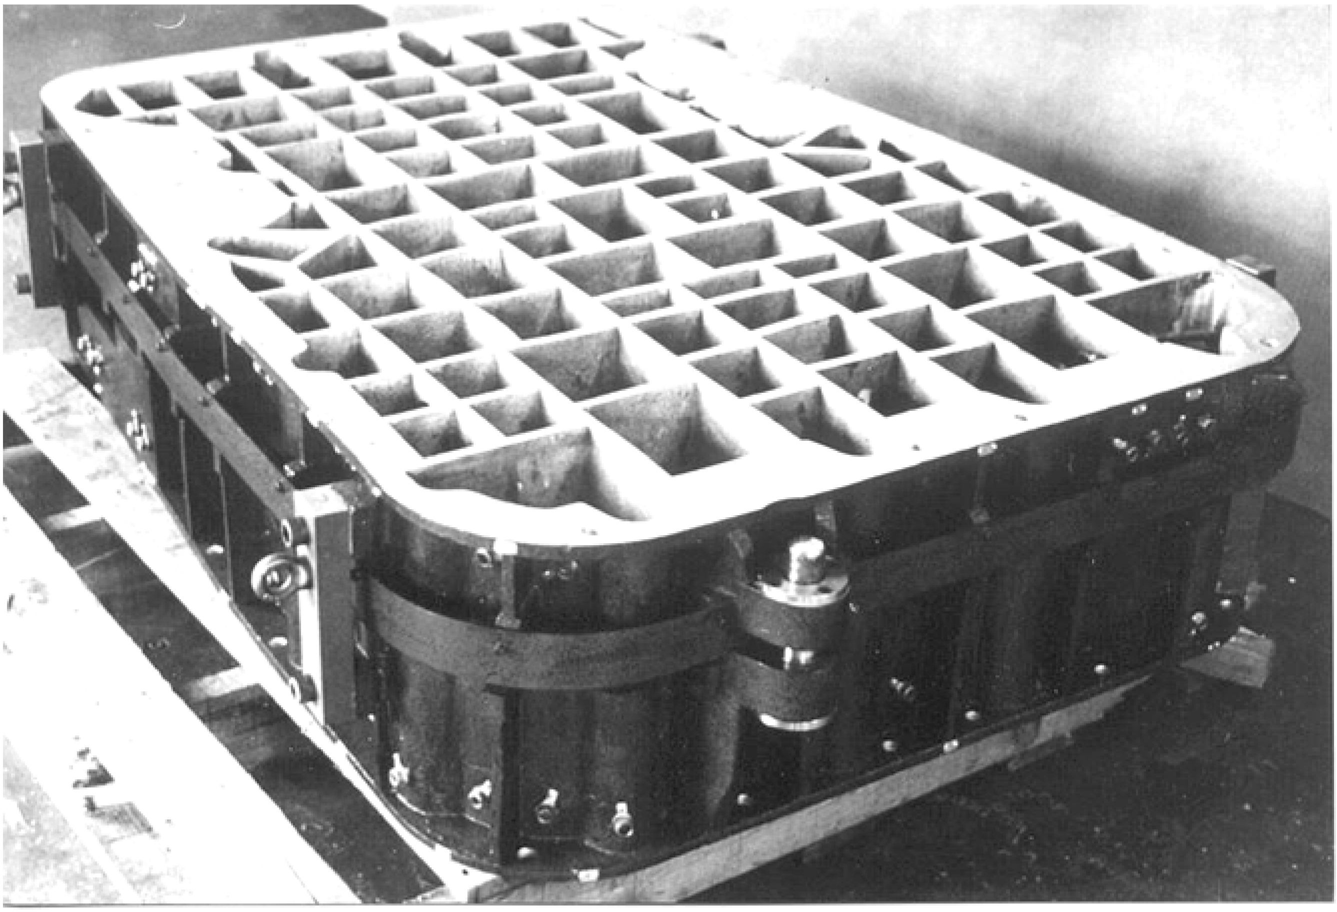

Fig. 13 Lightweight nickel shell mold with cast aluminum egg-crate stiffener. Courtesy of Ford Motor Company

Monolithic metal tools are the only realistic option for high-volume work (greater than 40,000 parts). Aluminum is commonly used at the lower end of this range, where its machinability and low density provide some economic benefits. However, the rapid wear that accompanies the use of glass fiber reinforcement and the difficulty of achieving the highest surface finishes make P20 tool steel the most popular material for high-volume automotive work.

The mold design loop needs to address the flow, thermal, and structural characteristics of the tool set. Failure to address each of these issues will result in lack of control over the part impregnation, curing, and dimensional control, respectively.

Flowpath Design. Gating and venting is an obvious area of concern with respect to part quality. The injection port(s) need to be sized and situated such that the cavity can be filled in an acceptable time and without any macroscopic air entrapment. Likewise, vents should be positioned adjacent to the last points to fill. This may be difficult to achieve when relying on intuition alone, but fortunately several commercial and semicommercial computer-based flow modeling packages (Ref 18, 19) are now available that predict flow front advancement (Fig. 14) and ease this aspect of the design process (Ref 20).

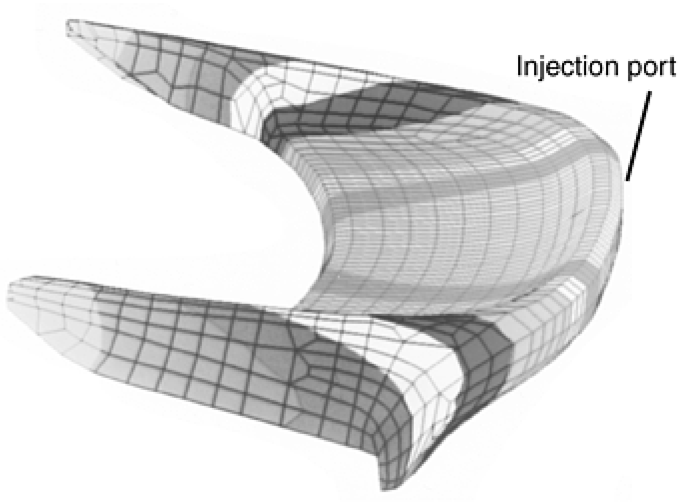

Fig. 14 Mold filling simulation showing fill time contours. Courtesy of Ford Motor Company

"Race-tracking" is a practical problem that most molders encounter at some stage. Here, the resin flows preferentially (usually at the periphery of the part) in the gap between the preform and the edge seal. This leads to short-circuiting between the gate and vent, and the resulting air entrapment is likely to scrap the part. The problem arises because of the large difference in permeabilities between the relatively dense preform and even small gaps (e.g., 1.0–2.0 mm, or 0.04–0.08 in.). It is worth recalling that a random preform has approximately the same flow resistance as a 0.2 mm (0.008 in.) channel. Clearly the solution lies in controlling both the dimensions of the preform and the cavity itself. In practical terms, this means close attention to preform fit using either steel-rule die cutting or an automated cutting table. At the same time, the mold body needs to be sufficiently rigid to restrain deflections due to either incoming fluid pressure or the reinforcement compression.

Heating. Electrical resistance heating, steam, hot water, or hot oil circulation are used commonly. Steam, water, and oil require a circulating path in the mold body. In the case of shell molds, pipes can be added to the rear face of the shell, while they can be cast-in-place for ceramic, Kirksite, or metal spray molds. Gun drilling is generally used to transport the fluid in monolithic molds. Fluid-circulating systems often incorporate a supplementary chiller. Electrical systems comprise resistance heating elements in the form of strips, cartridges, custom castings, fabrics, or embedded in rubber or mineral pads (in the case of polymer composite molds). Since poor thermal design can extend the overall cycle time, it is important that the heating system is matched to the temperature distribution that is required. For fluid systems this includes the location, depth, and size of the heating circuitry. It is also necessary to balance the flow rate through different areas of the heating circuit in order to achieve uniform heat transfer into the laminate. The siting and sizing of heating passages is usually done empirically. However, the use of relatively simple thermal analysis provides a much greater degree of confidence in heating circuit design.

Structural Design. Molds for RTM components typically have a large surface-area-to-volume ratio. Thus, the mold-bursting forces can be substantial. Even relatively low pressures (<5 bar) generate deflections that can seriously affect the component thickness and fiber fractions. The molds and their supporting structure must therefore be sufficiently stiff. Even when using precompacted reinforcements there can be significant loft remaining in the preform, and this has to be compressed in order to close the mold. The resulting compaction force maintains the preform integrity during impregnation, thus preventing fiber wash. Pressures in excess of 5 bar may be involved in order to achieve the desired fiber fraction.

Fluid pressures depend strongly on the materials and process. Structural reaction injection molding may involve cavity pressures at the injection point of up to 50 bar, while conventional RTM is generally a decade lower. Vacuum assistance will increase the driving pressure gradient for impregnation while using atmospheric pressure to resist mold separation. With high injection pressures monolithic metal molds are generally unavoidable and are usually press- mounted. Lightweight tooling options for high- quality components require careful design to ensure that mold deflections are within acceptable limits, and although hand calculations suffice for simple geometries, finite-element analysis is normally necessary for large and complex parts. Adequate joint support is also necessary to maintain seal integrity. This prevents resin overspill and loss in

control over cavity pressure. Consideration should be given to the likely pressures during both impregnation and laminate curing, since the latter are often higher (Fig. 15).

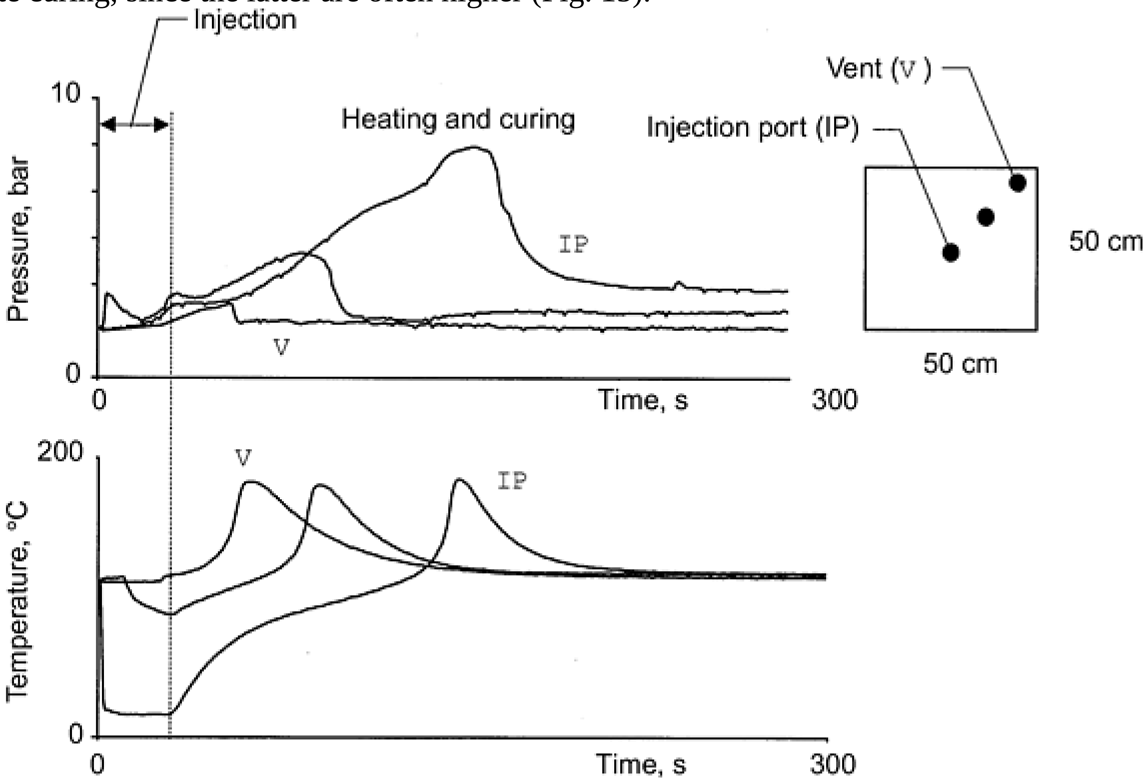

Fig. 15 Pressure and temperature cycles during nonisothermal RTM

With the exception of the vacuum infusion process, it is common to gate the mold in the center and vent in the corners or to gate and vent on opposite edges. The edge condition determines the control of the resin flow. Solutions range from pinching the reinforcement between the mold halves to create a restriction to a fully machined and telescoping flash-gap. Although the "pinch-off" is used widely, this is a low-volume manufacturing option and implies postmolding trimming stations. Investment in net edge tooling based on a carefully controlled flash gap or perimeter seal is preferable for most operations. However, this requires accurate reinforcement placement, which is unlikely to be achieved without investment in preforming equipment.

Outlook

Resin transfer molding was the subject of intense research and development during the 1990s (Ref 21). Early efforts were stimulated by the automotive industry via a series of high-profile demonstrator studies. This has translated into significant new business for the supply base, although most RTM-intensive applications to date are confined to low production volumes. The 2000 European market for finished RTM parts was estimated at 30,000 tonnes (Ref 22). This is attributable in part to the supply infrastructure, since many of the existing molders are small, independent operators with limited capital budgets. Manufacture of cosmetic auto-body panels by RTM also runs into competition with alternative techniques as volumes increase beyond approximately 25,000 units/yr, where the lower materials costs associated with SMC and RRIM may become more attractive. Exceptions occur when the excellent potential of RTM for component integration can be exploited, exemplified by the high-volume manufacture of European automotive spoilers in the mid-1990s. The identification of markets where liquid molding offers a unique economic solution provides the most promising way forward. One such area undoubtedly includes vehicle structure. As pressures for emissions and mass reduction open up the market for lean-weight technologies, liquid molding offers the only feasible *low-cost* solution for building integrated body structures in composite.

The aerospace sector represents another important growth area for liquid molding. Much of the early interest was stimulated by the potential for cost reduction versus prepregs. As the technology developed it has become evident that opportunities extend beyond simple substitutions and that by using different textiles techniques new damage-tolerant structures can be developed that were previously restricted to metals. In this sense, RTM is likely to be used alongside existing prepreg processes. Resin-film infusion or vacuum-impregnation techniques will likely be used where prepreg is displaced for large structures and relatively simple shapes such as aerodynamic surfaces.

Vacuum Infusion

Arlen Hoebergen, Centre of Lightweight Structures TUD-TNO, The Netherlands; J. Anders Holmberg, SICOMP AB, Sweden

---

Introduction

VACUUM INFUSION is a resin injection technique and is derived from resin transfer molding (RTM). A resin injection technique generally consists of the following production steps:

- Dry reinforcement is placed in a mold.
- The mold is closed.
- Resin flows through the mold and impregnates the reinforcement.
- The resin cures.
- The mold is opened and the product is demolded.

A general way of distinguishing between different resin injection techniques is how the pressure gradient is applied to force the resin to flow through the mold. In the case of vacuum infusion the pressure gradient is created by vacuum on the outlet port. The resin injection tank and inlet port are at ambient pressure, as opposed to resin injection techniques (such as RTM) where the resin injection tank is pressurized.
The use of vacuum as the driver behind resin flow has a large impact on the application of the technique and the actual process in the workshop. The major advantage of using vacuum is the absence of large forces on the mold. Standard RTM techniques require strong and stiff tooling. The larger the product, the more difficult and expensive this becomes. This is why the first success for vacuum infusion has been in large products that are made in small quantities. The major disadvantage of using vacuum is the sensitivity to leakage. A leak will result in air flowing into the mold. This often results in void-rich areas in the cured part. In RTM (with a pressurized resin tank and an outlet at ambient pressure), a leak in the mold would just result in resin spillage.

Besides, air will flow into the mold much easier than resin will flow out of the mold (i.e., the viscosity of air is much smaller than the viscosity of the resin).

Although vacuum infusion is considered a recent development, the first production trials date back to the 1940s with a method called the Marco Process (Ref 1, 2). In the following years, a number of trials were carried out using vacuum as the driving force for resin injection. Developments increased in the 1970s and 1980s due mainly to the threat of environmental legislation. The main impetus for the development has always been the elimination of styrene emission. The technology was developed as an alternative to open-mold manufacturing processes like hand lay-up and spray-up. Vacuum infusion was considered as a low-cost alternative. Besides, with minor modifications the molds used for hand lay-up and spray-up could also be used for vacuum infusion. With new legislation coming into force, more and more companies switched to vacuum infusion in the 1990s. The legislation generally focused on the two elements of styrene emission. In many Western countries, the maximum allowable concentration of styrene at the workspot (mac value) has been reduced from about 100 to 20 or 25 ppm (Ref 3, 4). In addition, environmental emissions have been limited (exhaust) (Ref 5). For many companies with mainly open-mold manufacturing, this meant investing in ventilation equipment to keep the styrene level low and filters to remove styrene from the exhaust.

While the reduction of styrene emission is evident, the technology has a number of additional benefits. The quality consistency is an important benefit since it has allowed the technology to be used in the advanced composites industry as well. Currently, the aviation and even the aerospace industry are strongly interested in the application of this technology.

Although vacuum infusion has been in use since the 1960s, it is still a “new” technology and is not fully matured. The developments in this manufacturing technology have been enormous in the past 20 years, resulting in a large number of different injection processes described in the literature. The information about these developments often has focused to a great extent on their differences, and frequently new techniques were designated by new exotic abbreviations, such as vacuum-assisted resin injection (VARI) (Ref 6), bladder infusion process (BLIP), Seeman composite resin infusion molding process (SCRIMP) (Ref 7, 8), and others (Ref 9). However, the commonalties between these techniques must be acknowledged. Only then will it be possible to learn and understand the technology in full, and therefore to exploit modifications fully.

In this article, vacuum infusion as a process is detailed with respect to other manufacturing techniques for composite materials, including RTM. This includes mechanical properties, production volume and process economics, followed by a section showing different technological applications. Next, a comprehensive description of the technology is provided, starting with a theoretical section on the resin flow and how this can be enhanced, and continuing into a more practical description with concentration on how a part can be made. The practical focus is continued in a section that deals with equipment and materials requirements. Representative component properties and some brief design guidelines are presented. Finally, a brief outlook is made on new developments, markets, and applications of the technology.

Vacuum Infusion

Arlen Hoebergen, Centre of Lightweight Structures TUD-TNO, The Netherlands; J. Anders Holmberg, SICOMP AB, Sweden

Technique Characteristics

Vacuum Infusion Compared to Other Methods. From a technical point of view, vacuum infusion is a derivative of resin transfer molding. From a production and manufacturing point of view, RTM is considered as a competitor or an alternative to prepreg processing and compression molding using sheet molding compounds (SMCs); for example RTM can be considered viable when the production volume will not justify SMC press molding. Vacuum infusion, on the other hand, has been developed as an alternative to open-mold hand lay-up and spray-up techniques. However, developments in the technology have shown that vacuum infusion can also be an alternative to prepreg compression molding and prepreg vacuum bagging.
When choosing the most cost-efficient manufacturing technology for a certain part several criteria play a role. Important criteria are:

- The number of parts (production volume)
- The size and geometry of a part
- The required performance (i.e., stiffness and strength per unit weight)
- The required surface finish

In an ideal situation, the design, material, and manufacturing technique are selected and optimized to obtain the most advantageous performance-to-cost ratio for the part. In Fig. 1 several press molding, injection molding, and open- mold manufacturing techniques are shown schematically with respect to the possibilities of production volume and part performance. This figure shows that while vacuum infusion initially was developed to replace hand lay-up and spray- up in the area of small production volume of large parts with low performance, it is now clear that vacuum infusion actually is applicable in much wider areas:

- Up to an intermediate number of parts (i.e., 1000 a year)
- Small and large parts
- Low and high performance parts

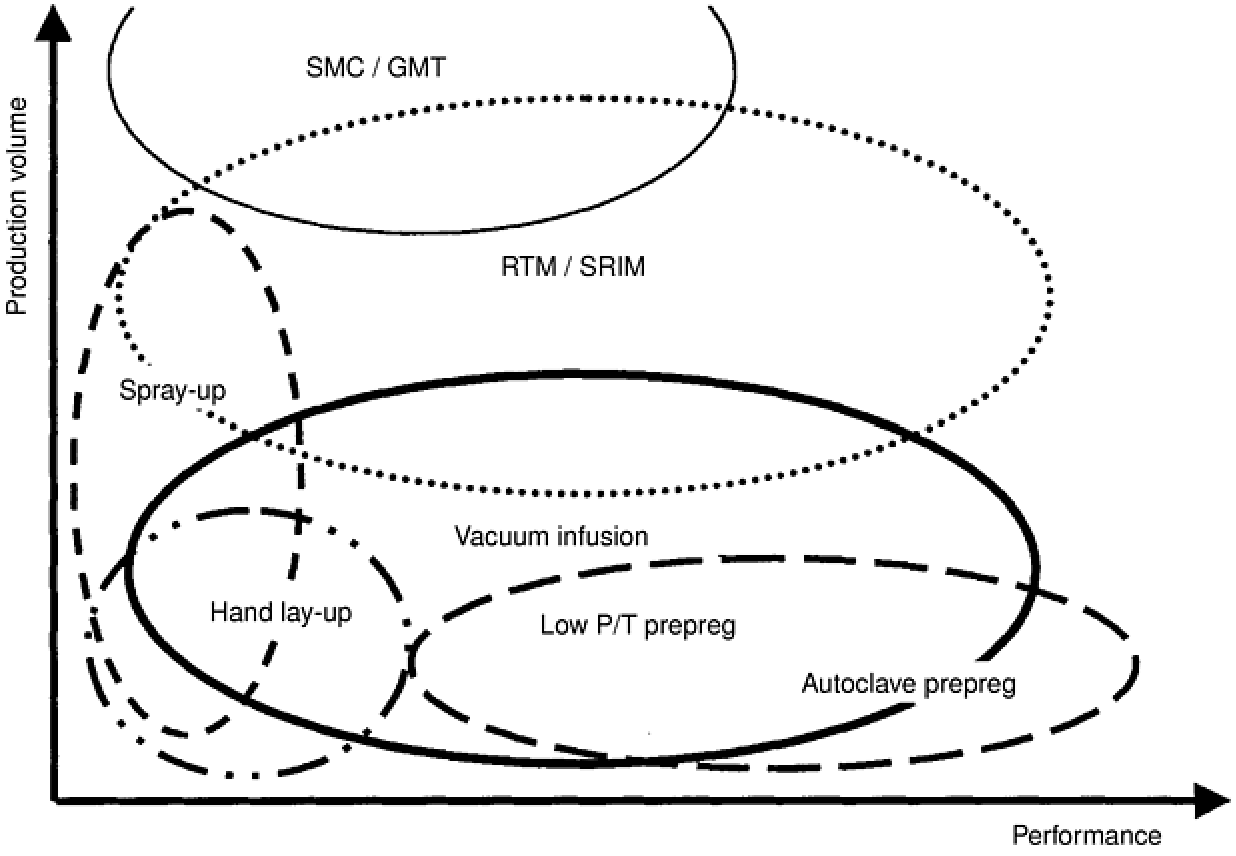

Fig. 1 Production volume and relative part performance that can be achieved with various production techniques. SMC, sheet molding compounds; GMT, glass mat thermoplastics; RTM, resin transfer molding; SRIM, structural reaction injection molding; P/T, pressure/temperature

Vacuum Infusion Versus RTM. Vacuum infusion is a derivative of RTM. From Fig. 1 it is clear that the areas of applicability of RTM and vacuum infusion overlap. In a way, the technologies also overlap as well. There is no clear boundary between RTM and vacuum infusion. The tooling and the method to apply the pressure gradient determine the technique, to a large extent. The tooling selection is obviously strongly related to the production volume and the product size (see Fig. 2), and the pressure gradient selection is subsequently related to the tooling. There is no confusion in the extreme conditions: RTM in a stiff mold with 500 kPa (5 bar) pressure on the resin inlet, vacuum infusion with a thin foil as one mold half, and only vacuum on the resin outlet. But what about a vacuum infusion process with one stiff mold half and a semirigid glass-fiber/polyester second mold half? To speed up the process, one can apply pressure on the inlet (e.g., +100 kPa, or +1 bar) during the initial stage of the injection. What kind of process is this? It is clear that it is not important how we name the technology, as long as the operator knows the process and the engineer understands the physics behind the process.

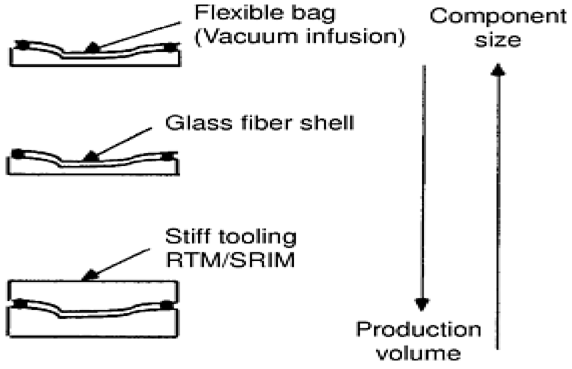

Fig. 2 Tooling selection related to production volume and component size

In a way resin injection techniques can suffer from the same problems plastics in general did in the 1950s. Because of bad design and bad applications, plastics were considered inferior by many. There are no bad resin injection techniques, only bad applications of them. The versatility of the technique must be understood; subsequently the part, the material, *and* the technique must be designed to get the optimal solution.

Possibilities and Limitations of Vacuum Infusion. The manufacturing method poses limitations on what can or cannot be achieved. Although it is said that virtually everything is possible with vacuum infusion, there are a few constraints.

Geometry. In principle, there are no geometrical limitations for vacuum infusion: three-dimensional curved, shelllike structures and closed hollow parts are all possible. The practicality and the accessibility to place the dry reinforcement in the mold system are the most important criteria to decide on the economical viability of the part. Details in the geometry can cause problems, such as:

- Sharp edges in the part can disturb the flow pattern of the resin (see the section “Technique Description” in this article).
- Thickness variations in the part can also cause disturbances in the flow pattern. However, the main problem lies with the resin system. A good cure of the thin part often results in a very large exothermal temperature rise in the thick part. The thickness of the laminate itself is not a problem, provided the resin has been selected carefully. Laminates of a few tenths of a millimeter as well as up to 100 mm (4 in.) have been manufactured with vacuum infusion.

Component Size. The manufacture of very large parts using vacuum infusion has been a matter of courage rather than technology development, due to the cost of scrap parts. When a part with a surface area of 100 m^2 (1075 ft^2) can be made, why not a part of 200 or 500 m^2 (2150 or 5380 ft^2)? Again, limitations are related to a practical problem: accessibility of the part (before and during the injection). In addition, the larger the part, the bigger the risk that something can go wrong. In general, to justify the greater risk, the manufacture in one-production shot must have clear advantages above the manufacture in two or more sections.

Parts Integration (Core Materials and Metal Inserts). Similar to other injection techniques, as well as to hand lay-up and prepregging, vacuum infusion can accommodate the application of various kinds of cores and inserts. However, honeycomb cores are usually not applied in vacuum infusion, although the honeycomb can be covered with some type of sealing foil to prevent resin from penetrating into the honeycomb. Cores must be made of closed-cell materials, but still can result in void-rich areas due to cell collapse. A small test on new material is always recommended.

Fiber Content. Two aspects determine the fiber content of the part: the fiber reinforcement used and the pressure applied. This is why parts with a broad range of fiber contents (15–65 vol%) can be made.

Surface Finish. The mold system used and the resin/reinforcement combination determine the surface finish of the part. In general, a good quality surface on one side of the part is very feasible.

Net Shape Molding and Tolerances. Net shape manufacture is rare with vacuum infusion. Usually, edges need to be trimmed. In addition, the foil side of the part can have sharp ridges of resin due to folds in the foil. In some cases these ridges need to be removed by sanding. Obviously, small tolerances can be best achieved with stiff tooling and, if required, special tooling is made to ensure small tolerances at specific spots in the part.

Economy. Table 1 gives a general overview of the different cost categories in the manufacturing process; of course, details will depend on specific product characteristics.

Table 1 Comparison of different cost categories for different manufacturing processes

	Vacuum infusion	**RTM**	**Hand lay-up**	**Spray-up**	**Low P/T prepreg[(a)]**	Autoclave prepreg
Workshop requirements	$$	$$	$$$$	$$$$	$$$	**$$$**
Equipment	$$	$$$	$	$$	$$$	**$$$$$**
Tooling	$$	$$$$	$$	$$	$$	**$$$**
Ancillary materials	$$$	$$	$	$	$$$	**$$$**
Raw materials	$$	$$	$$	$	$$$	**$$$$**
Labor	**$$**	**$**	**$$**	**$**	**$$$**	**$$$**

(a) P/T, pressure/temperature

Workshop Requirements. For hand lay-up and spray-up, ventilation equipment is required. For prepregging, workshop conditioning (temperature and humidity) is usually required. When using vacuum infusion or RTM, workshop conditioning is not required, although some kind of temperature control is advised.

Equipment. For vacuum infusion, a small vacuum pump and an overflow vessel are sufficient. RTM requires injection equipment. Spray- up involves a spray gun, and hand lay-up can be done with a simple roller and brush. Low pressure/temperature (P/T) prepreg will require a vacuum pump as well, and it is usually combined with a simple oven. Autoclave prepreg obviously requires an autoclave.

Tooling. Tooling for vacuum infusion, hand lay-up, spray-up, and low P/T prepreg can be simple and relatively cheap. For autoclave prepreg, tooling usually gets a bit more expensive, and for RTM, tooling will be most expensive.

Ancillary Materials. Hand lay-up and spray- up do not really require ancillary materials, but vacuum infusion does involve a foil, sealant tape, tubes, and hoses. The same applies to the prepregging technologies where foils, peel ply, and bleeder materials are used.

Raw Materials. Vacuum infusion requires more-expensive reinforcement materials than spray-up, but is much cheaper than prepregging materials.

Labor depends very much on the part characteristics. Compared to hand lay-up, vacuum infusion can gain time in the placement of the dry reinforcement in the mold, but will lose time during the sealing of the foil on the mold and during the injection.

Advantages. Vacuum infusion has been developed as a low-cost technique that is able to compete in cost with spray-up and hand lay-up while having a number of advantages. The main advantage and impetus behind the development of the technology is the elimination of styrene emission, combined with the ability to work with a simple mold system (only one stiff mold, as with spray-up or hand lay-up). This results in an improved internal and external environment over open-molding techniques (Ref 10). Other advantages are:

- Improved laminate quality (better impregnation and higher fiber content)
- Improved consistency of the product properties (properties are less dependent on the craftsmanship of the employee). This can enable use of lower design safety factors, resulting in a more efficient design (Ref 11).
- Less material use (compared to hand lay-up and spray-up, less resin is used and there is less waste on the product edges, i.e., overspray).

Disadvantages. When a company decides to apply vacuum infusion, it must be recognized that the technique also poses requirements on the part design, processing conditions, and the training of employees. Good training of the employees is essential to prevent production failures. A main disadvantage of the technology is the absence of control tools that can be used to assist the workshop employees. For example, mistakes in laying down the dry reinforcement cannot be identified before the injection starts. Other disadvantages of the technology are:

- Sensitivity to leakage, which makes the process critical for mistakes
- A good surface finish can be difficult to achieve, especially when thin and thick laminates are combined. When the whole part is cured at once, a high exothermal temperature peak and large cure shrinkage may result, which increase the risk for print through.
- Waste. Many ancillary materials often are used only once (foil, sealant tape, tubes, hoses, valves) and discarded after demolding.

Applications

Early developments of vacuum infusion were mainly performed in the marine industry to reduce styrene emission from open-mold manufacturing. This is manifested by the fact that most successful applications demonstrated today are fiberglass-reinforced polyester boats and yachts. However, vacuum infusion is feasible for many more applications than just replacing hand lay-up and spray-up for marine applications. This has been demonstrated recently by new products manufactured with vacuum infusion. The new products range from fiberglass solar cell housings to carbon fiber stealth ships. Examples from different sectors are given in Table 2 (Ref 12, 13, 14, and 15).

Table 2 Examples of applications and parts made with vacuum infusion

Sector	Applications
Marine	**Hulls, decks, and hatches of yachts, hulls and decks of recreational boats**
Transportation	**Roof and floor of refrigerated container, automotive exterior body panels, train fronts**
Aerospace	**Rudder of small aircraft**
Industrial	**Fan blades, part for fish counting unit, toilet bowl, oil separator**
Energy	**Solar cell housings, wind turbine blades, electrical insulation materials**
Infrastructure	**Lighting columns, bridge deck**
Military	**Hull of composite armored vehicle, hull of stealth corvette**

In the following paragraphs, typical applications of vacuum infusion are presented with the purpose of showing the versatility of the process.

Sailing Yachts. The most well-known application for vacuum infusion is the manufacturing of hulls for sailing yachts. Both single shell and sandwich hulls have been manufactured. A representative example is the manufacturing of a 17 m (55 ft) sailing yacht at Conyplex, the Netherlands (Ref 12) (see Fig. 3). The hull consists of a gelcoat, unsaturated polyester resin, multiaxial glass fiber reinforcements, and a balsa core. To facilitate placement of the core in the female mold, contoured sheets of balsa are used. Slits in the balsa open up when the contoured sheets are bent. These slits play a role in shortening the fill time. Infusion of the resin is carried out in one step and with one resin injection tank, using a polyamide bag and a “fishbone” arrangement of resin distribution channels. In Fig. 4 the white glass reinforcement, not yet wetted with resin, can be clearly distinguished from the dark areas, already impregnated with resin, around the resin distribution channels. This type of infusion requires only one resin injection tank, which is easy to monitor. The outlet ports are located all around the flange of the hull.

Fig. 3 Contest 55 sailing yacht with hull manufactured by vacuum infusion. Courtesy of Conyplex Shipyard, Medemblik, the Netherlands

Fig. 4 Flow front progress during the infusion of a Contest 55 hull. Courtesy of Conyplex Shipyard, Medemblik, the Netherlands

At Conyplex, this resulted in a reduction of both labor cost and cycle time, besides the benefits generally linked to vacuum infusion, such as reduction of styrene emission and better quality. Other common applications of vacuum infusion for sailing yachts include decks and hatches. Popular resins other than polyesters are vinylester and epoxy.

Recreational boats are made in larger numbers than sailing yachts and are still mainly produced by spray-up or wet lay-up. However, stricter legislation on solvent emissions forces the producers to move toward closed-molding techniques. An example where the producer has shifted from spray-up to vacuum infusion for the manufacture of hulls for large recreational boats is Ryds in Sweden. To keep the process rational as they moved from spray-up to vacuum infusion, they used a thin glass fiber shell instead of a bag as the male mold. The female mold is similar to a spray-up mold that has a modified flange construction. The lay-up consists of a heavy combination fabric (a random mat material with a special internal feeder) supplemented by glass fiber weaves for additional strength and stiffness. The combination fabric has high permeability and is easy to manually place into the mold on top of a slightly tacky gelcoat layer. Rapid infusion and cure is facilitated by circumferential infusion of a low-viscosity polyester resin. The injection channel is visible on the untrimmed edge of the boat shown in Fig. 5. The cost estimates made after production of 150 boats showed that both material and labor costs are higher with vacuum infusion than spray-up (Ref 10). The reasons for this are cost and handling of the reinforcements. Noticeable savings when using vacuum infusion instead of spray-up can be found in areas of energy consumption for ventilation, maintenance, and spare parts for spray- equipment, maintenance and cleaning of work areas, clothing and personal protection equipment, and finally, a reduction of total waste and landfill costs. Other gains are an improved and more consistent laminate quality and a weight reduction.

Fig. 5 Vacuum infused 5.1 m (17 ft) boat hull

Military Ships. A good example of cost-effective manufacture of high-performance composites with vacuum infusion is the hull panels for the Visby class corvette. The panels consist of carbon fiber/vinylester skins and polyvinyl chloride-based core. With ordinary wet lay-up, one side of the sandwich has to be laminated and cured first before the other side can be laminated. The rolling operation also requires a significant amount of labor for large surfaces. With vacuum infusion, on the other hand, the whole sandwich is impregnated with resin in one step and with reduced labor (see Fig. 6). In addition, the vacuum-infusion process for the hull panels results in a high fiber content and a consistent laminate quality. In a secondary operation, the hull panels are joined together to form larger parts (see Fig. 7). The principle of the manufacturing procedure is illustrated in Fig. 6. The bottom reinforcement, core material, and top reinforcement are placed on a large flat table. Resin inlets and a distribution channel are placed along one long side of the table (on the left in Fig. 6). For this application, slots machined in the core enhance the resin flow.

Fig. 7 Stern section of the Visby class corvette. Courtesy of Kockums Shipyard, Karlskrona, Sweden

On the Visby corvette, the stern, hatches, and other parts are also made by vacuum infusion.

Armored Vehicles. Vacuum infusion has also attracted the attention of manufacturers of composite armored vehicles. Vosper Thornycroft, United Kingdom, has used vacuum infusion to manufacture a two-piece hull for a prototype Advanced Composite Armoured Vehicle Platform (Ref 15). The choice of vacuum infusion to inject epoxy resin into multiaxial E-glass was based on relative cost estimates and comparisons with wet lay-up, prepreg processing, and RTM for production numbers greater than 100. Benefits of vacuum infusion for this application include more consistent and higher quality than with wet lay-up, lower manufacturing costs than prepreg processing, and the option to use thicker fabrics than possible with wet lay-up.

Transportation. For a long time, small to medium quantities of body panels have been produced with different vacuum infusion techniques for cars, trucks, and buses. Low costs for tooling and part-specific equipment make these processes more economical than steel stamping for small series production. Usually the lay-up of body panels consists of a gelcoat layer followed by one or several layers of highly permeable reinforcement and cores. Gelcoat, dry reinforcement, and cores are applied manually into a female fiberglass mold. The second mold half is, in general, a flexible fiberglass shell. A small injection machine is commonly used to automate mixing of the resin components. The injection machine also shortens the cycle time due to pressurization of the inlet.

Body panels are also produced with hand lay- up and spray-up, but vacuum infusion has several advantages over these processes. The most important are cleaner production, more consistent quality, better laminate properties, and shorter cycle time for most applications.

Technique Description: Theory and Background

Flow of Resin. To use vacuum infusion technology, it is good to understand the basic physics behind the flow of a liquid through a porous medium. For a Newtonian liquid, the one-dimensional flow through a porous medium can be described by Darcy's law (Ref 16):

$$\frac{Q}{A} = \frac{K}{\mu}\frac{\Delta P}{\Delta x}$$

where
Q = volumetric flow rate (m^3/s)
A = cross section area (m^2)
K = permeability (m^2)
μ = viscosity of the liquid (Pa · s)
$\Delta P/\Delta x$ = pressure gradient (Pa/m) What is the use of this law?
Before making a part using any resin injection technique, it is desirable to predict or assess the resin flow pattern. This is used in placement of the resin inlet and outlet ports. Other considerations are whether the part will be filled completely and how fast it will be filled. All of this is preferably known before the start of manufacture.
The fill time is important for both small and large parts. For small parts, the cycle time is critical to an economically viable production. Resin gel time can be critical in larger parts. Besides, the longer the injection lasts, the more things can go wrong. From Darcy's law we can easily conclude the following (assuming that other parameters remain constant):

- The bigger the pressure difference, the quicker the part is filled.
- The lower the resin viscosity, the quicker the part is filled.
- The higher the permeability, the quicker the part is filled.

What is obvious from Darcy's law is the influence of part geometry and injection strategy (location of inlet and outlet ports) through A and Δx on fill time. However, for specific geometries and injection strategies we must work out Darcy's law together with the equation of mass conservation to see this influence. Now, this all might seem very obvious, but, considering Darcy's law, where should the focus be in part manufacture?
In vacuum infusion, the maximum pressure difference is atmospheric pressure, about 100 kPa (1000 mbar). The absolute pressure of the vacuum in the mold during production can vary from about 2 to 40 kPa (20 to 400 mbar). The resulting pressure difference between inlet and outlet is then between 60 and 98 kPa (600 and 980 mbar). Consequently, the resulting influence on fill time cannot be more than a factor of two.
When a part is being made, most companies use a resin system that is developed for injection purposes. The resin viscosity usually varies from about 100 to 400 mPa · s (although resin systems with lower and higher viscosity are also used). Most of the time the resin has a viscosity of about 200 to 300 mPa · s. Consequently, the resulting influence on fill time is between a factor of two and four.
Although pressure difference and resin viscosity both influence the production, this influence is only minor when compared with the influence of the reinforcement permeability and injection strategies.
Permeability is a geometrical property of the reinforcement and describes how easily the resin can flow through the material. It is often considered as a constant in Darcy's law. The permeability can be experimentally determined. However, since Darcy's law has been used for many industrial applications, much work has been done in predicting the permeability of a porous medium. The Carman-Kozeny model is most frequently used. This model relates the permeability to the porosity. In the case of fiber reinforcement, the permeability can be related to the fiber volume fraction (see also Fig. 8) with the following formula:

$$K = \frac{1}{C \cdot S^2} \cdot \frac{(1 - V_f)^3}{V_f^2}$$

where
K = permeability (m^2) C = Kozeny constant S = specific surface area (m^2/m^3) V_f = fiber volume fraction
The Carman-Kozeny relation is an approximation, usually only valid for a limited range of fiber volume fractions. Therefore, this relationship can only be used accurately as an interpolation formula. The Kozeny constant still needs to be determined experimentally.

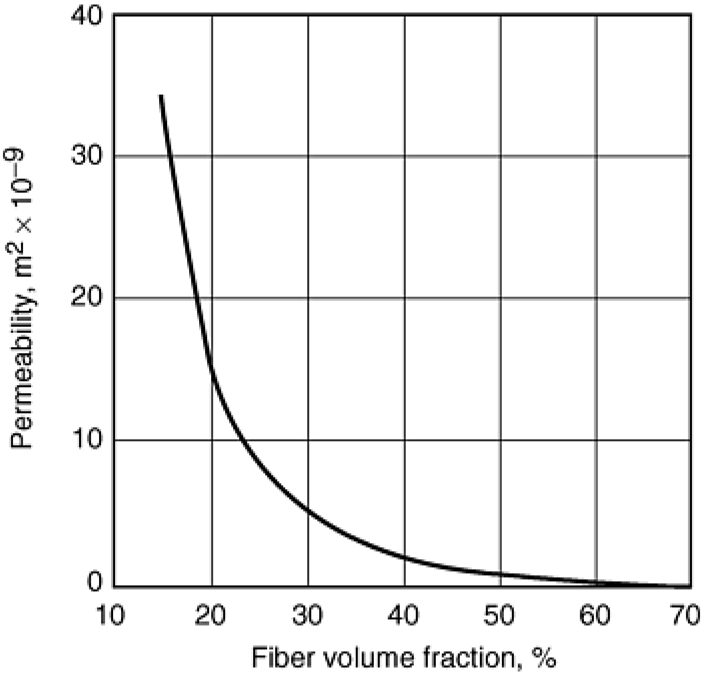

Fig. 8 Permeability as predicted by the Carman-Kozeny model

A major difference between matched-tooling RTM and vacuum infusion with a foil is the compression of the reinforcement. In RTM the reinforcement compression is dictated by the mold cavity, while in vacuum infusion the compression is related to the pressure (vacuum) in the mold cavity. The dry reinforcement in the mold is a resilient, compliant layer, which will be compressed upon evacuation of the mold. In general, random mat materials are more resilient, that is, compressed more at a given pressure than woven rovings or multiaxials. A typical compression graph of a random mat is shown in Fig. 9. Note that the compaction pressure available during processing is the ambient pressure (approximately 100 kPa, or 1000 mbar) minus the pressure within the vacuum bag. Although at a compaction pressure above 40 kPa (400 mbar) (absolute pressure within the vacuum bag below 60 kPa, or 600 mbar), the amount of compression seems not very significant, the influence on the fiber volume fraction and, consequently, the permeability is still of significance.

Reinforcement type and binder content influence the amount of compression. This is shown in Fig. 10. The type of random mat in this graph has a high binder content. This reinforcement is, consequently, relatively stiff and difficult to compress. The combination fabric (a random mat material with a special internal feeder) is easier to compress, and the woven roving can only be compressed initially. It must be realized, however, that wet and dry compression can differ significantly, for example, if the resin dissolves the binder. Theoretically, the compression of the reinforcement also causes the reinforcement to spring up a bit during the injection (as the flow front passes and the local pressure increases) (Ref 17, 18). This results in a decrease in fiber volume fraction and, consequently, an increase in permeability. Hence, in vacuum infusion, permeability is not a constant!

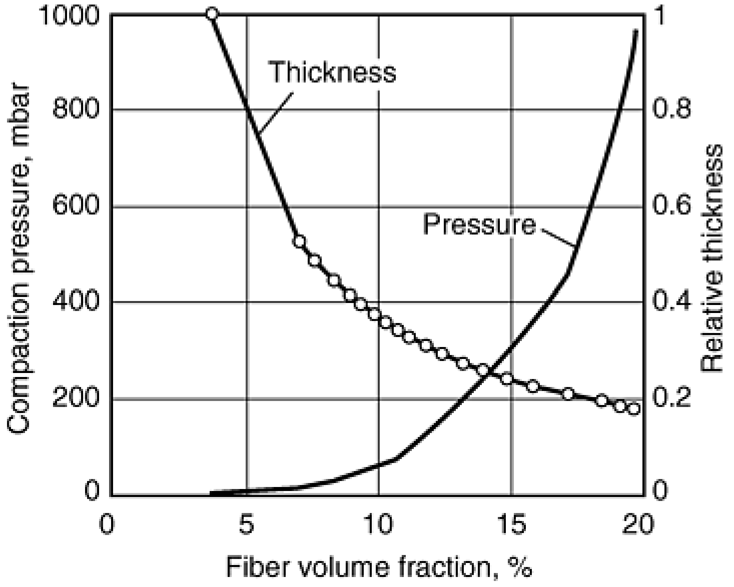

Fig. 9 Influence of compaction pressure on thickness and fiber volume fraction for a random mat reinforced composite

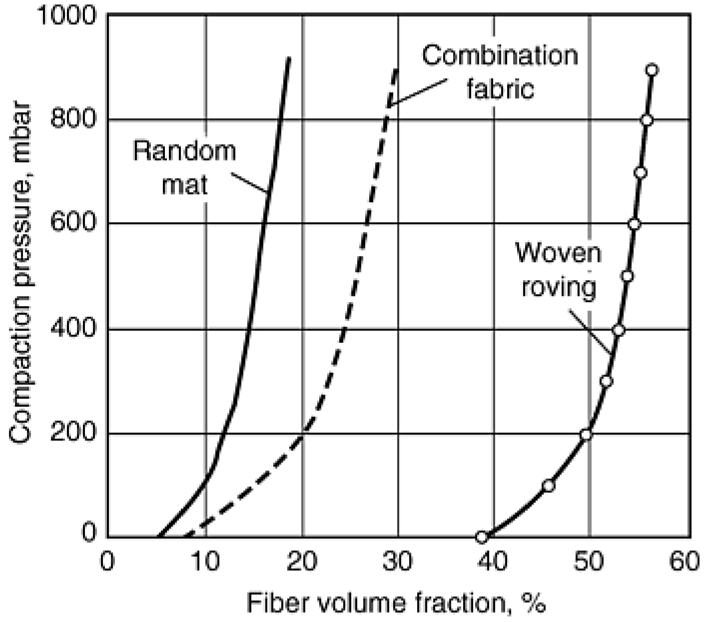

Fig. 10 Influence of compaction pressure on fiber volume fraction for three different reinforcements

The Carman-Kozeny relationship shows that the variation in permeability for the same material, but at different fiber volume fractions, is very large. It is not unusual to obtain a factor of ten difference between different fiber contents. Between different materials, the differences can be even larger. This immediately shows the importance of the selection of the fiber reinforcement, since fill time is inversely proportional to the permeability.

The laminate in a part often consists of a few different layers of reinforcement. When porosity and permeability differences between the layers are not too large, the overall permeability can simply be calculated using a rule of mixtures (Ref 19). However, large differences between the layers result in a more complex situation with three-dimensional flow. A simple rule of mixtures, consequently, gives a too-optimistic value for the overall permeability. This is due to a three-dimensional flow that occurs when poorly permeable layers are impregnated by the resin flow from highly permeable layers. Knowing this effect, we can use highly permeable layers as resin feeder material. This can be applied either within the laminate using an internal flow layer (such as cores or a random glassmat) and thus creating a resin rich core, or outside the laminate with an external flow layer (using any feeder material). The external flow layer can be separated from the actual laminate using a peel ply and therefore, the flow layer can be removed from the laminate after cure.

Finally, it must be recognized that the reinforcements in the mold are not the only producers of resistance to the resin flow. Every tube, valve, and so on results in resistance to flow and can therefore also influence fill time. To compare these influences, it is possible to characterize all items in terms of permeability.

A tube can be characterized with permeability by using the relation:

$$K = 1/8\ r^2$$

where K is permeability (m^2) and r is inner radius tube (m). Clearly, when a tube is treated like a permeable medium it must be recognized that at constant pressure difference the fill time (for the tube) is also proportional to the squared length of the tube.

In conclusion, the permeability of the reinforcement being used has a large impact on the fill time of the part. Unfortunately, reinforcement suppliers do not give the permeability of their materials. In addition, measurement of the permeability is not straightforward and is influenced by the fiber volume fraction of the reinforcement (i.e., the amount of compression in vacuum infusion) (Ref 20, 21). However, an estimate of the reinforcement permeability can be made easily (see the discussion of reinforcements in the section “Equipment and Material Types and Forms” in this article). Approximate values of permeability of various materials are shown in Table 3.

Table 3 Permeability of reinforcements, flow layers, and tubes

Material	Permeability, 10^{-9} m^2
Glass reinforcement	
Multiaxial	**0.05–0.30**
Woven roving	**0.05–0.30**
Random mat	**1–4**
Combination mat	**4–8**
Cores and flow layers	
Contoured balsa (25 mm, or 1 in.)	**3**
Flow layer grid	**10**
Flow layer braiding	**50**
Tubes	
Internal diameter 5 mm (0.2 in.)	**800**
Internal diameter 10 mm (0.4 in.)	**3000**
Internal diameter 25 mm (1 in.)	**20,000**

Injection Strategy. How does the injection strategy, that is, the location of the resin inlet and outlet ports, influence the fill time of the part? There are three basic injection strategies to consider:

- Strip injection (edge injection of a rectangular plate) Fig. 11(a)
- Point injection of a circular plate Fig. 11(b)
- Circumferential injection of a circular plate Fig. 11(c)

Each injection strategy can be considered as a combination of these three.

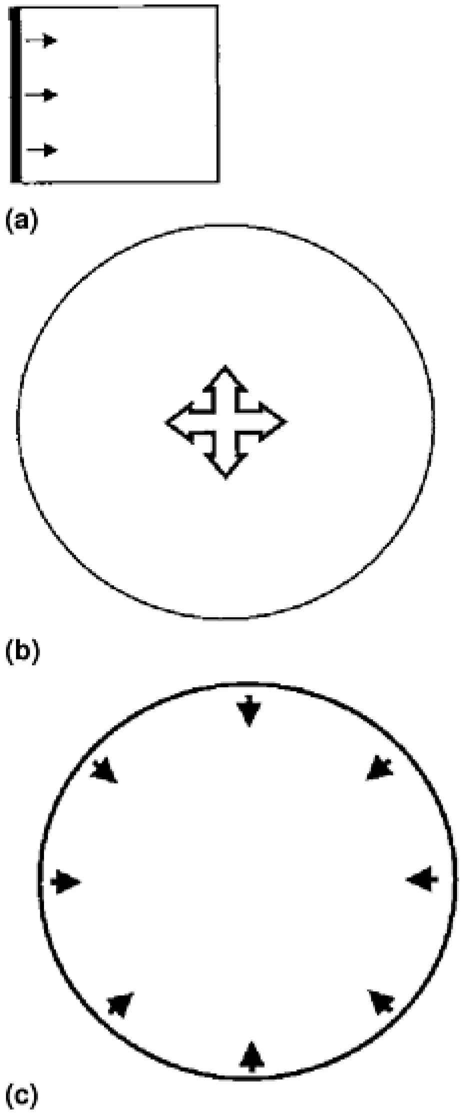

Fig. 11 The three basic injection strategies to consider. (a) Strip injection. (b) Point injection. (c) Circumferential injection

For each of these injection strategies, we can work out Darcy's law in conjunction with mass conservation equations to get the flow front progression and fill time of the part. Consider the injection of flat plates with the following geometry and injection strategy:

- Strip injection of a rectangular plate, 1 m (3.3 ft) long
- Point injection of a circular plate, 2 m (6.6 ft) in diameter
- Circumferential injection of a circular plate, 2 m (6.6 ft) in diameter

The position of the resin flow front versus time for these three injection strategies is shown in Fig. 12. In this example, the vacuum in the mold cavity is set at 10 kPa (100 mbar).

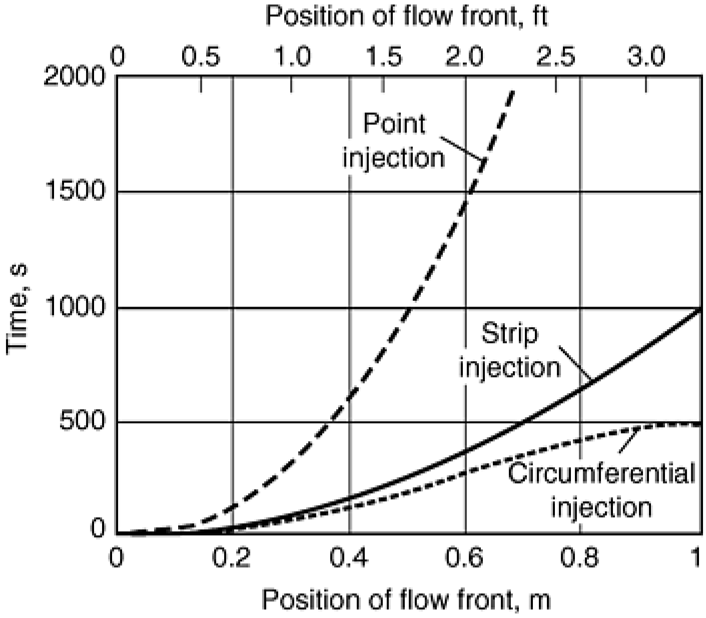

Fig. 12 Flow front progress, in time, for the three basic injection strategies

The strip injection under this specific circumstance takes 1000 s. It can be seen that the flow front progress slows down in the course of the injection. This is due to the decrease in pressure gradient with flow front progression. The pressure difference between resin inlet and resin outlet, and the resulting pressure gradient with flow front progression is shown in Fig. 13. The point injection under these conditions takes over 4500 s. The flow front slows down much more than during the strip injection because the length of the flow front increases with flow front progress (the diameter of the flow front increases). The pressure gradient drops much quicker as compared with the strip injection of a rectangular plate (see Fig. 14). During circumferential injection the opposite takes place. The flow front actually speeds up at the end of the injection, and the part is filled in only 500 s. The pressure gradient is shown in Fig. 15.

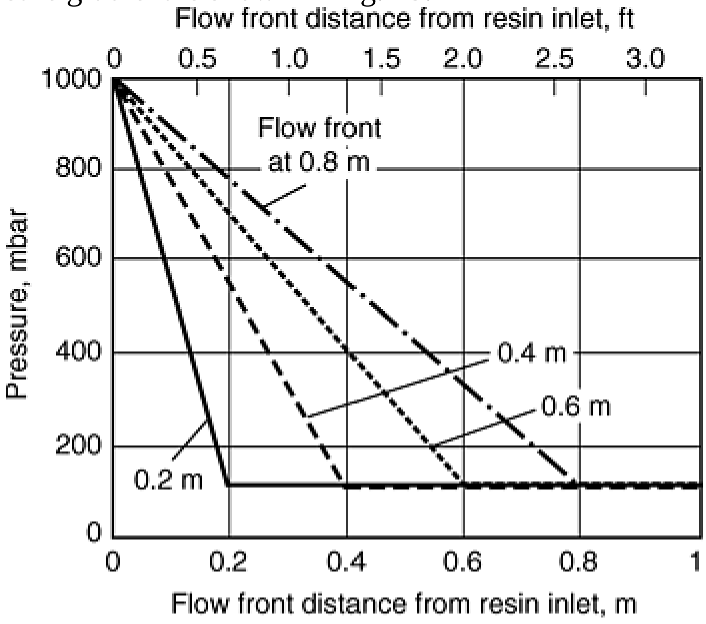

Fig. 13 Pressure gradient during strip injection of a rectangular plate at four flow front positions

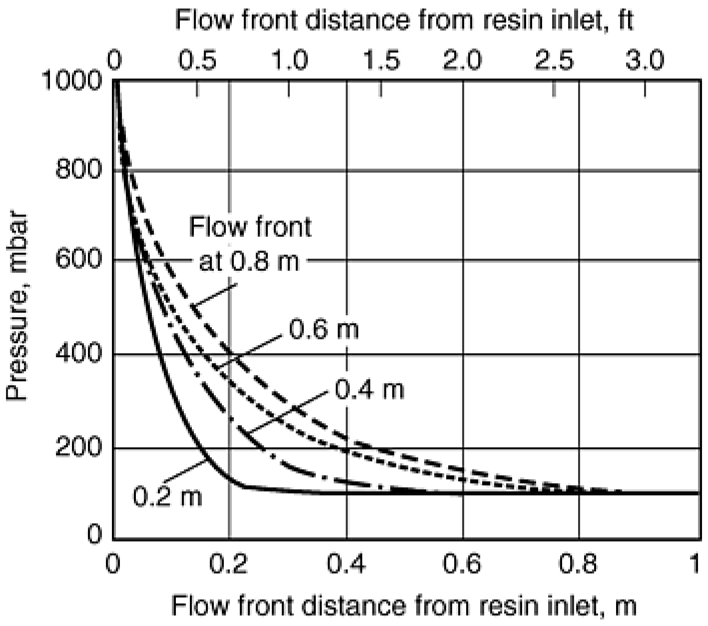

Fig. 14 Pressure gradient during point injection of a circular plate at four flow front positions

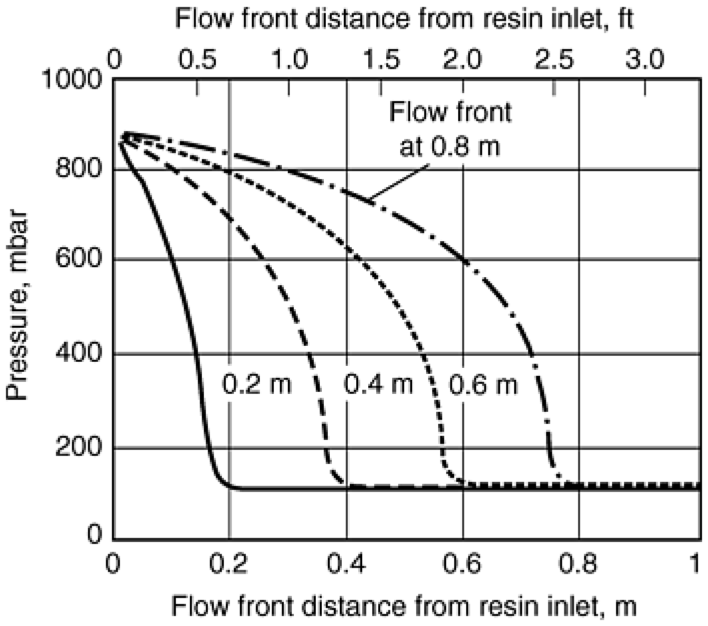

Fig. 15 Pressure gradient during circumferential injection of a circular plate at four flow front positions

The repercussions of the injection strategy on the fill time can be very significant. When we compare two injection strategies for a flat rectangular plate of 1 × 2 m (3.3 × 6.6 ft), edge injection from the short side will take about 25 times longer than a fishbone injection (as shown on the Contest hull in Fig. 3 and 4).

From these simple examples we can conclude that injection strategy parameters that influence fill time are:

- Injection distance
- Ratio of length of the injection channel and length of the flow front (The possible variation in this ratio during injection should also be considered.)

Dry Spot Formation. So far we have discussed the influence of resin, reinforcement permeability, and injection strategy on the fill time of the part. However, a major issue concerning the injection strategy is to fill the part completely, without dry spots. Dry spots are formed when the resin flow front encloses part of the reinforcement that is not directly connected to an outlet. This results in entrapped air, which can result in either

a none-impregnated spot or a void-rich area in the laminate. There are three major ways in which part of the laminate can become enclosed by resin:

- *Differences in injection distance:* In Fig. 16 a cover box is shown. When this part is injected from one side to the other there is a large difference in the distance that the resin needs to flow. Along the edge, the distance is much smaller than over the top of the box. Consequently, a dry spot will be formed.
- *Differences in reinforcement permeability:* In Fig. 17 a rectangular panel is shown. The central part consists of a poorly permeable fabric, while the rest consists of a highly permeable random mat. When this panel is injected from one side to the other, the resin will flow faster around the woven fabric than through the woven fabric, resulting in a dry spot.
- *Runner channels ("racetracking"):* In Fig. 18 a panel with ribs is shown. It can be difficult to drape the reinforcement around the ribs. This will result in a small gap (channel) between the edge of the rib and the reinforcement. This gap will have a high permeability, and resin will flow through this channel easily. Therefore, the area between the ribs can be enclosed.

The examples given previously are typical in plane problems. However, similar problems can occur through the thickness of the part. In Fig. 19 a cross section of a panel is shown. One side of the panel is quite thick, while the other side is thin. Because it is a large panel and the reinforcement has low permeability, a flow layer is placed on top of the laminate. When this panel is injected from the thick side to the thin side, the following can occur: the resin flows through the feeder material and starts impregnating the reinforcement. The through-thickness impregnation, however, is quite slow. Accordingly, the thin part is impregnated before the thick part, and a dry spot can be formed.

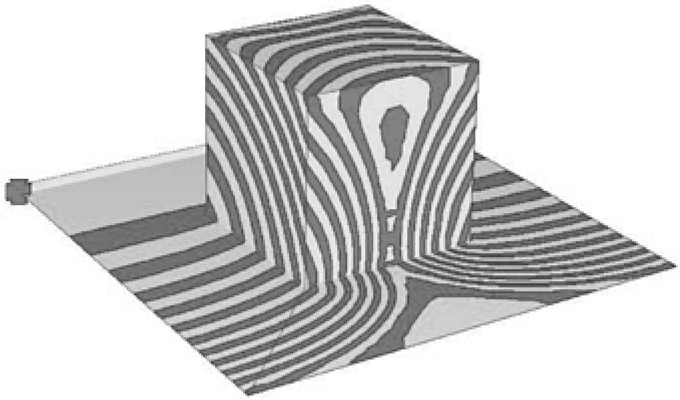

Fig. 16 Flow front simulation of the edge injection of a cover box

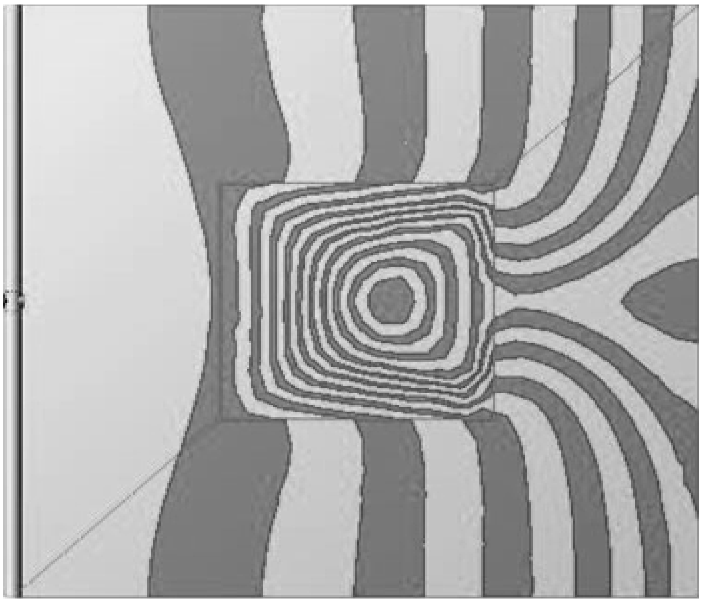

Fig. 17 Flow front simulation of a panel with a central part of a poorly permeable fabric

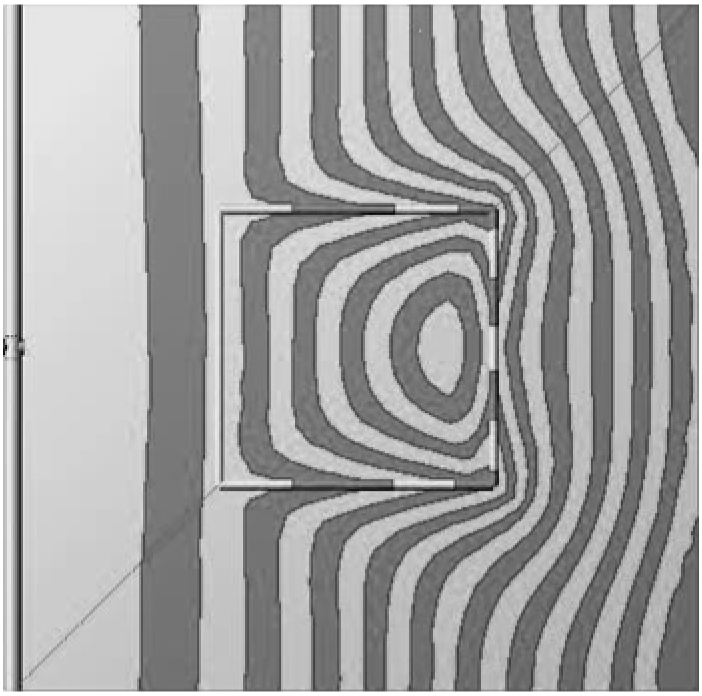

Fig. 18 Flow front simulation of a panel with ribs

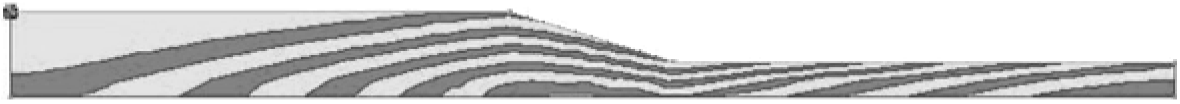

Fig. 19 Cross section of a panel with a thick and thin part and a flow layer on top of the laminate

The mistakes in the examples mentioned previously are quite obvious. However, as the part complexity increases, similar problems can occur and they are not always as easily recognized. Fortunately, flow simulation software is available. Based on part geometry, permeability and injection strategy flow front progression in time is calculated. For complex geometries, this kind of software is very helpful to determine the appropriate injection strategy (Ref 12, 22, 23, and 24).

Vacuum Infusion

Arlen Hoebergen, Centre of Lightweight Structures TUD-TNO, The Netherlands; J. Anders Holmberg, SICOMP AB, Sweden

---

Technique Description: How Parts Are Made

Vacuum infusion is a versatile technique. Before starting the production of a part, it first must be determined how the part will be made. It must be realized that vacuum infusion is just one option and that other techniques might be suitable as well. In the ideal situation, a comprehensive list of part requirements forms the basis for a concurrent development and selection of design, materials, and production technology. This ensures that the optimal solution can be obtained.

Injection Tests. When vacuum infusion has been selected for manufacturing the part, the following general testing sequence is advised:

- *Small scale injection tests (flat panels):* In order to judge both the reinforcement (handling, permeability) and the resin (handling, viscosity, impregnation of reinforcement, cure), simple injection tests can be carried out on small rectangular panels. This provides an initial screening of the materials (see also the section "Materials" in this article).
- *Full scale simplified injection tests:* Difficult sections in the part can be investigated with injection tests using relatively simple tooling on a 1 to 1 or 1 to 2 scale. For example, a change of thickness in the part can be investigated with an injection test on a flat panel. The same can be done with an insert or rib. A corner or an edge can be investigated using a simple bend aluminium plate as tooling.
- *Full scale section injection test:* Finally, a full scale section of the part can be made in the production mold. This final test ensures fine- tuning of the process and elimination of possible mistakes.

The injection tests are carried out concurrently with the development of the appropriate injection strategy. When the part is complex, a flow front simulation tool can also be helpful.

Mold Preparation. The mold must be cleaned properly. Damage to the mold must be repaired carefully so as to not affect the airtightness of the mold. Finally, a release agent must be applied. Careful cleaning and proper application of the release agent will greatly prolong the life span of the mold.

Application of Gelcoat and/or First Layer. Depending on the size and the requirements of the part, a gelcoat can be applied. The gelcoat should not be applied on the flange of the mold that is used for sealing. First, a hand lay-up layer can be applied on the gelcoat. This layer is applied either to get better durability properties (using a resin system other than the injection resin) or to protect the gelcoat layer during lay-up of the dry reinforcement and to assure good adhesion between the laminate and the gelcoat. Large parts often require several days or

even weeks to put all the reinforcement in the mold. Without the hand lay-up layer, the gelcoat would be damaged and adhesion would be poor.
Placement of Dry Reinforcement and Cores in the Mold The dry reinforcement and cores (if used) are placed in the mold. For small parts, the reinforcement could be preformed to speed up the cycle time (as in RTM). For large parts, the reinforcement (sometimes precut) is placed in the mold and secured (if required). Securing the reinforcement and cores in the appropriate position can be difficult, especially with complex geometries and vertical surfaces. In order to secure the reinforcement, three methods can be used:

- Temporary clamps and fasteners (will be removed from the part before or after the infusion)
- Permanent mechanical fasteners, such as staples (will remain in the part)
- Adhesives, such as thermoplastic binders, hot-melts, or glue

A permanent securing method (mechanical fasteners or adhesives) can affect laminate properties (see also the section "Representative Component Properties" in this article).
Placement of Distribution Channels and/ or Flow Layers. When a flow layer is used on top of the reinforcement, this layer is usually placed on the reinforcement with a peel ply in between. This enables the removal of the flow layer after infusion and cure of the resin. Based on the selected injection strategy, resin distribution channels (often plastic or steel helicoils) are placed on the reinforcement and/or flow layers. To ensure removal, the distribution channel is usually wrapped in a peel ply. This can also prevent the foil of the vacuum bag from being pressed between helicoils of the distribution channel and thus blocking the channel. However, it must be realized that the peel ply produces resistance to the resin flow. Multiple wrapping of the injection channel with a peel ply will result in a very slow injection. When an internal flow layer is used (reinforcement layer with high permeability), it is best to ensure that the resin distribution channel is in direct contact with this layer to ensure fast infusion.
Placement of Inlet. The resin inlet can be integrated into the mold and, in this case, the resin distribution channel must be properly connected to the resin inlet. In many cases the resin inlet is a plastic tube that is placed on the mold flange and sealed onto the mold with tacky tape. The tube must be properly connected to the distribution channels.
Placement of Outlet Ports on Top of the Reinforcement. The position of the outlet ports depends on the injection strategy. One can roughly distinguish two different ways:

- On the edge of the part
- Somewhere central on the part (not on the edge)

When the outlet ports are located on the edge of the part, the placement of an outlet port is very simple and easy. Often an "outlet channel" is placed around the part (sometimes only partially around the part). This channel can also be integrated in the mold. At the location where an outlet port is required, a simple connection is made between the reinforcement and the outlet channel. This connection can be made simply with some flow layer material.
If the outlet port is located somewhere on the part, it is slightly more difficult to properly realize an outlet port. Integration of the outlet in the mold is a foolproof solution. Obviously, if it is required to realize an outlet port through the vacuum bag, this can only be done after placement of the vacuum bag. Although there are special fittings available for this purpose, these outlets remain a possible location for leakage. Such a leakage might not destroy the part, but because it is located at the outlet it will be difficult to check the part for leakage prior to injection.
Closure of the Mold. Obviously, closing the mold also depends on the type of mold. When a flexible glass reinforced plastic shell is used, the seals are usually integrated in the mold. A slot in the mold with rubber or silicone o-rings is very effective. When a foil is used, the foil needs to be draped over the part and sealed onto the mold with tacky tape.
For any mold system it is possible to choose between a single or double seal. Because leakage is critical in vacuum infusion, a double seal is often the preferred solution. Flow layer material is placed in the cavity between the two seals and the cavity is evacuated, ensuring the absence of leakage (see Fig. 20).

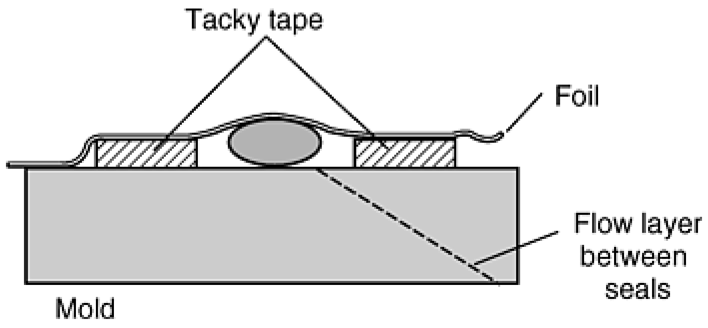

Fig. 20 Double sealing with a flow layer to evacuate the cavity between the seals

Proper draping of the foil over the part is a critical step. Clearly, the foil needs to be big enough to follow the geometry and completely cover the part. This is especially critical when a foil is used that cannot be stretched (such as polyamide foils). When the part is complex, this usually results in folds in the foil. These folds will need to be properly sealed as well (see Fig. 21).

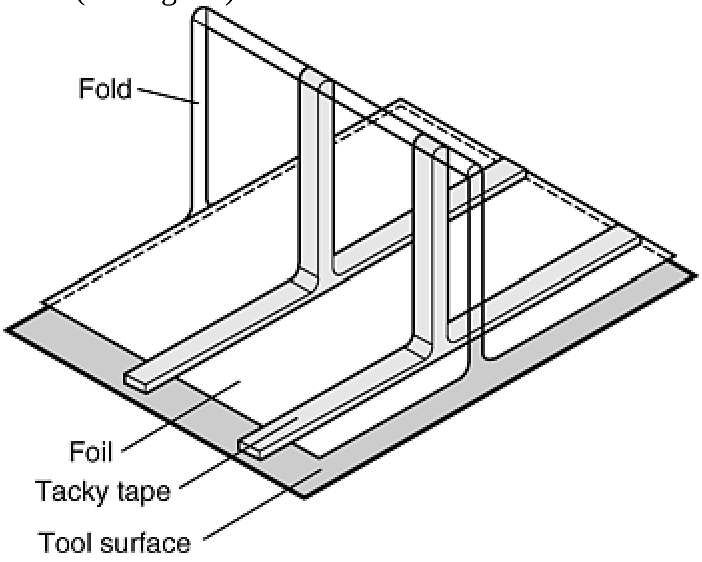

Fig. 21 Properly sealed folds in the foil

Application of Vacuum and Test for Leakage. When the mold is closed (foil is sealed onto the mold flange), the mold cavity can be evacuated. Clearly, the resin inlet hose must be closed. If a double seal is used, the cavity between the seals is evacuated first. The pressure (vacuum level) in this cavity and leakage must be checked. Although some companies rely solely on the pressure measured (if a certain pressure level is achieved, the seal is considered acceptable and there is not too much leakage), this is considered insufficient. To control the leak rate, the following method, applied by most companies, is considered simple and good: the hose to the pump is closed and the pressure decay is measured (after 1, 2, etc. minutes). This results in a leak rate of x mbar per minute, which is a good unit for deciding on acceptance of this leak rate. For the cavity between the seals, a leak rate of 100 or 200 Pa (1 or 2 mbar) per minute is often considered acceptable.

Then the mold cavity can be evacuated. When a fiberglass shell is used, this is a matter of starting the pump or opening a valve and waiting for the required injection pressure. When a foil is used, excess air has to be removed first. When the foil is just pressed onto the reinforcement, the valve to the pump is closed. The pressure in the mold cavity should be close to atmospheric pressure (approximately 99 kPa, or 990 mbar, absolute pressure). Now the position of the foil is checked. Along all edges, the foil and the glass reinforcement are manually pressed tightly into the edge. This can prevent unwanted racetracking channels. Finally the pressure is slowly decreased to reach the required injection pressure. Foil and reinforcement are pushed into the edges to prevent these from bridging over edges.

The leak rate is checked in the same manner described previously. A sonic leak detector is normally used to find the location of leaks. Leaks in the foil are closed with a little bit of tacky tape. A leak rate of about 500 Pa (5 mbar) per minute is usually considered acceptable for large parts, although a leak rate of 1000 Pa (10 mbar) and even up to 1500 Pa (15 mbar) per minute is sometimes accepted.

As mentioned previously, vacuum infusion is very sensitive to leakage. It can be disastrous for the part. Checking and searching for leaks can easily take a day for a large part (such as a 17 m, or 55 ft, hull).

Preparation of the Resin. The resin for the infusion must be in the workshop at least 24 hours before the infusion to allow the resin to reach the same temperature as the workshop. Only after the leak rate is considered acceptable can the resin components be mixed. Mixing needs to be done carefully to prevent dragging in excessive air (which can cause bubbles in the part). The resin can be degassed before and after mixing, depending on the purpose. Before mixing, the resin can be degassed thoroughly to remove dissolved air (Ref 25, 26). After mixing, degassing can be used to remove small bubbles that are dragged into the resin during mixing. Degassing can, however, affect resin cure. Checking the resin temperature, viscosity, and gel time is good practice to prevent mistakes, especially for large parts.

Infusion of the Resin. When the leak rate is acceptable, the injection pressure is set and checked, the resin is mixed and the temperature and viscosity of the resin is checked, then the infusion can start. In the simplest method, a hose is fixed in a bucket with resin. The hose is opened (valve, or removal of a clamp) and the resin flows into the mold.

Needless to say, the hose must remain in the resin during the whole infusion. The resin level in the bucket must be monitored. When the hose is pushed to the bottom of the bucket, the hose can be closed and the resin flow will slow down.

During the infusion, the process must be monitored. When a foil is used, the resin flow front can easily be seen. In large parts, operators can walk on the foil (no shoes!) to monitor the process. Bubbles in the resin indicate a leak in the foil. The bubbles can be visually traced back to the hole in the foil, and the hole can be sealed with tacky tape.

Racetracking channels can cause dry spots. These dry spots can be removed using an emergency outlet that ensures the dry spot is impregnated with resin (see also the section “Equipment and Material Types and Forms” in this article).

Finishing the Infusion. Even though the resin has filled the entire mold cavity, this does not mean that the infusion process is complete. Void content, thickness, thickness tolerances, and fiber content of the part are all affected by how the infusion is ended. The four main possibilities to finish the infusion are:

1. Close inlet
2. Close outlet
3. Close both inlet and outlet
4. Increase pressure at outlet and subsequently close inlet

To illustrate which option is good and which is not, we must look at the pressure in the mold cavity. Figure 22 shows the pressure in the mold cavity for a rectangular plate, just after the mold has been filled (the line labeled “mold filled”). At this moment, there is almost no compressive force on the reinforcement close to the inlet. This means that the laminate is thicker close to the inlet and contains excess resin, as compared to the vicinity of the outlet.

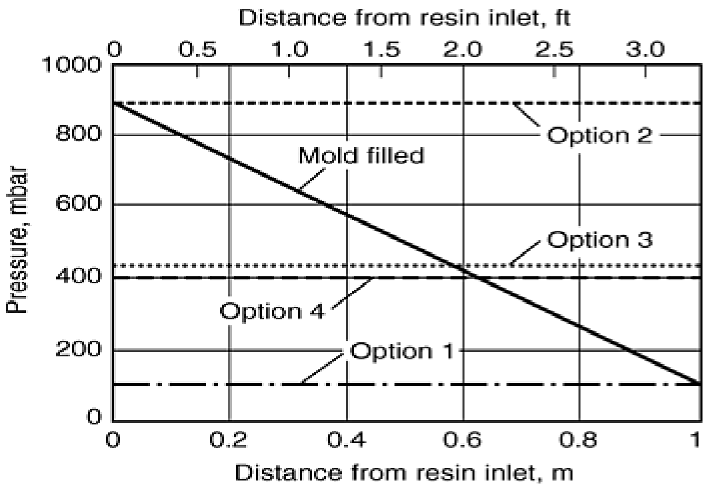

Fig. 22 Pressure in the mold cavity after filling the part and after ending the infusion. See text for discussion

If the inlet is closed first, the pressure in the entire mold will decrease to reach the infusion pressure (the line labeled “Option 1”). Excess resin will flow toward the outlet and the thickness of the part will reduce, leading to a high and homogeneous fiber content. However, air bubbles present in the part will increase in size, and this will be most prominent in the part close to the inlet since the pressure drop close to the inlet is much larger than near the outlet. In addition, there is also the risk of degassing of the resin. This means that air, dissolved in the resin, will form bubbles since the amount of air that can be dissolved in resin is smaller at lower pressure. Clearly, this is not a desirable situation.

If the outlet is closed first, the pressure in the entire mold will increase to atmospheric pressure (the resulting pressure will depend on the relative position of the resin tank with respect to the mold; see the line labeled “Option 2”). Although this will cause bubbles to decrease in size, the thickness of the part will slowly increase due to the resilience of the reinforcement, resulting in a laminate with low fiber content. Gravity may also cause resin flow on vertical surfaces, leading to poor thickness tolerances. Again, this is not desirable.

Closing both inlet and outlet at the same time will result in pressure equilibrium somewhere in between the atmospheric pressure at the inlet and injection pressure at the outlet (the line labeled “Option 3”). This is a good way to end the infusion. However, in circumstances where a small leak persists, this method can result in a part with many voids and bubbles. In this case, Option 4 is more favorable. The pressure at the outlet is first increased (for example, from 10 to 40 kPa, or 100 to 400 mbar, absolute pressure). Then the inlet is closed. This will result in an equilibrium pressure, as shown with the line labeled “Option 4” in Fig. 22, and at a leak, a small pressure gradient will remain. In an optimized process, the inlet can be closed before the mold is entirely filled. If properly made, the excess resin present in the mold will flow toward the outlet during the pressure equalization and complete the infusion with a minimum of resin spillage through the outlet.

In conclusion, increase the pressure and close only the inlet. The outlet can be closed after gelation of the resin when flow no longer is possible. When the resin has cured, all ancillary materials (foil, hoses, etc.) can be removed and the part can be demolded.

Equipment and Material Types and Forms

Molds. One of the main benefits of vacuum infusion is that the process only requires one stiff mold half. The other half of the mold can be either a flexible bag or a thin shell. The stiff part of the mold can be manufactured by most of the materials and techniques developed for other composite fabrication processes, such as wet hand lay-up, spray-up, or RTM. There are, however, two requirements that must be considered during design and manufacture of the mold:

- The mold must be absolutely airtight. This requirement seems obvious, but it cannot be stressed enough since any leakage through the mold is likely to lead to severe manufacturing problems and waste of

parts. If holes are drilled in a mold to realize a resin inlet or outlet, this may cause complex paths for leakage. The walls of such a hole should be sealed with resin; a seal at the outer edge of the hole may not be sufficient in this case.

- The mold must contain a flange to allow sealing of the bag or shell. The width of the flange depends on the details of the seal arrangement and the inlet/outlet design, but in general, 150 to 250 mm (6 to 10 in.) is sufficient.

The most cost-efficient mold type depends on the application. The most common type is composite tooling, and often wet lay-up molds can be converted to vacuum infusion molds by constructing a flange. Formed and welded sheet metal is often suitable for single curved shapes. Milled ureol blocks are feasible for complex shapes in a small series. In all these cases, it is important to make sure that all joints in the mold are airtight.
There are three main options for the flexible half of the mold:

- Disposable foil
- Reusable bag
- Thin glass reinforced shell

All three types are in common use today, and the selection depends on part geometry, resin system, and the number of parts to be produced. The disposable foils are usually made of polyamide (PA) or polyvinyl alcohol (PVA) and are of the same type as those used for prepreg consolidation. Re-usable bags are usually shaped or molded to the same geometry as the mold. The materials generally used are polyurethane and silicone. Like the stiff mold, reusable bags must be cleaned properly and may not be damaged. In addition, they can become charged with static electricity. A common problem for both disposable foils and reusable bags is the resistance to solvents in the resin system. Particularly, styrene is an aggressive solvent, and dissolution of the foil leads to either leakage or poor surface quality. Certain types of PA and PVA foils have proven to work well with styrene based resins.

Thin shells are usually made by applying tooling wax in the rigid mold half to build the part thickness. The tooling wax is then covered with a clear gelcoat followed by wet lay-up of glass reinforcement to a thickness of 1 to 5 mm (0.04 to 0.20 in.). The thickness of the shell should be such that it is rigid enough to handle, but still flexible enough to adjust for reinforcement overlaps and other irregularities in the mold and reinforcement. Finally, a layer of clear topcoat can be applied to ensure that the shell is airtight. The use of a clear gelcoat and topcoat is preferred since it allows observation of the mold-filling pattern during infusion.

Equipment. Vacuum infusion puts small requirements on investments in equipment. A basic setup is shown schematically in Fig. 23.

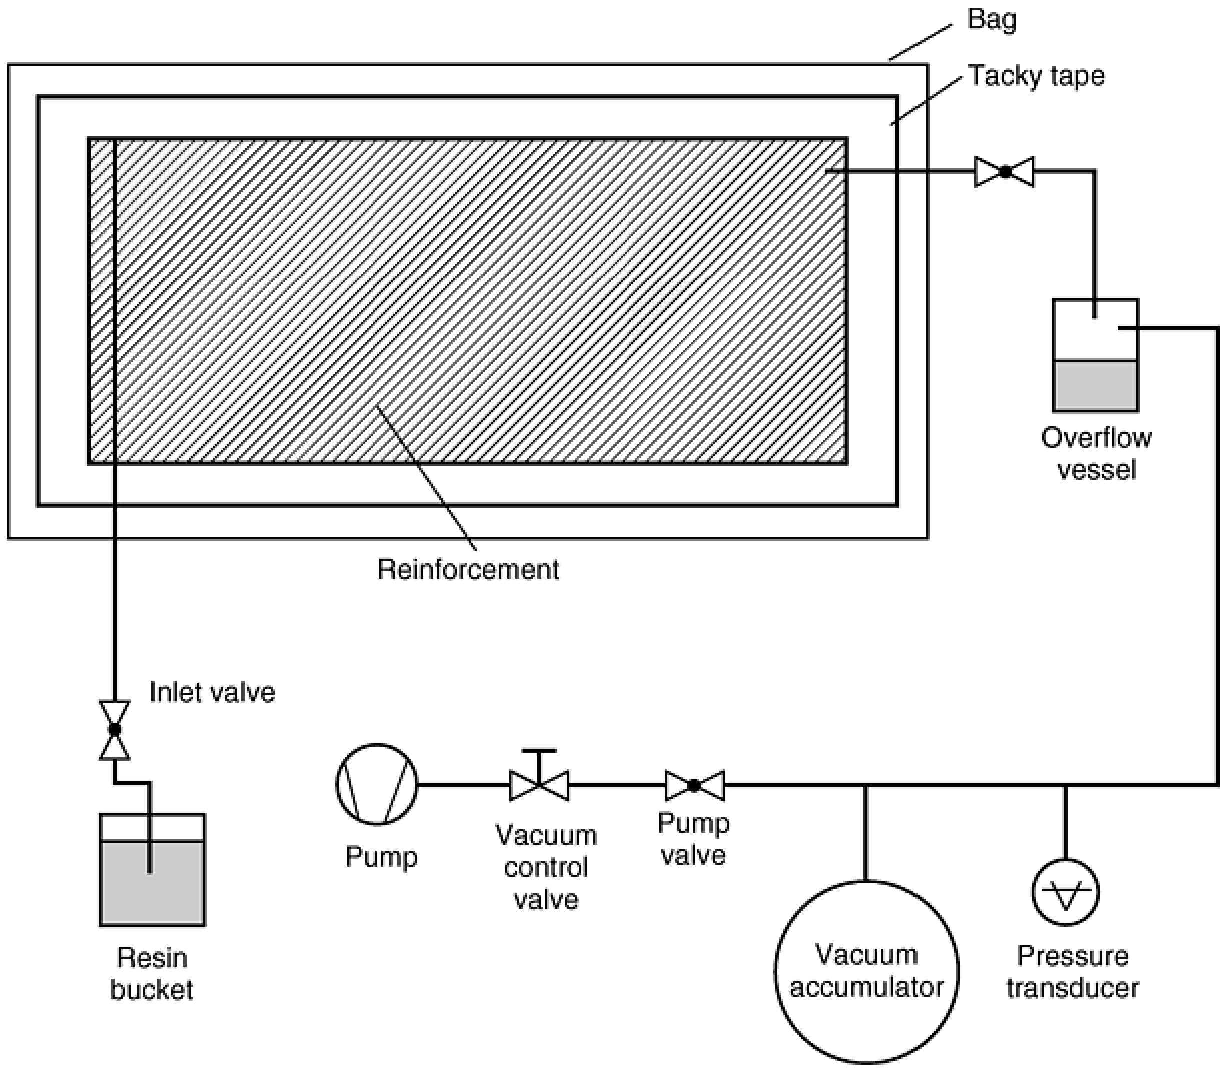

Fig. 23 Schematic of a basic vacuum infusion setup

Vacuum Pump. The vacuum pump should be capable of an absolute pressure of less than 10 kPa (100 mbar) without large oscillations. The capacity is of little significance since a small vacuum pump has a capacity of 10 m^3/h (350 ft^3/ h) or more. This is more than enough for most vacuum infusion applications. For large parts, however, a vacuum pump with a higher capacity will shorten the time required for evacuation of the mold cavity before infusion. A vacuum control valve should be connected to the pump to control the pressure in the mold cavity. This can, in the simplest case, be a valve to a leak. Finally, a relatively large vacuum accumulator can be an insurance against power breakdown. Without an accumulator, the part will most likely be scrapped if the vacuum pump shuts down during infusion.

Ancillary equipment for vacuum infusion is comprised of pressure transducers for process control, sonic leak detectors and other equipment for detection and location of leaks, mixing, degassing, and dispensing systems to reduce the amount of manual labor and open handling of the resins, and “emergency equipment.”

The possibility to use emergency equipment, such as additional inlet and outlet ports to prevent failure of the infusion of a large, expensive part, is a big advantage to vacuum infusion as compared to other closed-molding processes. The equipment can be very simple, but still effective (see illustration of emergency outlet in Fig. 24). Consider the case of a large air inclusion that will result in a dry spot if no action is taken. If the needle of a simple syringe connected with a small hose to the vacuum pump is pushed through the foil at the centre of the dry spot, the remaining air can be evacuated. Tacky tape around the needle should be pushed against the foil to prevent leakage. In a similar way, incomplete mold filling caused by blocked injection channels or premature gelation can be remedied by applying one or several emergency inlets at the flow front. Although this is complicated, it has been used successfully.

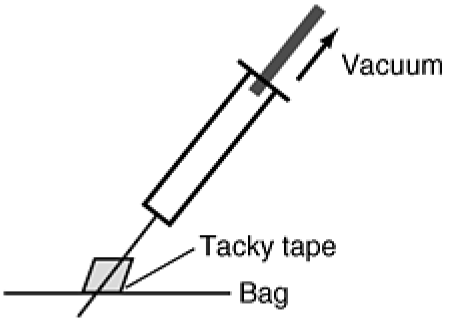

Fig. 24 A simple syringe with needle as emergency outlet

Materials involved include resins, reinforcements, cores, inserts, and ancillary materials.

Resin types commonly used with vacuum infusion are unsaturated polyester and vinyl ester, but also some epoxy and phenolic resins have been demonstrated as feasible. The resin system selection is usually a trade-off between performance, cost, and processing characteristics. The main processing characteristics of resins for vacuum infusion are described by viscosity and reaction kinetics. For practical purposes, gel time and exothermal temperature peak usually indicate the reaction kinetics.

The mold fill time is proportional to the resin viscosity, and so a low viscosity is desirable. A viscosity range commonly considered suitable for vacuum infusion is 100 to 400 mPa · s, which is the same as the desirable viscosity range for RTM. Higher viscosity resins can be processed with vacuum infusion, but at the expense of a long fill time and possible poor impregnation of fiber bundles.

The gel time, after which no flow is possible, has to be long enough to provide sufficient time for starting the infusion, completing the mold filling, and, if necessary, extracting excess resin. The gel time should also include some safety margin to account for deviations from nominal temperature and other factors that affect the fill time and gel time. Usually the gel time is tailored to fit each specific application by changing the resin formulation. For free-radical polymerizing systems (such as the styrene-containing systems), small changes are easy to attain by varying the peroxide content. Common gel times range from 20 minutes to several hours, depending on the application.

Reinforcement. As for resin systems, the selection of reinforcements is a trade-off between performance, cost, and processing characteristics. Most reinforcements that can be used for hand lay-up or RTM can be used for vacuum infusion, even though special measures might be necessary for placement of dry reinforcements into the mold and for reaching reasonable fill times. This means that unidirectional fabric, multiaxial fabric, woven roving, and random mat are all feasible reinforcements for vacuum infusion.

The fiber type is normally not important for the process, and reinforcements based on glass, carbon, aramid, flax, sisal, and so on can all be used for vacuum infusion. For specific fiber types, the processing characteristics may be critical (i.e., moisture in natural fibers, difference in wet and dry permeability).

The processing characteristics of reinforcements are related to two steps in the production:

1. Placement of dry reinforcement in the mold
2. Infusion of the resin

To enhance placement of the dry reinforcement in the mold, two different properties can be identified: drapability and shape stability. Drapability describes the ability of reinforcements to conform to a double curved shape. Drapable reinforcements conform easily to a double-curved shape with little force and without wrinkles. On the other hand, poorly drapable reinforcements will require cutting and division into smaller pieces before they can be used to cover a complex surface. Draping will always affect fiber orientation (Ref 27, 28). For vacuum infusion, where the dry fabrics are usually placed in the mold manually through cut-and-paste forming, it is important that the reinforcement is easy to handle. In addition, it is important that the reinforcement stays in the correct shape and position after manual forming. We have chosen to denote this property as shape stability.

For the infusion of the resin, important properties are permeability and reinforcement compression behavior. The reinforcement is compressed due to the vacuum that is applied in the mold cavity, and because the tooling is flexible. The atmospheric pressure exerts the force on the reinforcement. This results in two effects. Due to the compression of the reinforcement in and on edges, the reinforcement can either bridge an edge or create wrinkles (see also the section “Application of Vacuum and Test for Leakage” in this article). In addition, it will

affect the part thickness and fiber content and, consequently, the permeability of the reinforcement (see also the section “Permeability” in this article). Reinforcements with different architecture and binder content have significantly different compression behavior.

The permeability of reinforcement can vary significantly. Reinforcement suppliers do not (yet) provide data sheets with compression and permeability characteristics of their material. To obtain information about the permeability, flow experiments must be carried out. Several methods for this purpose are suggested in the literature (Ref 21, 29, 30). Two different methods can be distinguished: radial or parallel flow experiments. Both methods have their merits. Radial flow experiments give the whole permeability tensor in one experiment, while parallel flow experiments are less sensitive to errors and easier to interpret. With vacuum infusion it is easy to perform both types of measurements to obtain an estimate of the permeability (Ref 31). A convenient methodology to characterize permeability for a new reinforcement is:

- Carry out a point injection experiment (radial flow method). This will provide the principal directions of the permeability tensor (i.e., are there differences in permeability in different directions, and in which direction is the permeability highest or lowest).
- Carry out parallel flow experiments (strip injections) in the major and minor direction of the permeability tensor. This will provide estimates of the permeability in the principal directions.

These kinds of flow experiments can be easily carried out in a workshop to obtain rough estimates of permeability. When a reinforcement or reinforcement stack with known permeability is available, this can be done by comparative measurements. It is easy to carry out strip injections with a setup similar to the sketch in Fig. 25. The effective permeability of the lay-up in strip *i* is approximately:

$$K_i \approx \frac{t_{\mathrm{ref}} K_{\mathrm{ref}}}{t_i}$$

where K_i is permeability of strip *i*, K_{ref} is permeability of reference material, t_{ref} is fill time for the strip with reference material, and t_i is fill time for strip *i*. An important aspect in obtaining accurate results is to use the same size and length of injection hoses. The best result is obtained when the flow front progress in time is registered, and a plot of time versus the square of the flow front (t versus x^2) is made. The slope of the resulting line is a good indication for the permeability (which can be derived from Darcy's law; see the section “Flow of Resin” in this article).

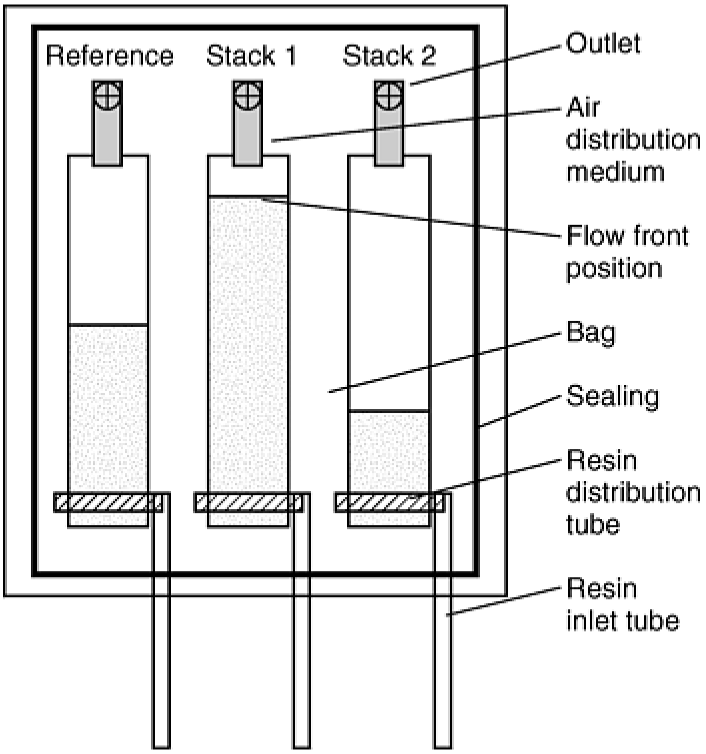

Fig. 25 Schematic of strip injection with multiple reinforcement stacks

There are a large number of reinforcements available on the market, and most of them can be used with vacuum infusion. The different reinforcement types do, however, exhibit significantly different processing properties with respect to vacuum infusion. The processing properties of the most common types are put in relation to each other in a qualitative manner in Table 4. Note that this table provides general information, and that for individual reinforcements, this can be different.

Table 4 Processing properties of different reinforcement types

Reinforcement type	**Drapability**	**Shape stability**	**Compaction**(a)	Permeability
Continuous strand mat	Poor to good	Medium	Poor	**High**
Combination fabric	Very good	Very good	Poor	**Very high**
Woven roving (plain weave)	Poor	Medium	Good	**Medium**
Woven roving (satin weave)	Good	Medium	Very good	**Low**
Multiaial	**Poor**	**Medium**	**Very good**	**Low**

(a) The ability of the reinforcement to compact to a high fiber content under 1 bar pressure (vacuum)

Cores. Some core materials selected to give the part strength and stiffness can be used to quickly distribute resin over the part surface. Contoured sheets of balsa or foam contain slits that enable the core to conform to double-curved shapes. The slits that open up when the core is bent are natural channels that can be used for rapid resin distribution. After complete mold filling and cure, the slits are filled with neat resin that joins the reinforcement cubes together but also adds significant weight to the product. If the slits are not wanted for resin distribution, they should be sealed with filler, as conventionally made for other composite manufacturing processes. A commercially available alternative to contoured cores are cores with machined grooves. Many small grooves will act as a flow layer, and a few large well-placed grooves can be used as resin distribution channels. Also, grooves in the core are a compromise that add weight to the product in order to gain processability.

For some applications, it is beneficial to use flow layer on only one side of the sandwich. In such cases, a perforated core should be used to allow resin to flow through to the other side of the sandwich.

Inserts. Metal or composite inserts can be conveniently used with vacuum infusion. As for other composite processes using molded-in inserts, it is important to choose materials and surface treatment such that the composite adheres well to the insert. Both the surrounding laminate and the insert have to be designed to avoid stress concentrations and thermal mismatch.

Ancillary Materials. A careful choice of ancillary materials for the vacuum infusion process can reduce costs and labor significantly. Pneumatic polyamide tubes, connections, and valves work well for many applications. They are easy to find, relatively low-cost, and rational to work with. All tubes, connections, and valves must, of course, be airtight and able to withstand vacuum pressure. Another important aspect is chemical resistance to the resin. The inlet valve must be possible to clean or cheap enough to dispose of after each injection. An effective and cheap inlet valve can be realized by using an inlet tube that can be folded and opened several times without breaking. Plastic or metal helicoil wires are ideal resin distribution channels.

For weight-critical applications, it may not be acceptable to use internal flow layers such as contoured core materials, continuous strand mats, or combination fabrics. For such applications, an external flow layer is used with a peel ply between the flow layer and the structural reinforcement. The requirements of the flow layer are such that it should enhance the flow in a balanced manner without absorbing an excessive amount of resin. If the geometry is complex, the flow layer should also be highly drapable. Suitable external flow layers are therefore highly permeable thin textiles in the form of nonwovens, coarse weaves, or welded nets.

The glue for positioning dry reinforcement on vertical surfaces has to be compatible with the resin and possible to apply in small amounts where it is needed. The glue should also adhere quickly to the reinforcement to enable efficient lay-up.

Representative Component Properties

Mechanical Properties of Components. The mechanical properties of composite components are primarily depicted by the fiber reinforcement (orientation, fiber volume fraction) and, for a few properties, by the polymer matrix. In general, this implies that the mechanical properties of a component made with a specific manufacturing technology are related to the reinforcement that can be used and the fiber volume fraction that can be achieved. In Table 5 the range of fiber volume fractions for different glass reinforcement types and production techniques is given. Three different types of reinforcement are distinguished:

- Random mat: chopped-strand mat and continuous-strand mat, as well as spray-up roving
- Woven roving and woven fabric
- Unidirectional (UD) reinforcements: rovings and tapes, also including multiaxials; stitched UD layers in different orientations

In Table 6 the mechanical properties for three different glass reinforcement types are given in a common range of fiber volume fractions (V_f):

- Random mat (10 to 30% V_f)
- Woven roving (balanced 0/90, 30 to 50% V_f)
- UD (40 to 70% V_f)

The values for mechanical properties given in Table 6 are averages based on literature data. Semi-empirical calculations result in slightly higher values for woven roving, UD (Ref 32), and random mat (Ref 33).

Table 5 Common range of fiber volume fractions for different reinforcement types in various production techniques

Manufacturing technique	Fiber volume fractions (V_f), %

Influence of Production on Properties. The main influence of the production technique on the mechanical properties is related to the fiber volume fraction that can be achieved. Production techniques that result in similar fiber volume fraction will result in similar mechanical properties. However, matrix-dominated properties, such as interlaminar shear, can be influenced substantially by the production technique and by the way the technique is carried out in the workshop. Unfortunately, there are hardly any data available. In the subsequent paragraphs, the influences of two important vacuum infusion production parameters are discussed: the influence of processing conditions on cure and resin properties, and the influence of reinforcement adhesives on mechanical properties.

Influence of Processing Conditions on Cure and Resin Properties. The cure of the polymer matrix is influenced by the processing conditions. As with any manufacturing technique that uses thermoset resins, the temperature and relative humidity can affect the cure of the resin. However, there is also evidence that absorption of resin components and/or desorption of components on the reinforcement (e.g., sizing) or core material (e.g., absorption of water) influence the cure of the resin. In a workshop, this can usually be recognized as a difference between gel time in the mold and in the injection tank. The gel time in the mold can be shorter as well as longer!

The vacuum in the mold cavity results in another effect that is prominent with resins containing styrene. The free-radical polymerization reaction is inhibited by the presence of oxygen. However, with vacuum infusion there is hardly any oxygen present in the mold cavity. This can result in a higher degree of cure of the resin and, consequently, a slightly more brittle resin matrix. In addition, this can affect secondary bonding.

Influence of Reinforcement Adhesives on Properties. With the vacuum infusion process, dry reinforcements must be placed in the mold. When the part is complex or has vertical surfaces, it is not always easy to keep the reinforcement positioned until the mold is closed and vacuum is applied. One of the methods for keeping the reinforcement positioned is with the use of adhesives. Adhesives on the reinforcement need to be used with caution because little is known about the short or long term effect on laminate properties. However, there is evidence (Ref 12) that the use of adhesives adversely affects the interlaminar shear strength.

It is clear that this issue will require further research to prevent failure of parts due to unknown effects of processing conditions on mechanical properties.

Design Guidelines

Even though, with more or less effort, virtually any part can be made with vacuum infusion, it is important that development and selection of the materials, manufacturing technique, and design are carried out concurrently. When vacuum infusion is selected, the materials and design of the part must be tailored to the process. Design of a part or component is often made based on the functionality of the product, raw material price, and performance requirements such as weight, stiffness, or strength. All too often, production engineering aspects are only considered at the end of the development process, when the possibility to make design changes is limited. Considering the manufacturing process at an early stage makes it possible to drastically reduce future production costs. Important factors to consider during design and choice of materials are described below.

Type of Tooling. The number of parts to be made and the geometrical complexity decides if foil or glass fiber shell is the best tooling type. If a fiberglass shell is to be an option, there has to be sufficient draft angles all over the part (generally 1 to 3°). A fiberglass shell will cost more than foil for a single shot, but is reusable. The fiberglass shell also enables production of parts with two relatively good surfaces, requires less labor during mold closure, and is less prone to leakage than foils. Foils, on the other hand, give larger geometrical flexibility and the possibility to change the injection strategy without tool modifications.

Placement of Dry Reinforcement in the Tool. A drapable and formable fabric can be used in large sheets without extensive cutting and it conforms easily to complex shapes. This is in contrast to some of the high-performance fabrics that are difficult to drape and handle. Accepting more weight in the part may enable selection of a reinforcement that results in a cheaper production.

Large radii and little double curvatures make preforming easier. Inner radii should be made larger than 12 mm (0.5 in.), if possible, and even larger for thick laminates.

Injection Strategy. What injection strategy should be chosen, and where should flow layers be placed? Can core materials be used for resin distribution? A slight modification of the design may not affect the performance of the product, but can result in a huge improvement in processability.

Another consideration is how the flow front pattern will develop and how inserts, potential channels at edges, reinforcement overlaps, and so on will affect it.

Cure. With vacuum infusion, the whole laminate is cured at once, in contrast to spray-up and wet lay-up techniques. Thick laminates with a low fiber content will therefore require special resin systems to avoid a detrimental temperature peak during cure. Variations in thickness in a part can cause problems as well. Either the thick part is exposed to a large exothermal temperature raise, or the thin parts show insufficient cure.

Parts Integration. Vacuum infusion is a process that enables a high degree of parts integration. Often the key to cost-effective production of products with vacuum infusion is parts integration, but there is a limit when further integration is no longer practical. Parts integration usually saves weight and reduces labor in secondary operations, but at the expense of more complex preforming or cutting and less robustness during infusion.

Vacuum Infusion

Arlen Hoebergen, Centre of Lightweight Structures TUD-TNO, The Netherlands; J. Anders Holmberg, SICOMP AB, Sweden

Outlook

Vacuum infusion is a technology still not fully matured. The research done since the 1980s has boosted the application of the technology. These applications, in turn, have revealed critical issues for the technology and have shown the need for further research and development. Two main areas for further research are:

- Material development
- Processing equipment and process control

Finally, the successful application of vacuum infusion and the material properties achieved (high fiber volume fraction and low void content) have triggered the attention of the aerospace industry.
New Applications. Vacuum infusion is expected to compete not only with autoclave prepregging but also with other traditional materials used in the aerospace industry. In recent years, developments have already focused on the application of vacuum infusion in this market segment. Until now, this has resulted mainly in small parts made for small aircraft, such as the manufacture of a rudder for the Euro Enaer Eaglet (see the section "Applications" in this article). Now that this has proven feasible, developments will focus on large parts for small aircraft, and it will not take long before an entire fuselage for a small aircraft can be made with vacuum infusion. Current developments also show that commercial application of small and large parts for large aircraft are within reach. These applications include spars, bulkheads, and control surfaces. This implies mainly carbon parts. Both relatively simple shapes (but rather thick parts—10 to 20 mm, or 0.4 to 0.8 in.) and complex shapes (such as a multirib design for a control surface with a top skin, bottom skin, and ribs) could be manufactured in one shot.
Besides these applications, the manufacture of high-temperature-resistant fairings for aerospace rockets also seems feasible. This would imply a vacuum infusion process carried out at elevated temperatures. Initial experiments carried out at the Centre of Lightweight Structures have shown the feasibility of such an infusion at temperatures as high as 150 ºC (300 °F) with subsequent postcure at even higher temperatures. Obviously, the appropriate high-temperature-resistant ancillary materials have to be selected, and the process must be well controlled and monitored, but this is feasible.
Material Development. Both resin suppliers and reinforcement suppliers have been working on special systems for injection. For resin systems, this implies mainly a low viscosity system with well-controlled curing behavior. Resin development will and must continue to provide systems with both good mechanical properties and low viscosity in order to facilitate not only processing, but also low shrinkage for a good surface quality. In addition, these systems need to have well-controlled cure behavior to prevent a detrimental temperature peak in thick laminates and, at the same time, allow for a proper cure in thin laminates. This will facilitate the manufacture of highly integrated complex parts.
In addition to the development of better and easier-to-handle resin systems, the characterization of resins and their cured properties must be investigated. Influences of processing conditions on cure behavior and, consequently, on the cured resin properties must be determined to prevent part failure and a resulting lack of confidence in the material and the technology.
Reinforcement development has focused on both drapability/shape stability and permeability. At this moment, easy-to-apply reinforcements with a high permeability, to allow fast infusion of parts, are available. However, this is at the expense of low fiber volume fractions and a relatively high cost. Reinforcement suppliers should continue this development to realize highly permeable, high fiber volume fraction reinforcements.
Core materials currently under development show good permeability, combined with small resin uptake.
Processing Equipment and Process Control. Where can vacuum infusion equipment be obtained? Vacuum pumps, pressure transducers and overflow vessels can all be found, but unfortunately, there are few equipment suppliers capable of delivering a comprehensive vacuum infusion tool kit, including the required process control tools.
It is still difficult to monitor the process properly and to determine, before the infusion, if there are no mistakes in the part, such as unwanted racetracking channels, leaks, wrong filling pattern resulting in dry spots, or too-long fill time resulting in premature gelation of the resin.
However, based on current developments it is anticipated that this kind of equipment will be available within the next five years. This will further prevent production failures and the scrapping of parts. As a result, the confidence in the technology will grow, making it easier for companies to switch to vacuum infusion and resulting in more applications being realized with the technology.

Compression Molding

Charles W. Peterson, Azdel bv, The Netherlands; G. Ehnert, R. Liebold, K. Hörsting, and R. Kühfusz, Menzolit-Fibron GmbH, Germany

Introduction

COMPRESSION MOLDING is the single largest primary manufacturing process used for automotive composite applications today. The process is also used to manufacture parts and components for other industrial and consumer applications. This article describes the basic design, materials, processing equipment, and techniques used, together with some application examples and market volume information.

A typical manufacturing chain involves the conversion of composite constituent materials, often using a semifinished product (or preform), into an end-use application. Fully formed parts are molded in matched metal compression molds that give the final part shape; usually these undergo secondary operations such as deburring, hole punching, insert assembly, and, in some cases, painting, and adhesion priming or friction welding for tertiary assembly operations with other parts and components. This type of composite component manufacture is based on either thermoplastic or thermosetting matrix materials reinforced, in the overwhelming majority of instances, by glass fibers. Emerging new materials also use combinations with natural fibers and polymeric fibers.

The three main groups of materials that are compression molded are:

- Glass-fiber-mat-reinforced thermoplastics (GMT)
- Long-fiber-reinforced thermoplastics (LFT)
- Sheet molding compounds (SMC) (thermosets)

The processing and applications of each of these materials is discussed in some detail following a general overview of the compression molding process.

Charles W. Peterson, Azdel bv, The Netherlands; G. Ehnert, R. Liebold, K. Hörsting, and R. Kühfusz, Menzolit-Fibron GmbH, Germany

Process Description and Characteristics

Compression molding techniques use a flow- forming process where a measured amount by mass of formable composite molding material is placed into an open compression mold and formed into the final component shape under the action of a high-speed, high-pressure press. Figure 1 shows a schematic diagram of a press mold and also how the molding material spreads to fill the mold cavity during the forming cycle. Figure 2 shows schematically a typical fully automated compression molding production line.

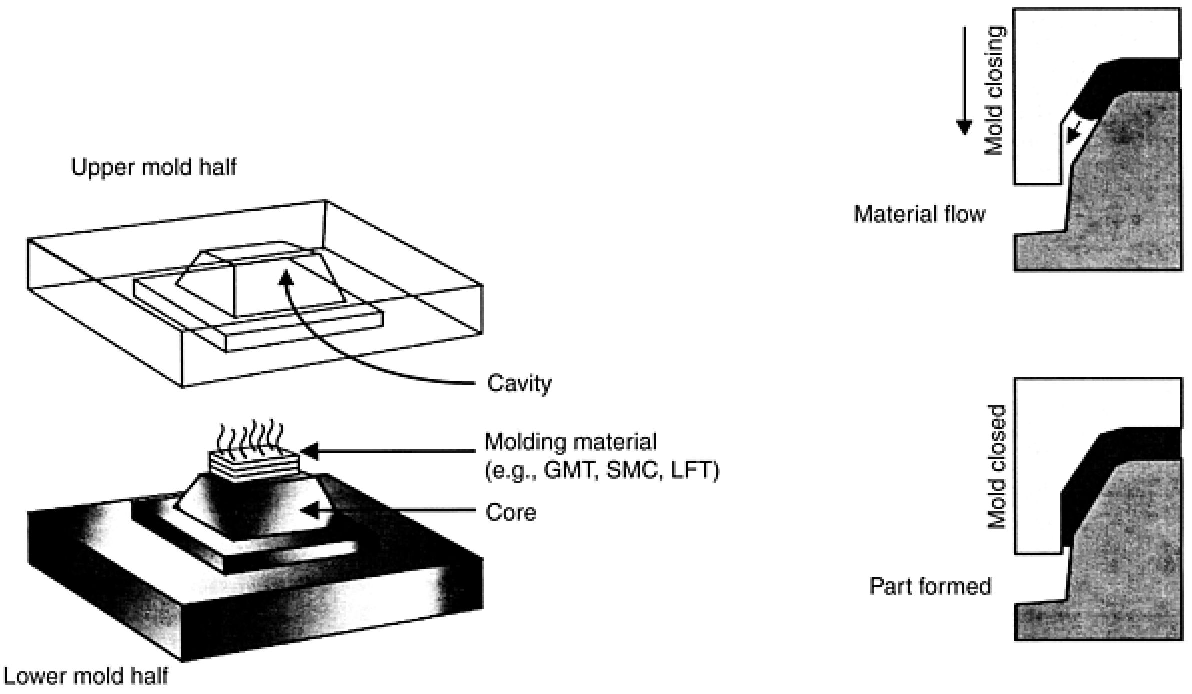

Fig. 1 Schematic diagram of mold cavity filling and part forming in compression molding

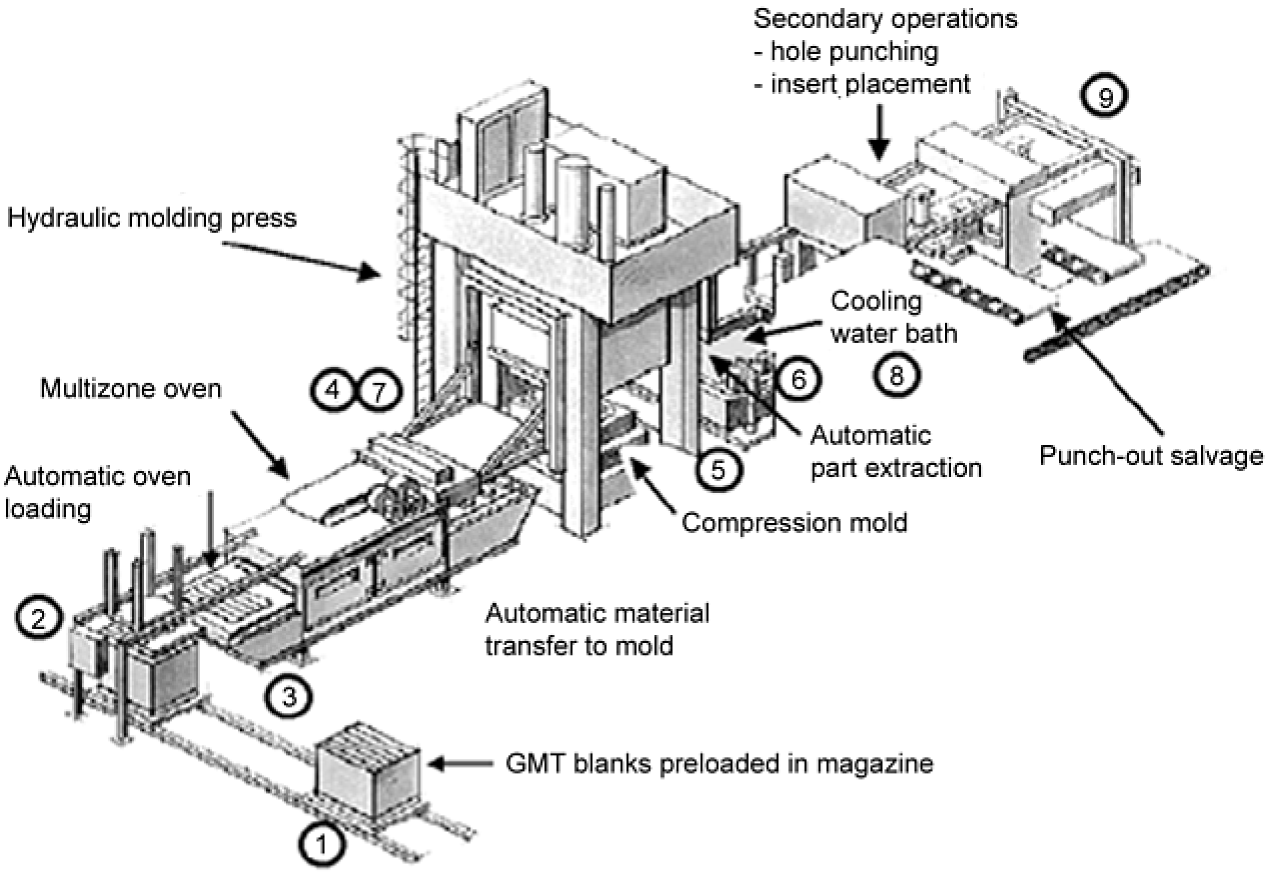

Fig. 2 Typical glass-mat thermoplastic (GMT) compression molding production line

Compression molding offers a number of attractive characteristics as a solution for particular applications. Important criteria that may influence the selection of a process are the number of parts produced, cost-effectiveness, and ability to produce physically complex parts.

Number of Parts Produced. The process hardware investments associated with compression molding become favorable from a minimum total production series of 100,000 parts per year, using single cavity tooling; for smaller series, other manufacturing technologies are often more cost-effective. In the automotive sector, annual

volumes could reach a maximum of 1,000,000 parts per annum using several molding tools in parallel for one application.
Cost-Effectiveness. The cost effectiveness of a compression molded application depends on several factors, such as hardware amortization, raw material and energy costs, recycling of trimmed waste, series size, cost of automation versus manual labor, material and machine yields, packaging, secondary operations, and so on. Examples of the economies of scale for thermoplastic process can be found in Ref 1.
Part Complexity. Compression molding applications typically exploit the same design flexibility of molded plastics, such as injection molding. Most complex geometrical shapes can be realized, including:

- Large surface areas, for example, 0.1 to 4 m^2 (1 to 40 ft^2) or more, although typically less than 1 m^2 (10 ft^2)
- Wall sections as thin as 1.3 mm (0.05 in.) (ideally with some concavity for dimensional stability)
- Complex ribs (1 to 10 mm, or 0.04 to 0.4 in., in width) and corrugated structures (Fig. 3)
- Bosses, flanges, tabs, spigots, hollow sections, massive hinges, interlocking features, snap fittings, and undercuts (Fig. 3, 4) (Ref 2)
- Molded-in features, such as metallic threaded inserts, ferrules, film hinges, compatible elastomers for sealing lips, decorative fabrics, printed films, high-quality painted surfaces (e.g., in-molded coatings), and auxiliary high- performance prepregs as local extra reinforcements (Ref 3)
- In-mold piercing of fixing holes and other openings
- Surface texturing, though the finest finishes are limited by glass fiber read-through
- Colored matrix materials in a broad range of colors for finished parts or base-coat colors for painted parts
- Welded assemblies to similar matrix materials (thermoplastics only), bonded structures, bolting, self-tapping screw bosses, snap fits, and riveting (Fig. 5)

Part Design and Process Engineering

Computer-Aided Part Design. A wide range of computer-aided design software packages is available that can be used to design and optimize composite structures. As for all fiber-reinforced composites, it is optimal to use a three-dimensional mechanical and physical property matrix to describe the material behavior. Optimal designs are found when the three-dimensional loading cases and where local material properties are known. For flow-molded parts, fiber reorientation and matrix segregation can be predicted with basic predictive software packages, in combination with flow-molding simulation software such as EXPRESS (M-Base, Aachen, Germany) (Ref 4) and CADpress (The Madison Group, Madison, WI) (Ref 5). As in most industries, a high degree of "evolution" exists whereby new applications copy and optimize features from predecessor and similar designs, thereby minimizing or eliminating complex computations. Materials suppliers and design agencies offer services and instruction ranging from simple approximations to full computational design facilities.

Process simulation is a modern and accurate technique for creating optimal designs and process productivity for large volume applications. Optimal designs are often the result of an iterative process involving a detailed, three-dimensional finite element model (FEM) that is first used for molding simulation and then for mechanical performance simulation. The model can be used to identify weak areas where failure is likely; the design of the part can then be strengthened in those regions and the model recalculated. The iteration process, assuming convergence, results in an optimal component. Processing design packages are able to predict fiber orientation, local cooling rates, and cavity pressures.

In compression molding, the properties of the final part depend significantly on the forming process itself. Important factors are flow patterns, fiber orientation, and effects such as freezing (thermoplastic material) or curing (thermoset material). These are not predictable for the engineer while designing the process and the mold; therefore, the use of modern simulation tools is very helpful and can eliminate the need for time-consuming trial-and-error methods.

One FEM-based software package that has been proven very useful is called EXPRESS, developed by the Institute for Plastics Processing (IKV) in cooperation with M-Base Engineering+Software. The program is embedded in the computer aided design and analysis environment and simulates the entire compression molding process; the software can be used to similate the curing effects of thermoset materials (sheet molding compounds/bulk molding compounds) as well as the freezing effects of thermoplastic materials (GMT/LFT). The process is made predictable, and the design of parts and molds made easier, faster, and more reliable. Geometric design and process conditions can be optimized before the mold is made.

EXPRESS enables the design engineer to study different variants and analyze the influences of input parameters at a very early stage of development. Therefore, errors in the process and failures of the final part can be predicted in the simulation, leading to shorter development time and minimized mold modifications. This enhances the quality of the final part and significantly reduces tooling and other costs.

One input parameter for the program is the part geometry. This is in the form of a 2.5D FEM mesh of the final product. Within this mesh, the positions of the molding material (known as blanks) are defined. Blanks can be multiple, overlapping, and can be applied with predefined fiber orientation. Also a very important issue for the simulation is the properties of the material. Rheological behavior, for example, is expressed by the Carreau-Model parameters as the fiber interaction coefficient determines how fibers interact with each other during flow. Data from the materials pressure-volume-temperature diagram is needed for the simulation of shrinkage and warp. Finally, processing conditions, such as mold and blank temperatures, have to be defined.

Using this input, EXPRESS calculates the position of flow fronts that can be analyzed to detect possible flow problems, such as uneven filling, weld lines, and air entrapments. When the flow simulation is done, a nonisothermal EXPRESS calculation generates the temperature distribution during the process. By considering the freezing effects when processing thermoplastic material, the program can also compute the resulting flow channel height throughout the mold, including the detection of early freezing problem areas. Another important result is the fiber orientation. This gives information about the non-isotropic character of the final part, because this is a very important item when processing long-fiber-reinforced plastics. Part warp is calculated from the predicted fiber orientation distribution and the cooling and curing (thermoset material) effects on shrinkage. This provides the engineer with useful information about the dimension stability of the final part. The program also calculates using anisotropic material properties, which can be imported to other computer-aided engineering processors for structural analysis of the part. Figure 6 shows a typical graphical output from EXPRESS.

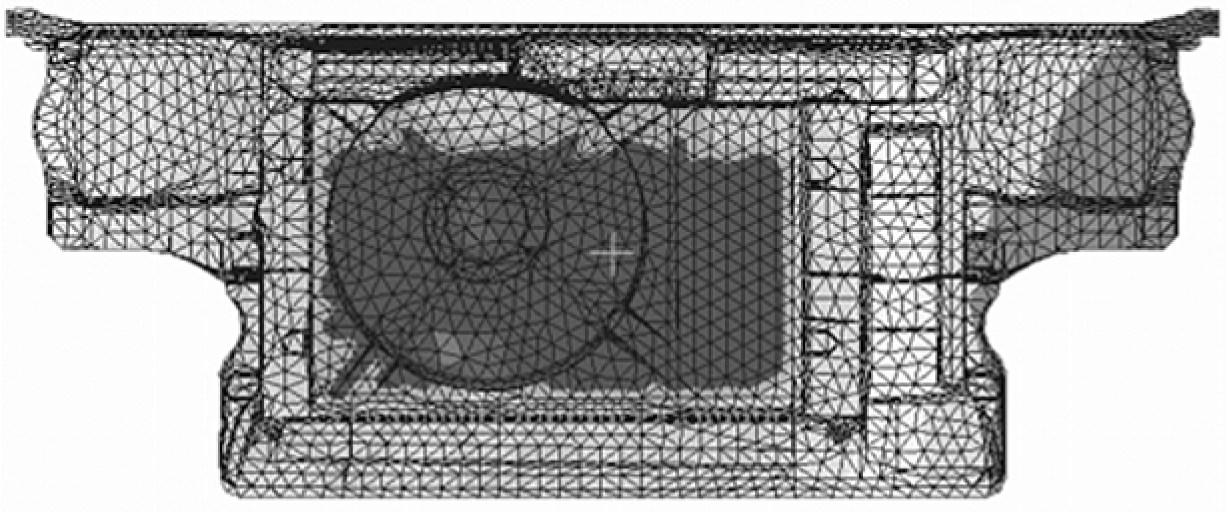

Fig. 6 Example of mold-filling simulation output from EXPRESS compression molding process simulation software

Design for Manufacturing. Traditionally, the compression molding industry grew from a number of entrepreneurs in the 1960s and 1970s who first molded thermoset parts and later adapted their equipment for thermoplastics, which became commercially available in the 1980s. As the industry matured, companies and applications grew rapidly during the 1990s, and several major machinery manufacturers from the metal forming and plastic injection molding sectors installed the first complete turn-key production facilities. Smaller molders also grew their own infrastructure, building on in-house engineering expertise, and many novel process patents were applied for. Today, several major equipment suppliers have established the most flexible manufacturing systems adapted to the key compression molding processes. Figure 2 shows the main features of a typical compression molding production line.

Compression Molding of Glass Mat Thermoplastics

Process Description

GMT compression molding is a continuous line process for the manufacture of large-volume composite parts. The process is most economical when it is run continuously to make one type of part without need to change the process conditions or mold tool. The steps in the process are described subsequently and in Fig. 2.

Step 1: Loading the Blanks. GMT blanks, purchased from one of the leading materials suppliers, arrive at the molder and are repacked into custom mobile "magazines" in a configuration that orients the blanks in the appropriate pattern for being loaded into the GMT heating oven (Fig. 7).

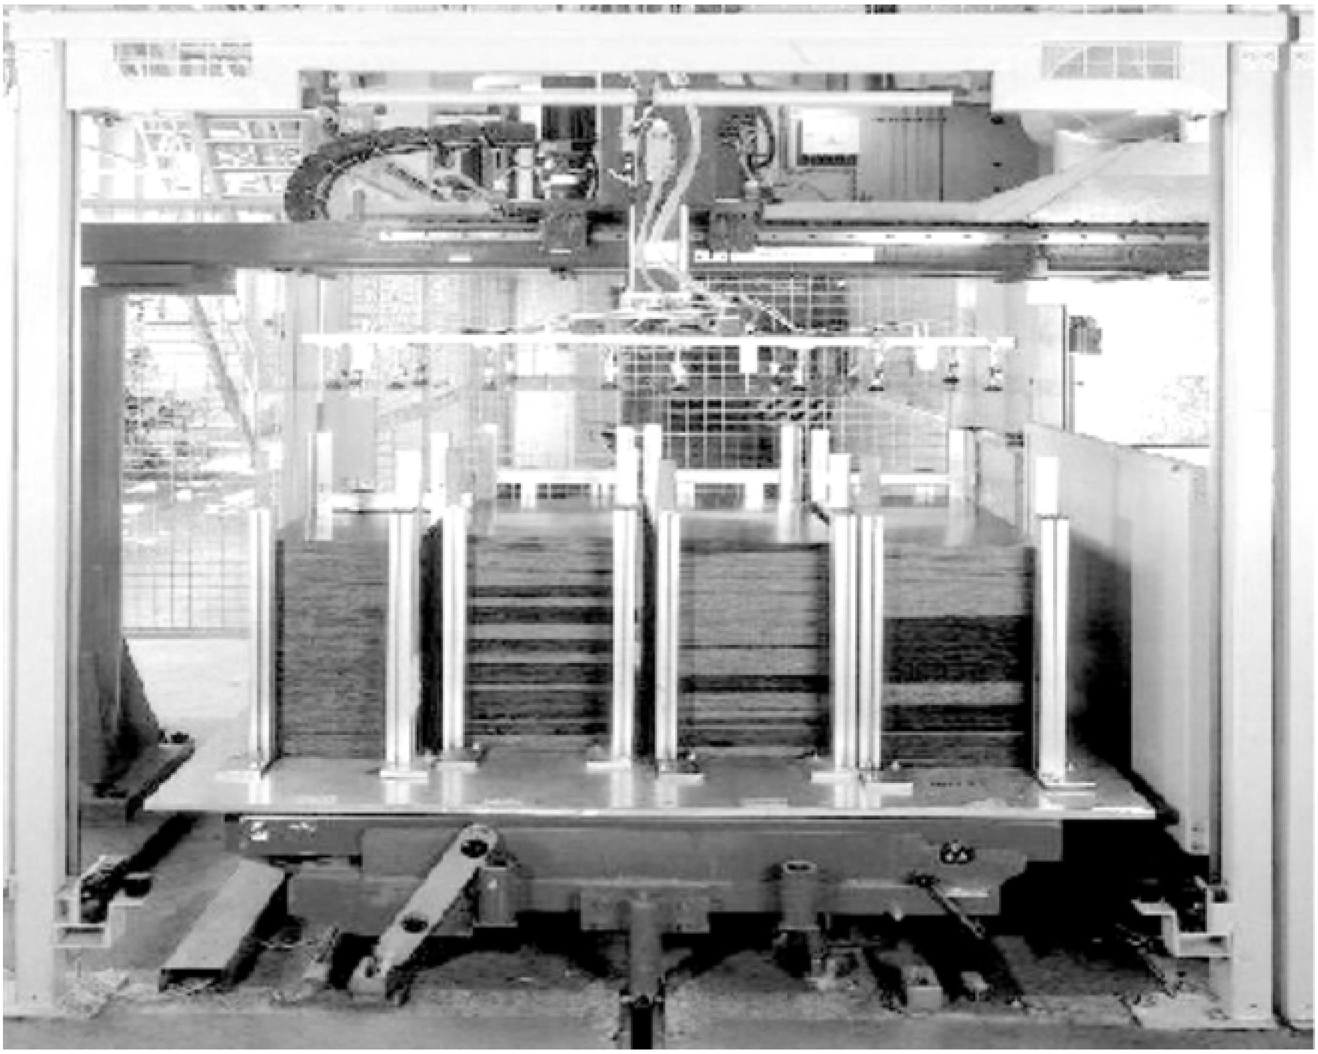

Fig. 7 GMT compression molding blanks under pick-up-and-place two-dimensional robot

Step 2: Delivery of Blanks to the Oven. The magazines are then rolled into place in front of the blank heating oven, guided by tracks, buffers, and end stops so as to position the blanks accurately underneath a two-dimensional pick- up-and-place robot system. At this point, the blanks are lifted by vacuum-assisted suction cups by the robot and placed down on an open steel wire mesh belt in the configuration appropriate to the charge pattern to be placed in the mold (Fig. 7).

Step 3: Heating ("Lofting") of the Blanks. The GMT blanks are transported on the wire mesh belt through a multizone heating oven. These ovens are typically long-wave infrared (IR) heating ovens. More recently, other methods of heating have become available, such as hot air impingement ovens, forced convection air ovens, ultraviolet flash ovens, contact ovens, and combination convection/IR ovens. Ovens are typically electrically powered; however, gas- flame heating is popular, especially in France. All have their relative merits; for example, hot air or convection ovens allow blanks of various thickness to be heated simultaneously at one temperature set point. This can be achieved with IR ovens, too, with locally adjusted oven segments for material of different thickness. Some ovens use internal pyrometers to feed back the temperature of the blank to the oven process controller, which adjusts the power distribution to optimize the heating conditions. The fundamentals of GMT heating are discussed in several technical papers (Ref 6).

A typical GMT oven cycle is shown in Fig. 8. In the first step, blanks are inserted cold and can be heated very aggressively until they absorb sufficient heat to approach the melting region of the thermoplastic matrix. Just before melting, the material should be moved to a cooler oven zone of lower radiation intensity, where the energy may stabilize through the material. During this phase, a lesser amount of heat is added, however sufficient to bring the material just above the melting point of the matrix. At the moment the matrix melts, the glass mat within the laminate begins to revert back to its original three-dimensional form in a process known as "lofting." Here the material thickness rises by a factor of two or three back to the original lofted height of the glass mats before lamination. In this state, the material now contains a lot of hot air, which is an insulating

material and has poor heat conductivity. The material then moves on to the next oven zone and is further heated to the appropriate molding temperature about 40 °C (70 °F) above the melting point of the material.

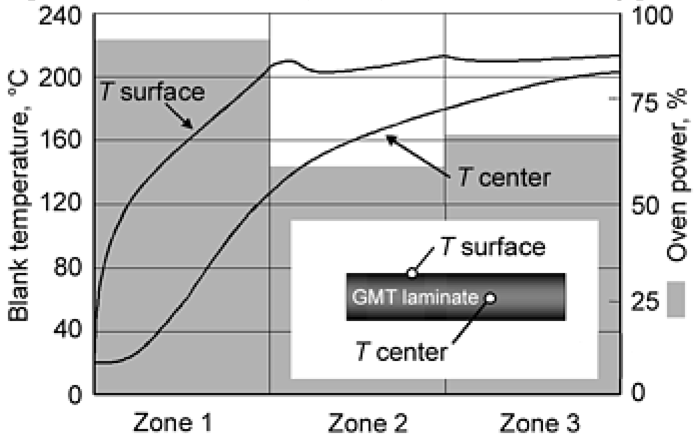

Fig. 8 Typical three-zone infrared oven cycle for heating of GMT blanks

Step 4: Transfer to the Mold. Once lofted and at the appropriate molding temperature, the material is transferred from the exit of the oven to the open mold cavity. This is typically automated, using needle grabber systems as shown in Fig. 9. Some novel patents exist in this area (Ref 7).

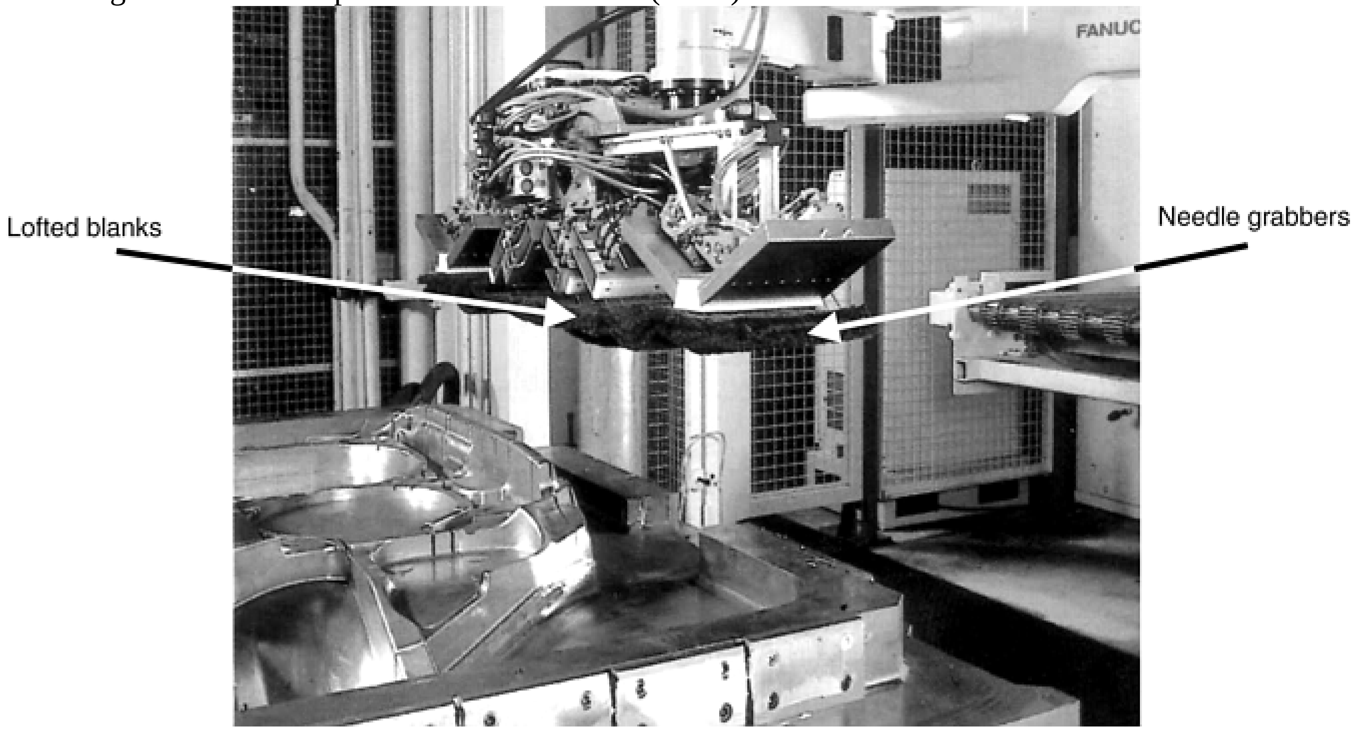

Fig. 9 Hot lofted GMT blanks being transferred from oven belt to the mold

Step 5: Part Forming. As soon as the blanks are placed in the mold, the loading grabber is rapidly withdrawn, and the mold closes under the action of a high-speed hydraulic press. The press cycle begins with a high-velocity, controlled closing cycle. Once the closing velocity can no longer be maintained because the viscoelastic resistance caused by the flowing material is so great, the press is programmed to switch to force control, and the mold closes further at a slower speed until the cavity is filled and the part solidified and formed. The graph in Fig. 10 shows the variation in cooling time with part wall thickness. Press cycle design is the task of experts; however, it can be systematically developed with the aid of in-mold pressure sensors, which allow the programmer to link the viscoelastic behavior of the material in the mold to the hydraulic constraints of the press (Ref 8).

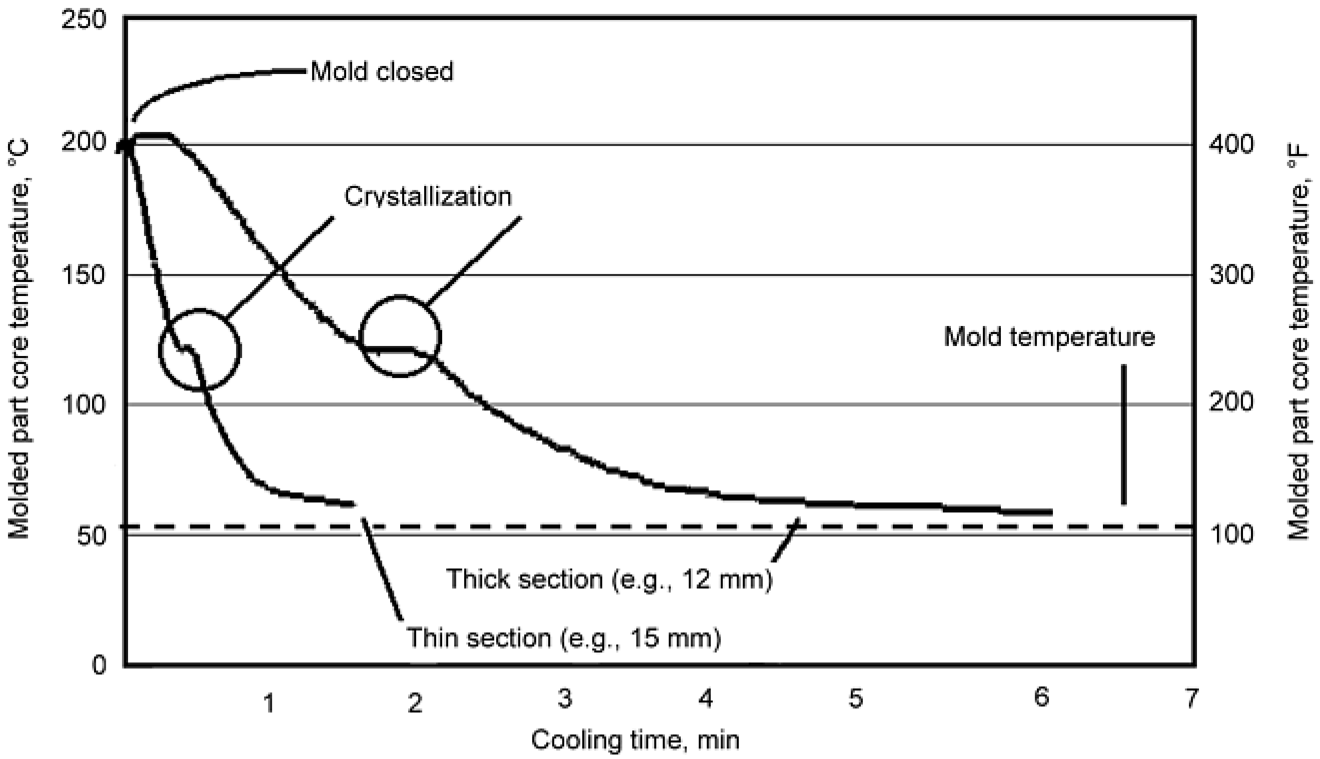

Fig. 10 Cooling curves for GMT moldings

Step 6: Part Ejection. Once formed and solidified, the press opens and the part remains in one-half of the mold cavity, ready for ejection and transfer to secondary operations further downstream.

Due to their shape, some molded parts need to be forced to remain in one-half of the mold to enable a controlled removal. For such parts, small undercuts are strategically designed into the part to ensure that it remains on one-half of the mold tool. The part is then ejected from the cavity with classical ejector pins, sometimes in combination with air poppet valves. In this ejection mode, the part is also forced/lifted over the undercuts designed to hold the part in the cavity. For major undercut features, moving cores or slides need to be pulled out of their cavity or special feature before ejection can occur.

Step 7: Recharging. As soon as the part is ejected, the sliding cores are repositioned in the cavity, a new charge of material is laid into the mold as described in step 4, and the molding cycle is repeated.

Step 8: Immediate Postprocessing. Parts hot from the press can, if sufficiently dimensionally stable, be conveyed on to a deburring station. If controlled shrinkage is needed, parts can be fixed to a cooling jig, sometimes water-cooled in a bath, or sprayed with waterjets to remove the heat from the part and allow it to take on the desired final shape (Ref 9).

Step 9: Secondary Operations. Parts then continue on to other downstream operations, such as drilling, milling, water-jet cutting, and so on, where further complex and contour features are added. Waste collected from these secondary operations can be reprocessed either by the molder in an LFT or injection molding process, or returned to the material suppliers who add small amounts of such waste into their GMT laminates (Ref 10, 11).

Process Optimization. The steps mentioned previously constitute a typical GMT compression molding cycle. State-of-the-art molding equipment is available that can produce thin wall-section moldings in cycle times below 30 s, using double cooling circuits in the mold, which allows the fastest removal of heat during solidification.

Multiple cavity tooling is also used to enable optimal use of the commercially available presses. It can also be advantageous for moldings, which are consumed in pairs, for example, left and right parts, front and rear, or parts that connect to each other.

A technical troubleshooting guide (Ref 12) explains in detail how many of the items in steps 1 to 9 can be optimized, and Ref 13 focuses on dimensional stability.

Mold Tooling

Compression molds are mostly machined from steel. They are designed for a vertical closing action whereby the molding material flows to fill the cavity at the start of the molding cycle. A robust and multi-stage dynamic guide system is used in combination with a parallel controlled hydraulic press to ensure the mold closes bringing the material under the high pressures (5 to 30 MPa, or 1 to 4 ksi). Such high pressures are needed to move the reinforcement structure throughout the cavity and ensure a high degree of air expulsion and composite consolidation. The main features of a compression mold are shown in Fig. 11. Advanced processes, such as in-mold coating (Ref 14) and vacuum-assisted molding are practiced in a few cases where very high-quality surface finishes are required.

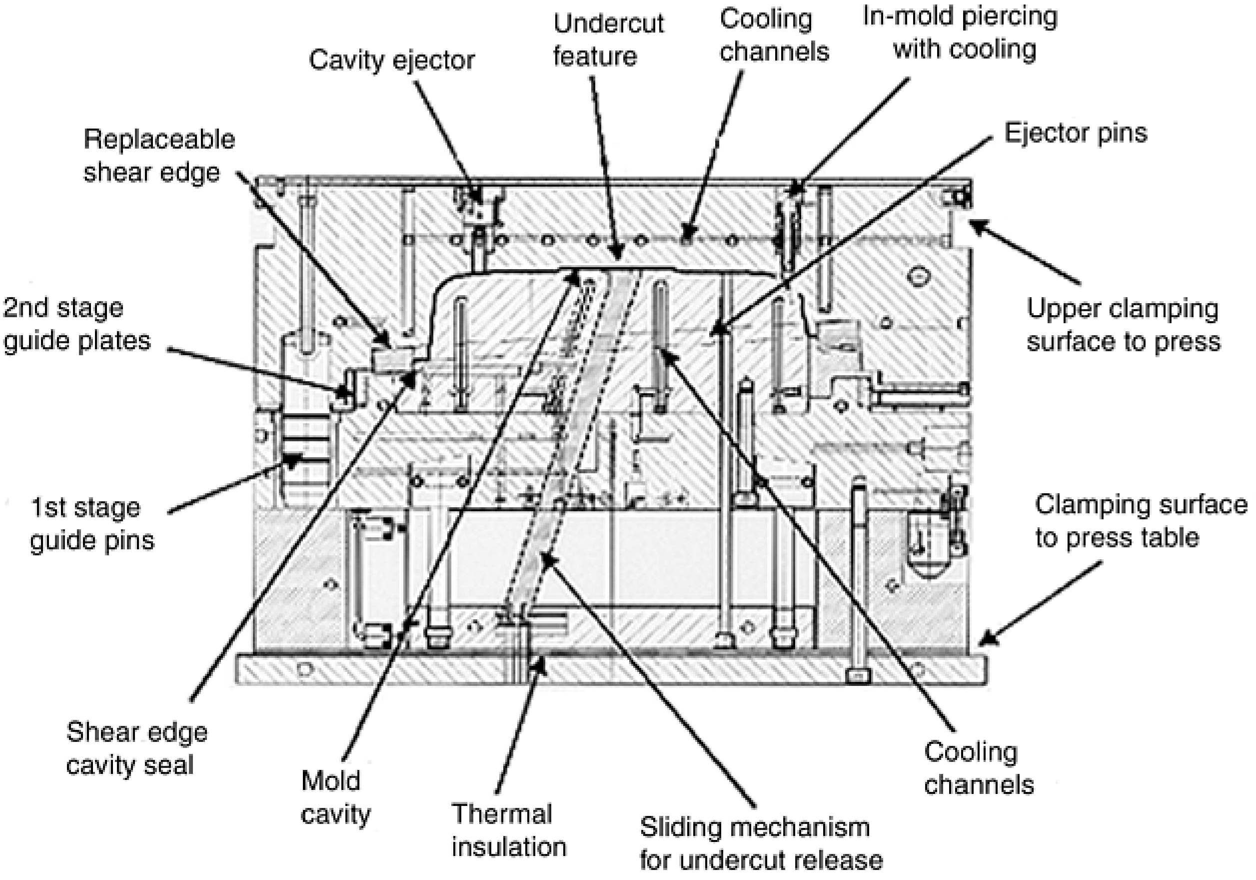

Fig. 11 Typical features of a compression mold (example shown is a mold design for forming a spare tire wheel well)

Secondary Operations

The most modern molds incorporate some trimming and hole-punching operations to take place in the mold cavity during molding (Ref 9). Once molded, parts typically undergo some or all of the following secondary operations often in the following order:

- Cooling in air or postcrystallization clamped to a cooling jig, sometimes under water or waterjet spray
- Deburring of flash from shear edges (e.g., manual knife tools, milling, routing, and flaming)
- Hole punching, drilling, contour milling, waterjet trimming, or laser trimming
- Plasma, corona, or fluoridation surface priming for adhesive bonding (Ref 15) and/or painting of parts
- Addition of subcomponents, for example, clip-on nuts, bolts/washers, crimp fixations, and so on
- Welding for thermoplastics to other compatible components, and bonding for thermosets to other materials

Tertiary Operations

Once the molded part has completed secondary operations, it can, in many cases be directly fitted or applied to its end-use application at the original equipment manufacturer (OEM). More often, a compression-molded part

is part of a subassembly or multifunctional module. In such cases, the molder has additional manufacturing facilities on site to complete the operations. Alternatively the part is passed on to a tier 1 supplier who further integrates the part into a module assembly that is supplied to the OEM, who is often able to eliminate many detailed, complex process steps. Such operations include:

- Application of soft-touch foam layers, noise absorption layers (e.g., instrument panels and underbody shields)
- Bonding/welding to other components
- Fixation of subassemblies, for example, automobile front-end components (Ref 16)

GMT Market Information

A typical value chain for compression molded composites is shown in Fig. 12, which represents the tier supplier system typical to the automotive industry. Here a decentralized supply infrastructure exploits a wealth of global knowledge and competitive creativity, which can include design, predevelopment, and manufacture of parts and optimized processes, which make the most cost- effective composite solutions. Following governmental legislation in the 1990s, a functional infrastructure was created for recycling of process reject and end-of-life compression molded parts. Original equipment manufacturers, molders, and raw materials suppliers are motivated to reprocess waste arising from all steps of the compression molding process. Most applications contain some reprocessed production waste products, ranging from a few percent up to 50% recyclate (Ref 10).

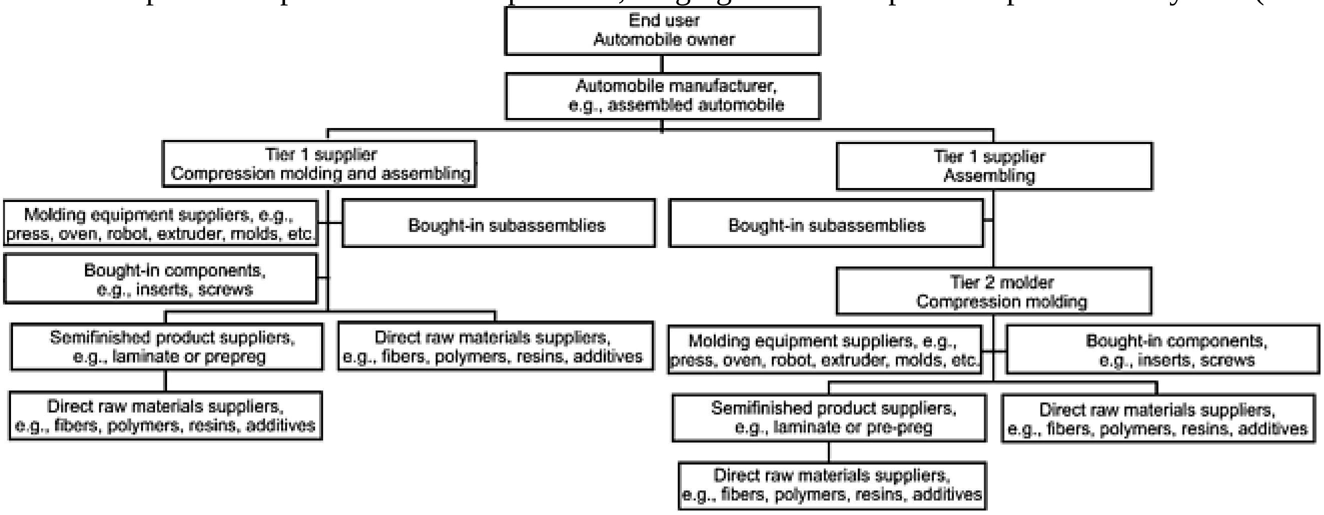

Fig. 12 Value chain for compression molding parts assembly

The GMT market grew during the 1990s, with an average volume growth rate of 21% per year. In 2000, production volume was 39,000 tons in Europe and 12,000 tons in North America. The growth in the 1990s was driven by a variety of technical and economic factors. Automotive applications were expanded in a number of areas (Ref 17, 18), especially where compression molded parts were able to replace steel structures. The production volume growth rate was lower at the end of the 1990s, despite the wider use of GMT in a growing number of applications. This was attributed to molded parts becoming lighter and thinner due to the following factors:

- Improved blank weight and flow consistency, giving lower reject rate
- Improved mold filling, given by higher flow materials
- Improved predictive design capabilities, maximizing materials utilization
- Design “evolution,” new applications exploiting advantages of predecessor designs
- Over-dimensioning of old designs being corrected, based on field performance data

GMT Material Advances

The rapid growth of the GMT industry has been firmly supported by materials development, which continues to move the frontiers of materials performance to new levels (Ref 1, 19, and 20). This allows parts to be designed and manufactured with improved economics and reduced system weight. These improved materials give direct savings on molded part costs due to advances in the following areas:

- *Development of materials with high flow capability:* The availability of very high flow materials allows parts to be designed with thinner walls and larger surface areas, thus reducing part weight and molding cycle times.
- *Development of improved glass mat technologies:* Glass mat reinforcements have developed to the point where they are very highly consistent in glass fiber distribution, blank weight distribution, local mechanical properties, and maximum load conditions.
- *Optimized matching of matrix and reinforcement:* The flow performance is a synergistic combination of fiber mobility and the viscoelastic characteristics of the thermoplastic matrix. Appropriate matching of the matrix and reinforcement allows predictable mechanical and physical properties, increased production part yields, design flexibility with detailed features, and wider process windows in secondary operations, such as adhesive bonding and hole punching.

Evolution of GMT Materials. The evolution of glass-fiber mat reinforcements can be illustrated by the development and use of four main types (Fig. 13):

- Needled continuous glass-fiber mat was a technology of the late 1980s and early 1990s. When judged by more recent standards, this material offers low consistency and low flow mobility. Applications were often robustly dimensioned and molded with long cycle times despite their good price-performance system costs. Such products remain popular because users have built up trust and experience with them. However, they are increasingly being superseded by more advanced technologies.
- Needled chopped glass-fiber mat (dry layed) was the most widely used glass mat technology in the 1990s. Through improved fiber dispersion techniques and double-sided needling methods, fiber mobility, blank weight consistency, and mechanical properties were significantly improved in both mean value and variation.
- Chopped fiber glass mat (wet layed) became much more widely used during the later 1990s, and further improvements were made to blank weight and fiber content consistency, as well as fiber mobility and mechanical property performance.
- Unidirectional/random hybrid glass mat (dry layed, needled) is a highly directionalized reinforcement structure made from a combination of unidirectional rovings and orthotropic fibers. Such composites have been successfully used in several generations of vehicle bumper beams, seat backs, and knee bolsters, where a highly directionalized reinforcement is desired in locations where high loads are carried in known directions.

Figure 14 shows x-ray photographs taken from rib fill testing of the first three types of glass mat reinforcement structures.

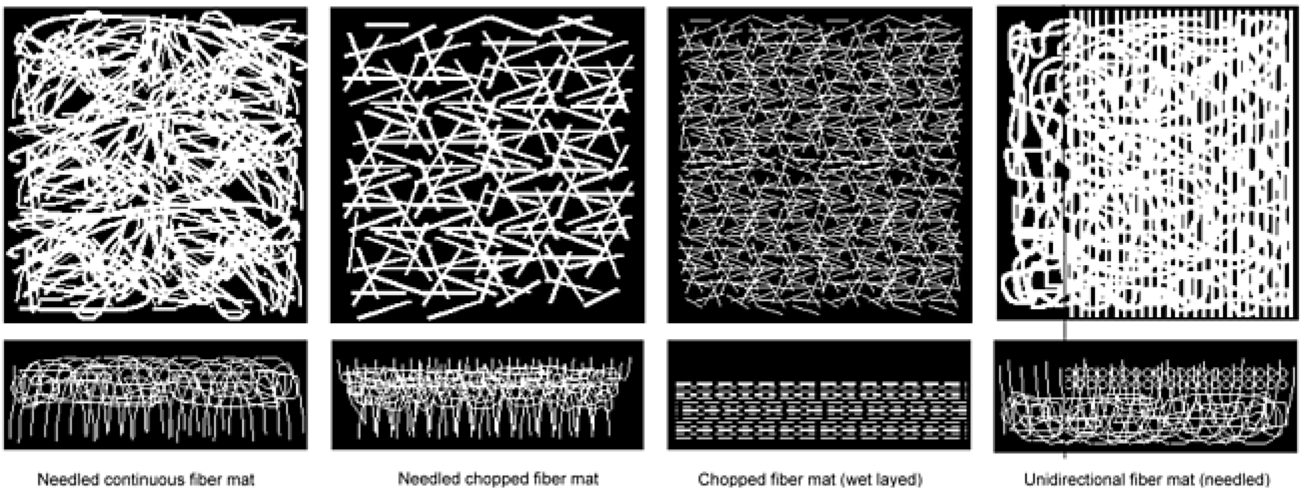

Fig. 13 GMT glass-fiber mat reinforcement types

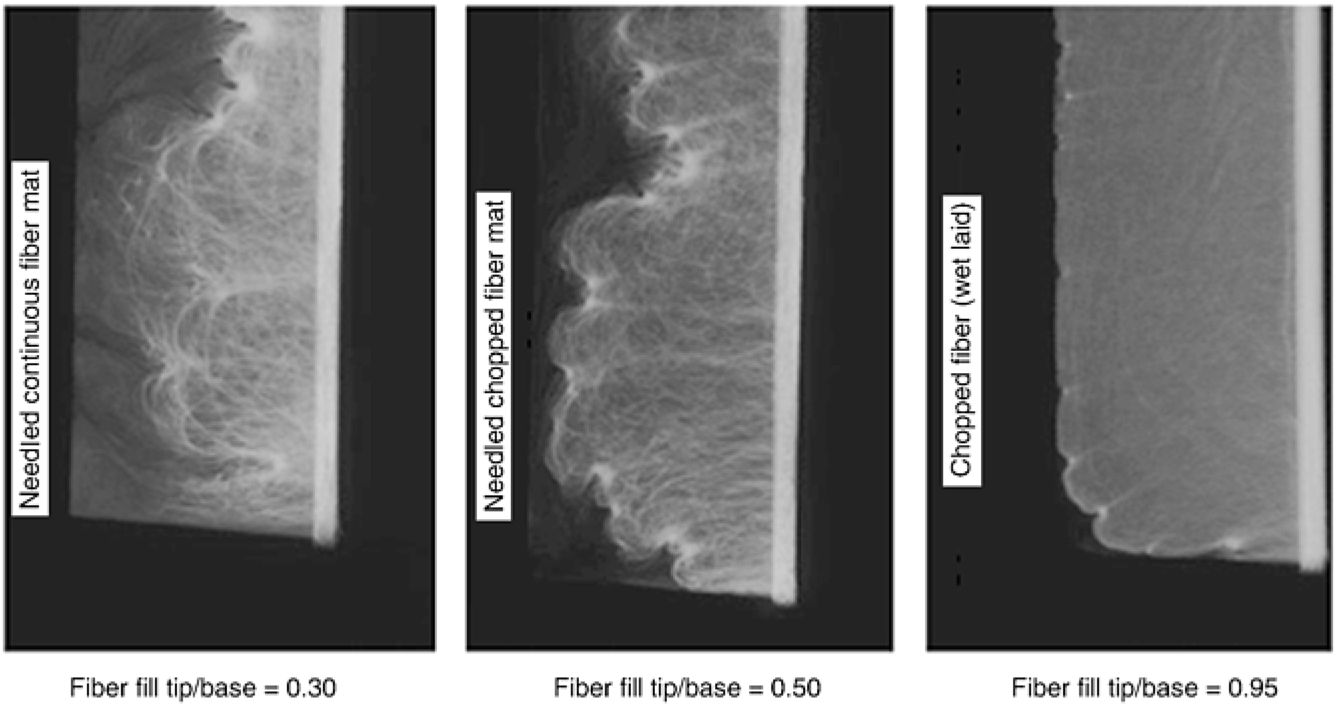

Fig. 14 Fiber mobility in deep ribs (3 × 38 mm, or 0.1 × 1.5 in.) for three different GMT reinforcement types

Parallel to these main generations of glass fiber mats are several significant hybrid reinforcements systems, such as:

- *Glass-fiber mineral-filled systems:* give a combination of high elasticity and toughness in high-energy-absorbing bumper beams (Ref 21)
- *Very high flow laminates:* allow designs with minimum wall thickness and deep, thin rib structures while maintaining high property consistency in engine noise shields
- *Fabric-reinforced mat systems:* woven fabrics made of glass fiber or polymeric fiber laminated together with mobile mats, which allow locally extremely high loads to be absorbed and dissipated through a molded composite structure. These are used in off-road sports- utility vehicles (Ref 22) for underbody shields, bumper beams, and structural door modules.

GMT Recycling and Reprocessing

The GMT materials process is well suited to incorporate high usage of GMT recyclate. Materials maintain their consistency in molded parts, with all the advantages of a long-fiber- enforced composite allowing an attractive economic and environmental package ideal for the large volume turnovers of the automotive industry. Such materials have typically very high laminate consistency and extremely good flow performance. Matrix degradation is not a significant problem because materials are restabilized online during lamination.

Reference 10 reviews typical mechanical and performance properties of the previous groups, and Ref 11 and 23 give examples of practical processes used for reprocessing GMT.

Molder and postconsumer GMT recyclate is also reprocessed outside of the traditional compression molding industry, for example in LFT and injection molding processes. Figure 15 shows an example of a heavy-duty grating module system widely used in animal pen flooring. Based on polypropylene, this system gives excellent chemical resistance, long-term performance, and a rapid payback when compared to other competing thermoset molded or pultruded systems. Other examples include railway sleepers, and electrical insulators, and plastic lumber for "street furniture."

Compression Molding of Long-Fiber Thermoplastics

Around 1990, long-fiber-reinforced granulate (LFG) materials were introduced into the market (Ref 24). These granulate materials consist of glass-fiber bundles that are impregnated with thermoplastic material. The material is manufactured in a thermoplastic pultrusion process where the glass-fiber bundles are cut into lengths of 12.5, 25, and 50 mm (0.5, 1, and 2 in.). The material has to be melted again in an extruder before molding. The molten charge is then placed into the mold. This can also be regarded as a very costly process, especially when considering the process parameter configuration (e.g., low rotational screw speed to maintain the fiber length of the granulate). For this reason, especially in the automotive industry, there was a demand for significant cost savings with similar or better material properties of the component. To reach this target, a direct process technology, avoiding the semifinished product manufacture and the double heating, was developed as a so-called long-fiber-reinforced thermoplastic (LFT) process. The direct LFT process contains continuous fibers (e.g., glass) and a thermoplastic matrix (e.g., polypropylene), which are fed into an extruder. The plasticated material is then extruded and cut. Afterwards, the plasticated material is directly placed into the compression mold and then formed into a component. In comparison to traditional processes (GMT, LFG, and SMC), the individual discontinuous production process steps are eliminated.

LFT Materials

For the direct LFT process, any kind of thermoplastic material can be used. The only requirement is that the compound tolerates a short time exposure to oxygen. For high-volume production, mainly polypropylene is used. The reason is that LFT penetrates the existing GMT market, which is based on polypropylene (PP). Other thermoplastic materials (e.g., polyamide, acrylonitrile-styrene-acrylate, and acrylonitrile- butadiene-styrene) can be used if required.

For the reinforcement, each type of glass roving (e.g., E-glass) with a compatible sizing suitable to the used thermoplastic matrix can be used. To get a good impregnation, a fiber of 1200 to 2400 tex usually is used for series production. Additional information can be found in the articles, "Glass Fibers" and "Thermoplastic Resins" in this Volume.

LFT Compression Molding Process

A customized extruder is used for virgin material. After plastication and homogenization of the thermoplastic pellets, the fibers are preimpregnated and cut into length in a proprietary process, followed by further homogenization at moderate back pressure (Fig. 16). Then the plasticated material charge is cut and transported to a handling device that feeds the molding press (Ref 25).

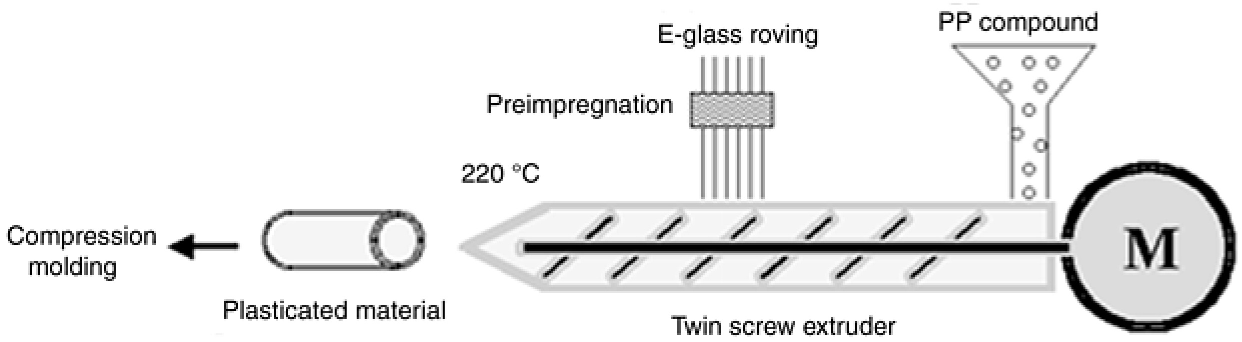

Fig. 16 Direct LFT plastication process

A continuous stream of compounded material leaves the extrusion line at a temperature of approximately 220 °C (430 °F) in the case of PP. The endless material output is cut to the correct length to deliver the molding input at desired charge weight. Equipment design and operating parameters are critical to maximize the molded component properties.

If recycled material is being used, scrap parts or cut-outs are first shredded to chips by using, for example, a single screw mill (Fig. 17). The maximum size of the chips (Fig. 18) depends on the size of the second extruder in the process chain. The recyclate then is plasticated in the second extruder and fed back into the virgin stream. This is a fully closed-loop recycling system.

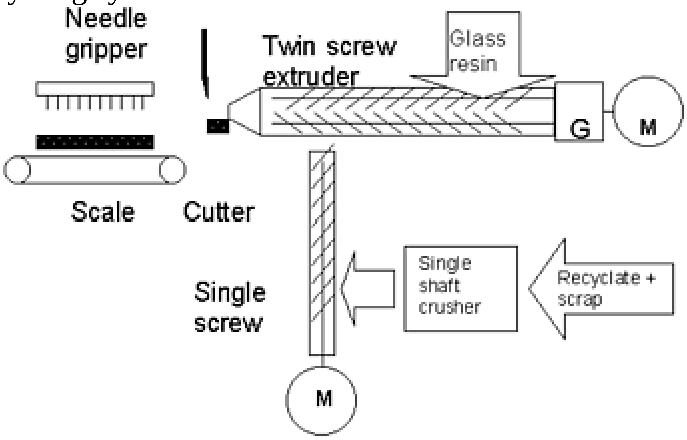

Fig. 17 LFT line including incorporation of recyclate

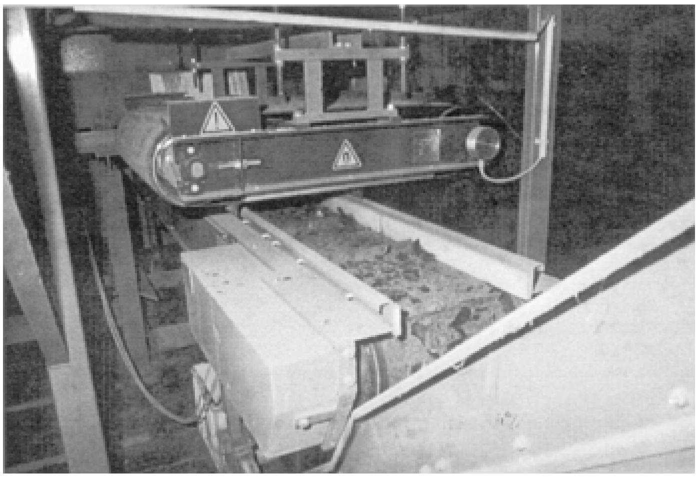

Fig. 18 Recyclate feedback in closed-loop LTF compression molding

LFT Applications

Typical applications can be found in the automotive industry for components such as front end support structures (e.g., Volkswagen Passat, Fig. 19a), floor panel covers (e.g., Skoda Fabia), trunk boxes, and battery covers. A nonautomotive application for LFT is a railroad car container.

Figure 19(b) illustrates the layout of a fully automated production line for the manufacture of the Volkswagen Passat B5 internal front end incorporating closed-loop recycling. Raw materials and recyclate are fed into separate extruders. Then, the plasticated material is placed into the compression mold. After molding, the untrimmed component is cooled before going on to secondary operations. After that, further holes and features are cut out in a four-step waterjet cutting process. The component is then washed and trimmed before transfer to the subcomponent assembly line. Several rivets are integrated into the component to ensure easy assembly (for example, of lamps, fan, and locking mechanism). As of 2000, the manufacturer was producing approximately 500,000 units per year. The molded component weight is nominally 4.2 kg (9.3lb); approximately 20% of the charge weight consists of cut-outs, which are recycled and reused.

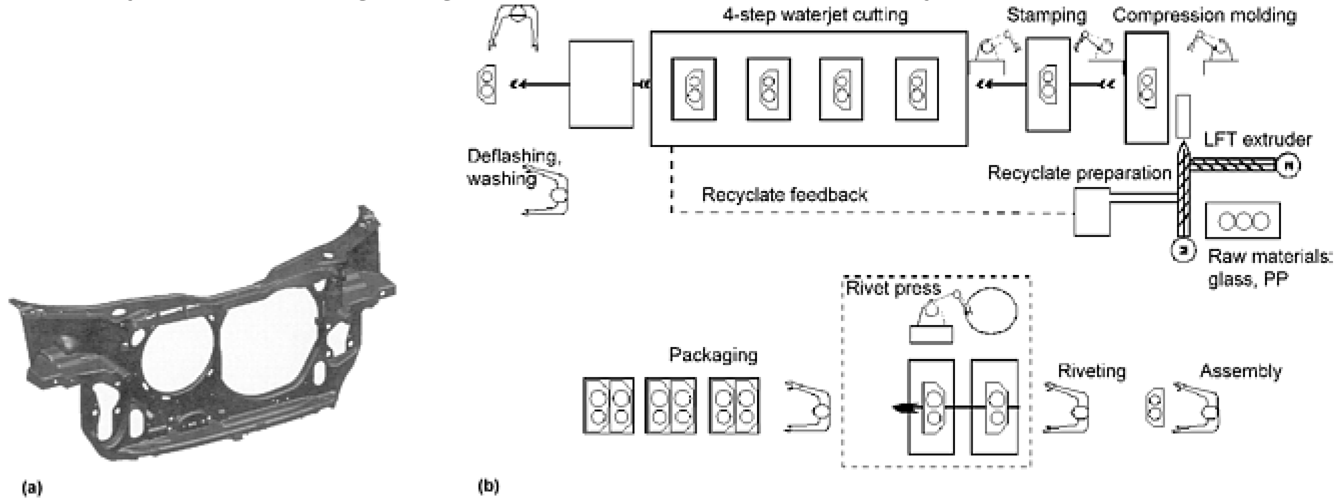

Fig. 19 Automobile front end technical support structure manufactured by LFT compression molding. (a) Volkswagen B5 Passat front end. (b) Production line

Comparison of LFT with GMT and SMC

One of the main targets in the development of LMT compression molding was to achieve similar or better materials properties than those of GMT materials. One of the main criteria influencing the mechanical properties is the fiber length. The fiber length distribution in LFT is illustrated in Fig. 20, which indicates a peak fiber length of approximately 50 mm (2 in.). The LFT fiber-length distribution ensures optimal values for elastic modulus, tensile strength, and impact toughness (Ref 26). Traditionally, GMT is produced with a constant fiber length of 25 or 50 mm (1 or 2 in.) and often treated with a needle punching process. The mechanical properties of GMT, LFT, and SMC testpieces are compared in Table 1. The glass fiber volume fractions for the GMT and LFT testpieces are identical; the LFT material includes 30% recyclate. In comparison with GMT, LFT material features superior modulus of elasticity due to the more effective use of the longer fibers (>30 mm, or 1.2 in.). On the other hand, LFT materials exhibit poorer energy absorption/dissipation behavior than GMT materials.

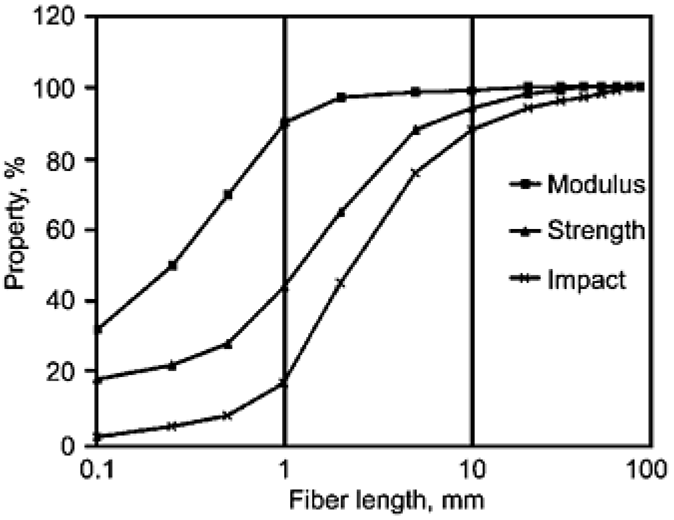

Fig. 20 Relationship between fiber length and properties for LFT materials

Table 1 Comparative properties of LFT, GMT, and SMC compression moldings

Property	LFT	GMT	SMC
Glass fiber content, wt%	40	40	30
Recyclate content, wt%	30	…	5
Tensile strength, MPa (ksi)	60 (8.7)	65 (9.4)	60 (8.7)
Tensile modulus, GPa (10^6 psi)	7.2 (1.0)	6.1 (0.9)	9.5 (1.4)
Flexural strength, MPa (ksi)	110 (16)	110 (16)	160 (23)
Flexural modulus, GPa (10^6 psi)	5.4 (0.8)	4.1 (0.6)	8.9 (1.3)
Impact strength, kJ/m^2	60	75	70
Density, g/cm^3	1.21	1.21	1.80

Note: All values measured on a testpiece taken from an automotive structural front end

The advantage of the LFT process and the LFT material can be summarized as follows: The process is much more cost-effective than GMT, not only due to the elimination of single process steps, but also because less manpower is needed for production. Also, cycle times have been reduced by 15% as a result of a better flowability of the plasticated material in comparison with the GMT. A further advantage of the LFT process is the component surface, where LFT avoids white spots of naked fibers occasionally found in GMT parts that result from poorly impregnated glass fibers, whereas the impregnation quality in the LFT process is superior.

GMT processing is also known for mold tool wear. The reason for this disadvantage is erosion caused by diesel effects, which occurs much less during LFT processing. Machinery stops also reduce the probability of undesirable materials degradation using the direct LFT extrusion process. A production line stop in GMT necessitates clearing the oven. This can also entail a high amount of material waste in the start-up procedure of the process. In extreme cases, waste has been reduced from about 6% with GMT to about 1% with LFT.

Some of the properties and characteristics of SMC, GMT, and LFT are compared in a spiderweb graph (Fig. 21). The economic efficiency can be calculated as a function of the component weight (Ref 1). Basis for the cost comparison of SMC, GMT and LFT is an annual production volume of 100,000 parts and a required molding pressure of 1,500 tons. All values illustrated in Fig. 22 are related to GMT, which was set to 100%. For lightweight parts (approximately 1 kg, or 2 lb), GMT shows cost advantages. LFT achieves break-even at a component weight of approximately 1.5 kg (3 lb), where LFT is favorable compared with GMT component costs.

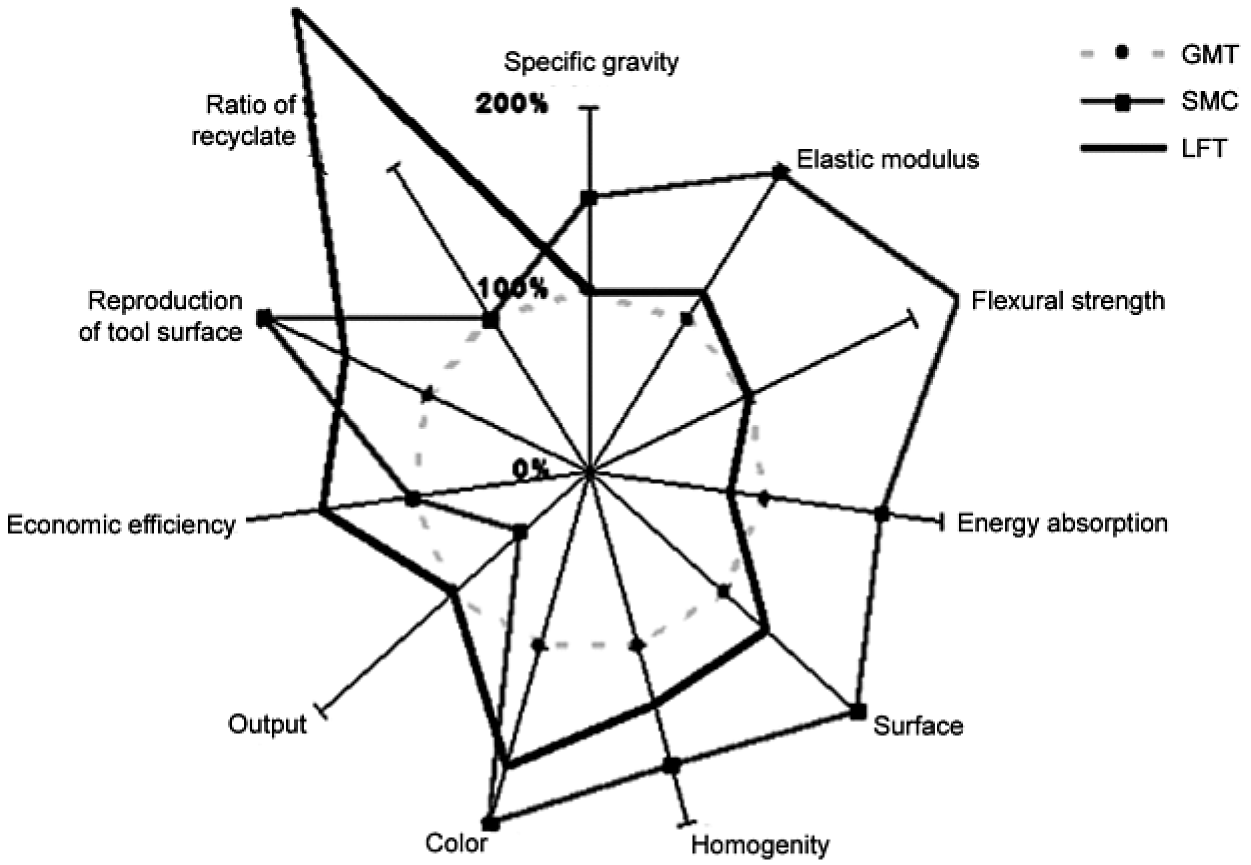

Fig. 21 Comparison of GMT, LFT, and SMC compression molding processes and materials properties

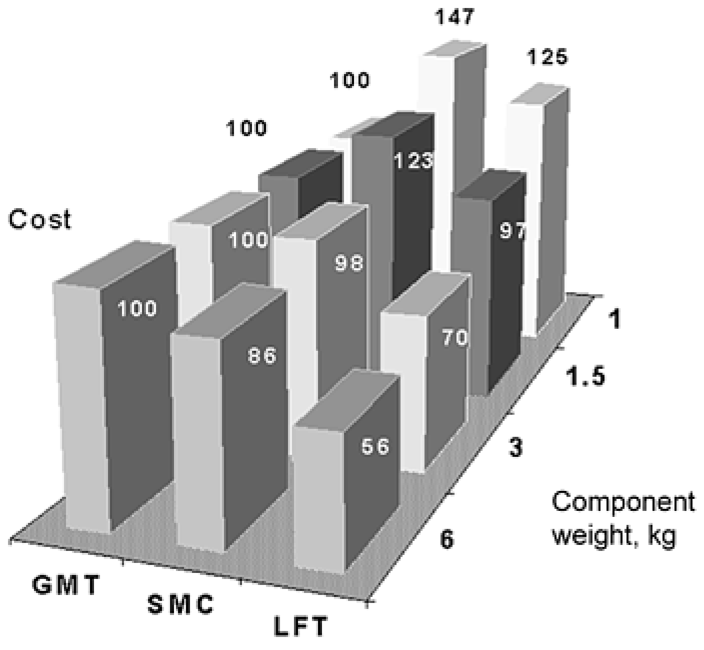

Fig. 22 Relative costs of GMT, LFT, and SMC compression molded parts

Advances in LFT

The direct LFT technology was successfully introduced into the market by Menzolit-Fibron in 1997 with the Volkswagen Passat B5 front end. Today, there are many applications for the technology.

Currently, in the front end market, there is a tendency that requires metal inserts to fulfill the increased crash requirements. In this field, injection molded hybrid parts with metal inserts are also realizable (Ref 27), where LFT also fulfills these standards by using metal inserts.

Due to the high flexibility of the LFT process, it is very easy to investigate alternative fiber and matrix materials, for example, natural fiber reinforcements (e.g., flax, hemp, sisal) (Ref 28) required by the automotive industry. There is still a high potential for material and process improvements for new successful applications manufactured in the direct LFT process.

---

Compression Molding of Sheet Molding Compounds

The range of applications for SMCs comprises molded parts with a weight of a few grams up to several kilograms. The processing methods used, are injection molding or compression molding and depend on the size, complexity of shape design, strength requirements, or cost calculation of the molded part. The largest share of the material is processed in compression molding. Molded parts are used in many different sectors of the industry. The range of application stretches from molded electrical insulation parts to force-transmitting and force-absorbing molded parts to painted automobile body panels with a “Class A” surface finish. The excellent flow performance of SMC permits the integration of parts in the design of molded parts, which has a cost-saving effect in the production of molded parts.

The composition of the SMC material has a special status among plastics, because the share of organic components, such as resins and additives, may be reduced to a share of 25%, depending on the formulations used. The remaining shares are inorganic and consist of aggregates (fillers) and reinforcing glass fibers. A typical composition might consist of 25% unsaturated polyester (UP) resin, 25% glass fiber, and 50% filler. This resource-saving material composition of SMC is completely in line with modern ideas of what a material should be.

The following information shows how versatile the design possibility of reinforcing-fiber structures can be, and how materials characteristics can be influenced by them. The range of application variations used in SMC extend from random-fiber reinforcement (25 and 50 mm, or 1 and 2 in., fiber length) all the way to unidirectional glass-fiber reinforcement.

Additional information on SMCs is provided in the article “Molding Compounds” in this Volume.

Development of SMCs

In the 1950s, the possibility of thickening UP resins with alkaline earth oxides and hydroxides was discovered in the United States and the Federal Republic of Germany. This proved to be the foundation for the production of SMC. Initially, the material was manufactured by means of impregnating glass-fiber mats on simple two-roll systems. However, crack-free components with good surface finishes could only be manufactured later after the discovery of the vibration- reducing effect of polyethylene powder in the UP resin matrix. Applications in the electrical industry soon followed.

A new impregnation system with top-mounted wide cutters for glass-fiber rovings was developed in the United States, in order to avoid the use of expensive glass-fiber mats, to rationalize the manufacturing process, and to reduce the cost of the material. The American designation for sheet molding compound (SMC) was adopted as an international standard.

As early as the 1960s, cable distribution cabinets, strip lighting, and housings for electrical appliances were already being manufactured using SMC. Owing to the efficient molding technique, components able to carry higher loads soon followed, such as cylinder head covers or oil pan covers for diesel traction engines.

Studies of the effects of thermoplastics dissolved in styrene in UP resins led to the development of low-profile unsaturated polyester (LP- UP) resins in the 1970s. For the first time, this material was used successfully for the production of automobile body panels with an acceptable surface finish quality.

Various front ends of automobiles in the United States and the removable sunroof of the VW-Porsche 914 in Europe were the first serial production parts made from LP-SMC.

Due to the relatively high finishing costs after painting in cases of large-area SMC automobile body panels, the application of the material made slow progress in Europe. Only with the advent of the use of the IMC method in the early 1980s and the later introduction of the vacuum compression molding technique did more applications for passenger cars follow in Europe, such as, for example, the engine hood of the Citroen BX. However, a faster pace of development was set in the field of interior and exterior parts for commercial vehicles.

The high-strength SMC materials developed in the early 1980s which featured a combination of unidirectional glass-fiber strands, random fibers, and a fiber share of 60% by weight, resulted in the use of the material for the bumpers of several new automobile models.

Material Characteristics of SMCs

SMC consists of a resin matrix into which reinforcing fibers are embedded. The composition of the matrix is adapted to the required characteristic profile. The characteristics of the resin matrix that can be influenced include:

- Resistance to chemicals
- Resistance to weathering
- Surface structure
- Flexibility (module of elasticity)
- Dyeability
- Shrinkage
- Flame retardation
- Strength characteristics (pressure and impact resistance)
- Dynamic characteristics
- Surface hardness

The following characteristics can be influenced through reinforcing fibers(distribution and fiber structure):

- Strength and rigidity characteristics (depending on the fiber distribution and the predominant direction of the fibers)
- Shrinkage/warping (depending on the fiber distribution, the predominant direction of the fibers, or flow orientation)

The SMC material can be adapted to the specified requirement profile by changing its structure or its composition

SMC Matrix Resins

SMC is a variable system of components, which, depending on the intended purpose of use, may be composed according to their physical and mechanical characteristics and thus, is suitable for use in a wide range of applications. A wide selection of UP resins, additives, hardeners, fillers, and reinforcing fiber structures is available for the optimization of SMC formulations. A standard SMC paste formula is:

Component	Parts
Unsaturated polyester resin	**100**
Monostyrene	**10**
Hardener	**1**
Inhibitor	**Depends on reactivity and flowability**
Pigment	**Depends on color desired**
Fillers	**80–210**
Thermoplastic additive	**10**
Mold release agent	**5**
Thickener	**1.5**

Orthophthalic acid, isophthalic acid, terephthalic acid, and bisphenol-A resins are used as UP resins. Vinyl ester resins, which do not belong to the group of UP resins, have opened up another area of application for SMC, especially in the case of molded parts being subjected to dynamic or sudden impact loads.

With the development of the low-shrink (LS) and low-profile (LP) UP resins, it is now possible to manufacture molded parts with an excellent surface finish quality. Curing shrinkage has been reduced, and dimensional stability, dimensional accuracy, and surface finish quality have been improved significantly. Sensitivity to microcracking and sink marks above ribs or bosses has been reduced considerably.

Unsaturated polyester resins shrink during curing by about 6 to 9% by volume. Through the addition of 20 to 40% by weight of a high polymer dissolved in styrene, the curing speed during warm curing is reduced or eliminated completely. The chemical reaction usual for highly filled polymers for UP resins may be assumed as similar to unfilled systems. However, the kind of reaction as well as the start and duration of the reaction will be different.

Based on its curing shrinkage, SMC is classified in three groups (Table 2). Standard UP resins are always used in cases where mechanical or physical characteristics are given higher priority over surface finish quality. Dyeing is possible in a wide range of colors.

Table 2 Classification of structural molding compounds according to their shrinkage behavior

SMC	**Additive**	**Condition in the resin**	Polymerization shrinkage, %
Standard SMC	Polyethylene powder	Two phases	**0.15–0.3**
Low-shrink SMC (LS-SMC)	Solution of polystyrene	Two phases	**0.06–0.14**
	Polycaprolactol in styrene monomer	Two phases	**0.06–0.14**
Low-profile SMC (LP-SMC)	Solution of polymethyl methacrylate (PMMA)	Two phases	**≥0.04**
	Polyvinyl acetate (PVAC)	Single phase	**≥0.04**
	Liquid rubber	Two phases	**≥0.04**
	Saturated polyester	Single phase	**≥0.04**
	Cellulose acetobutyrate in styrene monomer	**Single phase**	**≥0.04**

Low-shrink UP resins, like standard UP resins, can be dyed with pigments. However, the available range of colors is somewhat limited due to the two phases typical for this type of resin system. The shrinkage, which is

reduced in comparison to standard resins, has a positive effect on the accuracy and warpage of the molded part as well as the quality of the surface finish.

Low-profile UP resins do not exhibit any shrinkage or even show an increase in volume. These resins cannot be dyed uniformly due to the whitening effect occurring during curing. This type of resin is often used in applications of molded parts that are later spray painted.

Monostyrene Additive. The addition of monostyrene to the formulation serves the purpose of reducing the viscosity of the resin paste in order to achieve good wetting of the glass strands and in order to add the styrene to the formulation, which escapes during manufacturing and processing.

Hardener. The hardener consists of an organic peroxide, which has a curing effect (polymerization) on the UP resin in the compression mold under supply of heat. In order to achieve optimal curing conditions for the molded part, several organic peroxides of different types may be combined.

Inhibitors. The addition of an inhibitor is intended to serve a two-fold purpose. On the one hand, it provides good shelf-life properties over a prolonged period of time for the resin matrix, and on the other hand, it can be used to vary the flow time of the SMC in the mold by modifying the concentration.

Fillers are used for the purpose of reducing thermal shrinkage, resulting in an improvement of the quality of the surface finish of the molded parts. Also, the transport of the reinforcing fibers during the flow process in the mold is improved, and the sensitivity of the matrix to cracking during the curing process is reduced. The most frequently used fillers for SMC formulations are calcium carbonate, aluminum trihydrate, and kaolin.

Calcium carbonates exhibit a low oil-absorption rate and thus may be added in a relatively large amounts to UP resins. They reduce thermal shrinkage and impart a smooth surface finish to the molded parts.

Aluminum trihydrate is a noncombustible, non-water soluble, and nontoxic white powder. When mixed with the UP resin, it adds flame- retardant characteristics to that material. The effectiveness of aluminum trihydrate is based on the disintegration into aluminum oxide and water:

$$Al_2O_33 \cdot 3H_2O \rightarrow Al_2O_3 + H_2O$$

The disintegration begins at 180 °C (350 °F) and ends at 600 °C (1100 °F). This is a strong endothermic process with 1970 kJ/kg (470 cal/ g) aluminum trihydrate. The endothermic reaction cools the flame contact area and keeps it, with a sufficiently high share of aluminum trihydrate, below the disintegration temperature of the polymers. The water being released under the reaction reduces the combustion speed. Aluminum trihydrates as fillers have a flame-retardant effect, do not release any halogens when exposed to a flame, and exhibit a low level of flue gas density.

Kaolins are mainly used for molded parts in which high priority is given to chemical resistance.

Thermoplastic Additive. A finely ground polyethylene powder is added to standard SMC as a low shrink agent. Aside from improved flow characteristics of SMC, polyethylene reduces the shrinkage of the UP resins, which has a positive effect on the sensitivity to cracking and the quality of the surface finish of the molded parts.

Mold Release Agent. To guarantee trouble- free removal of the molded parts from the mold, parting compounds are added to the SMC paste. As a rule, these consist of zinc or calcium stearates. The function principle of stearates can be traced back to a change in the solubility between unhardened and hardened UP resins. During the curing process, the stearate at the surface of the UP resin becomes incompatible and causes the formation of a molecular zinc stearate layer between the molded part and the surface of the mold.

Thickeners. Thickening of UP resins is achieved with alkaline earth oxides or hydroxides (MgO, $Mg(OH)_2$, CaO, $Ca(OH)_2$) via the carboxyl groups of the UP resin (Ref 30). Thickening of UP resin with CaO is, in comparison to MgO, only possible with the addition of H_2O. Due to the sensitivity of the thickening behavior with CaO, the overall content of H_2O in the UP resin must be monitored and kept as constant as possible. In case of UP resins exhibiting poor thickening behavior, the addition of H_2O may also be required when MgO is used. The advantage of UP resin thickened with CaO lies in the lower absorption of H_2O when the molded parts are stored in water.

The so-called maturation time of SMC in order to increase viscosity can, depending on the formula and the storage temperature, be between one day and several weeks. Suitable compression molding viscosities depend on the application and are between 20 and 80 × 10^6 mPa · s. The thickening results in a nonsticking and relatively rigid semifinished SMC product, which is easy to handle and provides good resin paste and glass fiber transport during the flow process and avoids the concentration of resin.

Other Additives. More wear-resistant surface finishes can be achieved through the addition of solid microglass beads. The UP resin shrinks during curing, causing the glass beads to protrude above the surface. Owing to their hardness, the resistance to wear can be improved in this way.

For the purpose of reducing the density of SMC, a portion of the fillers may be replaced with hollow microglass beads. The addition of conductive carbon black (soot) improves the electrical conductivity.
Matrix Preparation. Mixing of the resin paste may take place according to different procedures:

- Batch-oriented mixing and continual addition of a thickening agent
- Continual mixing process for all components of the resin paste

SMC materials manufactured in Europe are mainly manufactured in batch-oriented mixing processes of the raw material components and subsequent continual addition of the thickening agent. This processing method has proven itself to be best suited in the manufacture of many different SMC formulas. Dissolvers and so-called turbulence mixers are used as mixing tools in the batch-oriented mixing process.
The resin compound is mixed in large containers, which are then transported to the SMC impregnation system. There, the resin paste is extracted by means of a pump, while the thickening agent is added continually. Mixing takes place either in a static mixer or in a dynamic mixing system.
The continual mixing method is used in production processes in which the entire demand of the production can be satisfied with one or only a few different SMC formulas.

SMC Material Manufacture

- The production of SMC comprises the following processing stages:
- Paste preparation
- Dosage of two- or three-component paste
- Creation of a reinforcing fiber structure and its impregnation and packaging
- Thickening of the paste

Paste Preparation. In a batch-oriented preparation of paste, the individual raw materials are stored in large containers, silos, or tanks, and the prescribed quantities are metered to the mixing devices by computer-controlled dosing stations. Low- or high-shear mixers, depending on the process, are used to mix the resin paste. In the case of high-shear mixers, high temperatures are generated in the shear area, which requires a fine balance of the hardener/inhibitor combination as well as the selection of hardener in order to prevent a premature hardener reaction during the mixing process. Low-shear mixers process the paste mixture much more gently, which is evident by considerably lower paste temperatures. In many cases, the low-shear mixer is equipped with an additional downstream homogenizer in order to dissolve any possibly existing agglomerations. If, in the case of resin pastes intended for dyeing, the dye paste is added during the preparation of the paste, it is possible to process the paste in a two-component paste dosage system in the SMC plant. It is common practice to work without any addition of dye paste when preparing the resin paste, in order to reduce the cleaning time of the containers and mixing aggregates and to omit the time-consuming weighing of the dye pastes.
Paste Dosage. From the paste preparation, the paste is transported in large containers to the paste dosing station, which is installed adjacent to the SMC plant. Aside from the commonly used two-component dosing stations, the use of three-component dosing stations has become more widespread.
The function of two-component dosing stations is to continually control the dosage of the resin paste and the thickening agent and, in the case of three-component systems, the dye paste as well. A sensor system monitors the accuracy of the dosage. The accuracy of the dosage is either controlled gravimetrically or according to the Coriolis principle. The individual flows from the dosing station are mixed either in a static mixing unit or in a dynamic mixer.
SMC Impregnation. The construction of the SMC plant consists of the flat-surface dosing of the resin paste by means of a squeegee, the cutter for the purpose of cutting and dosing in reinforcing fibers, and the impregnation unit (Fig. 23). Prior to entering the squeegee box, a thickener is added to the resin in a two-component pump system, and the two components are mixed with each other. One squeegee each is used to apply the resin paste to the surface of films, which enclose the chopped glass reinforcing fibers from above and below. The fiber rovings are metered according to the drawing speed of the cutter and cut to a length of 25 or 50 mm (1 or 2 in.). The two-dimensional, unoriented staple fiber structure is created in a free-fall from the cutter onto the film coated with resin paste.

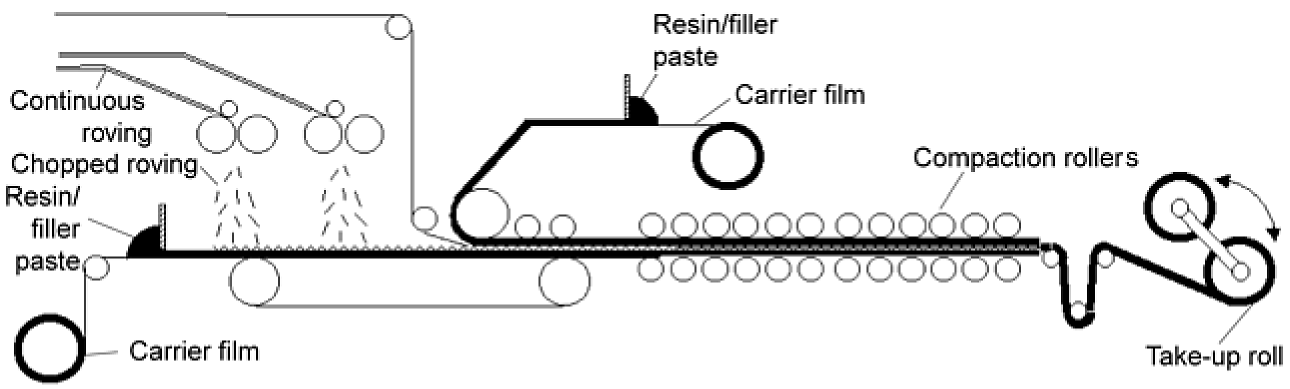

Fig. 23 Schematic diagram of the SMC impregnating system

The impregnating unit, consisting of twin belts and rollers, presses the resin paste applied to both films between the glass strands. At the end of the process, the impregnated SMC is wound up in coils or stored in containers in zigzag layers.

Cutting the Reinforcing Fibers. Cutting of the textile glass rovings takes place on a wide cutter. The essential components of the cutter are the feed roller, the rubber roller and the cutter roller. In this type of cutter (Fig. 24), the fiber is not really cut, but actually broken (Ref 31). The filament bundles are, depending on the roving quality, more or less connected to each other through the sizing material on the fibers. This cohesion between individual filaments of the fiber strands must be opened mechanically using a deflector device prior to the cutting procedure.

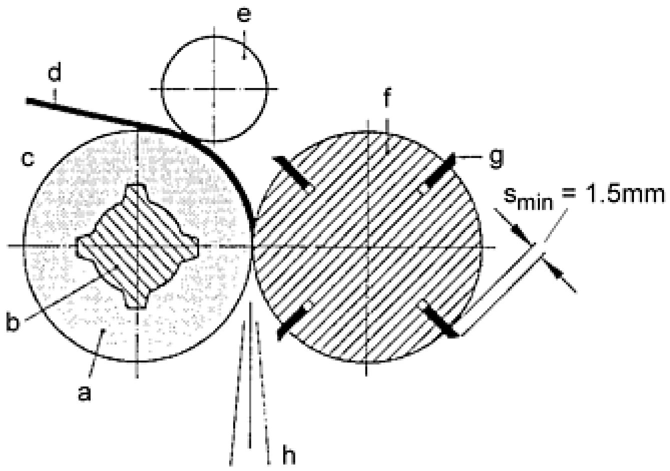

Fig. 24 Schematic diagram of cutting with feed rollers. (a) Rubber roller. (b) Hub. (c) Feed roller. (d) Fiber. (e) Tensioning roller. (f) Cutting roller. (g) Cutting edge. (h) Cut fibers

Technology of Modern SMC Facilities. System engineering of modern SMC manufacture has reached a high technical standard. The light construction of earlier systems has given way to more massive designs. This prevents elastic deformations in components of the systems, which may be caused by the forces occurring when the output capacity of the systems is increased. This has a positive effect on semifinished products made from SMC.

The quality of the SMC, is monitored by sensors that read, record, and further process the following parameters of a control circuit in the control unit of the SMC plant:

- Film tension
- Filling level at the squeegees
- Layer thickness of resin paste
- Distribution of reinforcing fibers
- SMC thickness
- Squeegee gap adjustment
- Winding tension of the SMC when winding into coils

The technology of the systems has been continually revised and improved in recent years (Ref 32). The following system components were the focal points in these endeavors:

- Impregnating section
- Automatic feed of winding cores
- Automatic packaging of SMC rolls
- Automatic transport of rolls to the maturation chamber

The impregnating units were extended, reinforced, and equipped with a high level of power reserves in order to improve the impregnating capabilities. Parallel guides guarantee an even thickness of the SMC.
Automatic feeding of winding cores and automatic packaging of the SMC rolls can also contribute to reducing the personnel requirements in production.
Immediately after packaging, the rolls are transported to the maturation chamber, which, for space-saving reasons, permits a continual vertical as well as horizontal throughput. The doctor blade control has been refined; however, the basic principle has not changed.
Maturation Process. Four of the rolls or pallets are placed on a pallet and then allowed to thicken for several hours in the maturation chamber. The matrix is thickened up to the point when the resin paste reaches the viscosity required for the flow process in the mold, the two films can be peeled off, and the SMC is ready for processing, free of sticking.

Fiber Reinforcement Structures

Impregnating systems with wide cutters for glass fiber roving are used for the manufacture of SMC. Randomly arranged glass strands 25 to 50 mm (1 to 2 in.) in length are used as reinforcement fibers. The initial products are textile glass rovings with 2400 or 4800 tex (weight in grams per 1000 meters). A roving consists of a grouping of several filament bundles with a fiber fineness (or strand titer) of 40 to 80 tex. The filament diameter is nominally 14 µm.
The structure of the SMC fiber is manufactured in the SMC plant and determines, aside from the fiber content, the mechanical characteristics. A distinction can be made between the following fiber structures:

- Randomly arranged chopped glass strands, mostly of a length of 25 to 50 mm (1 to 2 in.). For the purpose of influencing the flow characteristics in the mold as well as the surface finish quality, mixtures using fibers of both 25 and 50 mm (1 and 2 in.) can be used. The material designation for SMC with this fiber structure (Fig. 25a) is SMC-R (R = random).
- Randomly arranged chopped glass strands and continuous glass fiber strands with asymmetric fiber structure. The material designation for this structure (Fig. 25b) is SMC-C (C = continuous).

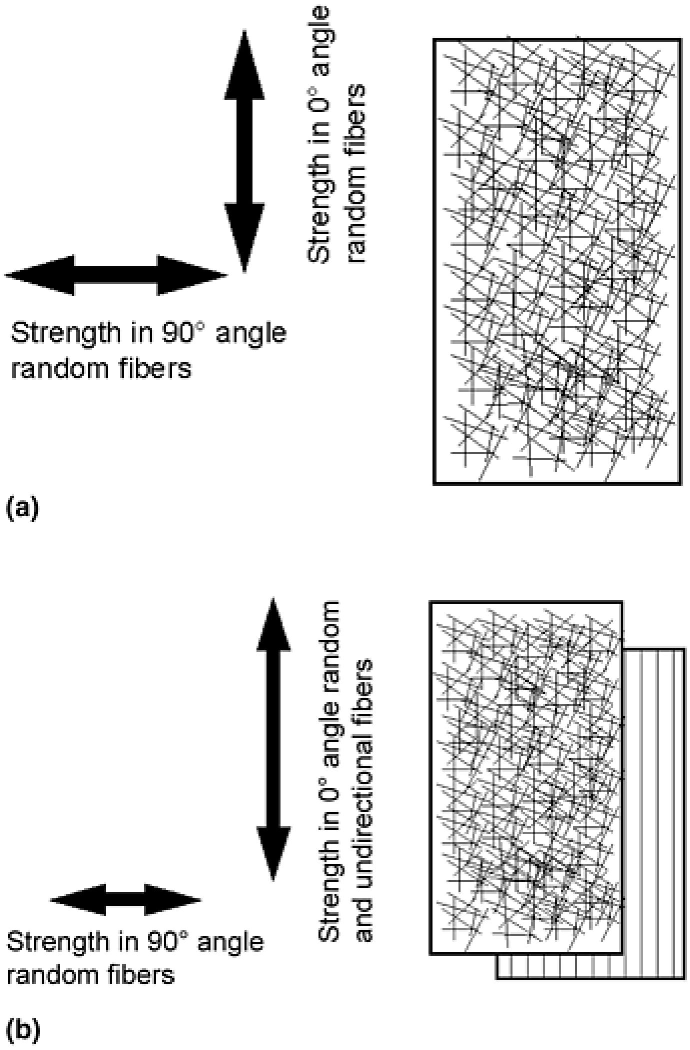

Fig. 25 Fiber patterns in SMC materials (fiber length 25 or 50 mm, or 1 or 2 in). (a) SMC with random reinforcing fibers (SMC-R). (b) SMC with random and unidirectional reinforcing fibers (SMC-C)

The SMC used in general applications is SMC-R. Of the three previously described fiber structures it is the one that allows the use of the simplest processing techniques due to its even flow characteristics. SMC-C is used for achieving a high level of mechanical properties. Due to the harder-to-control flow processes and material shrinkage, these materials are used predominantly for load-bearing components requiring higher levels of strength. These fiber structures are also known as multifiber structures.

SMC with Random Fiber Structure. The mechanical properties in SMC are predominantly determined by the structure of the reinforcing fibers. A two-dimensional, random fiber with largely even strength characteristics in *x* and *y* direction is most common. Changes toward one preferred direction, known as orientation, may occur during the flow process in the mold. In this respect, the design of the SMC blanks (dimensions, shape, number of layers) as well as the arrangement of the blank in the mold is of great significance. The aim is to retain the specified fiber structure in the SMC as much as possible throughout the flow process in the mold. Obstacles in the mold cavity (tapers, changes in cross section, ribs, spigots, dead ends, etc.) as well as the length of flow paths are taken into consideration when designing the SMC charge.

A reinforcing fiber content of up to 60% by weight can be achieved in the SMC while maintaining positive flow characteristics.

The mechanical properties of the molded parts change depending on the content of reinforcing fibers. However, the content of reinforcing fibers influences the compressive strength to a lesser degree than the tensile strength (Fig. 26). Should the glass fiber content exceed 65% by weight, the tensile strength values will surpass the compressive strength values. The bending strength, which is a mixed value from tensile and compressive strength, increases continually, but exhibits a flatter increase curve with a glass fiber content between 50 and 65 wt% due to the drop in compressive strength.

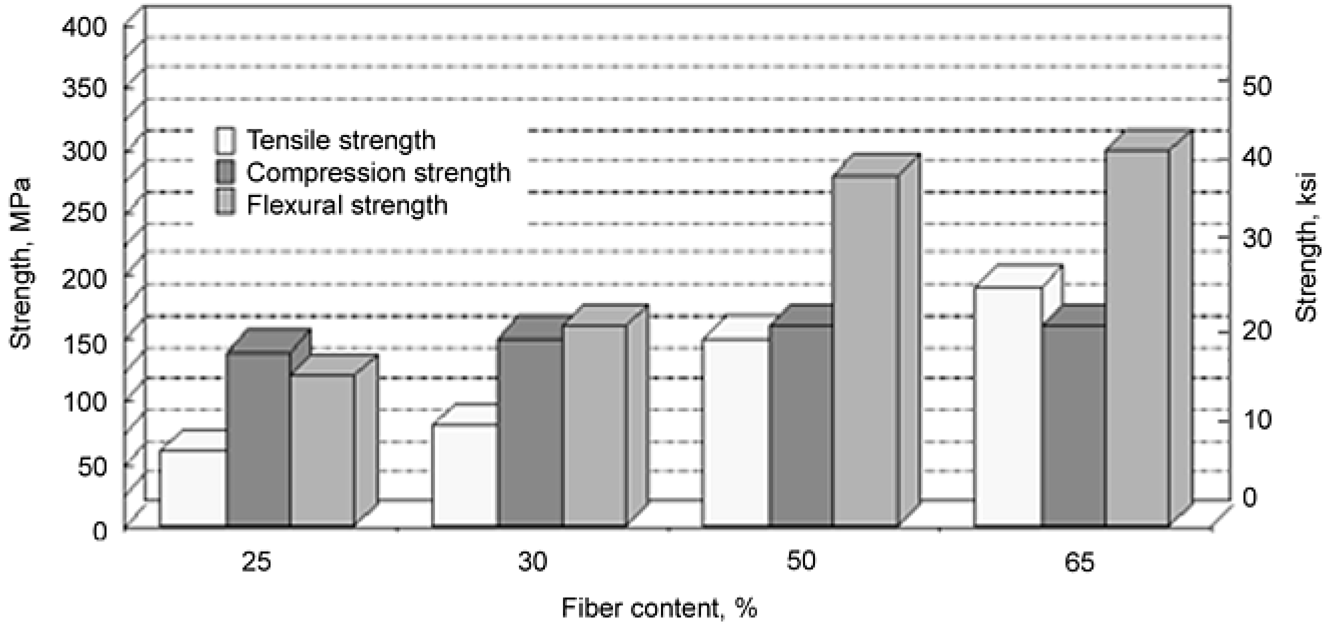

Fig. 26 Relationship between strength and reinforcing fiber content for SMC composites

The resin matrix can influence the rigidity or the flexibility of an SMC material. The matrix controls the interaction between the reinforcing fibers and can be adjusted by changing the composition of the resin paste to make it more rigid or flexible. Therefore, the modulus of elasticity data shown in Fig. 27 are to be understood merely as examples for a special SMC material; the modulus can be adjusted to suit a special application by charging the matrix composition.

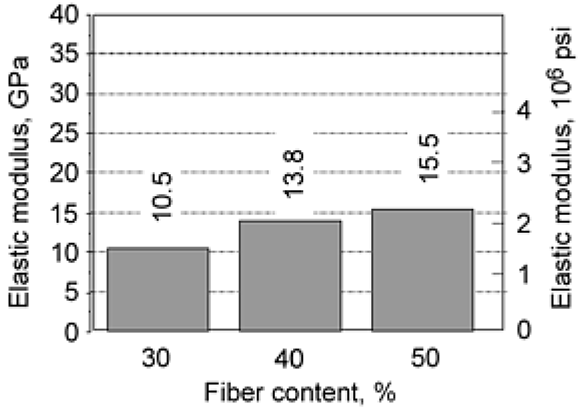

Fig. 27 Relationship between modulus of elasticity and reinforcing fiber content for SMCs with random fibers

High-Performance Compound (HPC) with Unidirectional Reinforcement. A fiber structure with unidirectional glass-fiber strands is built up for molded parts with high requirements on strength and rigidity. The manufacture of such fiber structures is achieved through the introduction of glass-fiber roving strands in the direction of SMC production.

The amount of the unidirectional glass-fiber strands lying in the test direction determines the level of tensile and compressive strengths. In the case of tensile loads, the forces are transmitted directly to the reinforcing-fiber strands, so that the influences of the matrix are eliminated to a large extent. In the case of compressive loads, the forces are acting vertically on the reinforcing fibers, which absorb part of the forces acting upon them. In this case, the matrix assumes a supporting function for the glass-fiber strands. This results in an increase of all values of strength characteristics.

An SMC material consisting solely of unidirectional glass-fiber strands only offers the strength of the matrix perpendicular to the fibers. In order to improve the transverse strength characteristics and to reduce inner stresses in the laminate, a random fiber structure is laid on top of the fiber strands (Fig. 25). This creates an asymmetrically reinforced-fiber structure (Fig. 28a), which can be partially compensated for by layering (Fig. 28b).

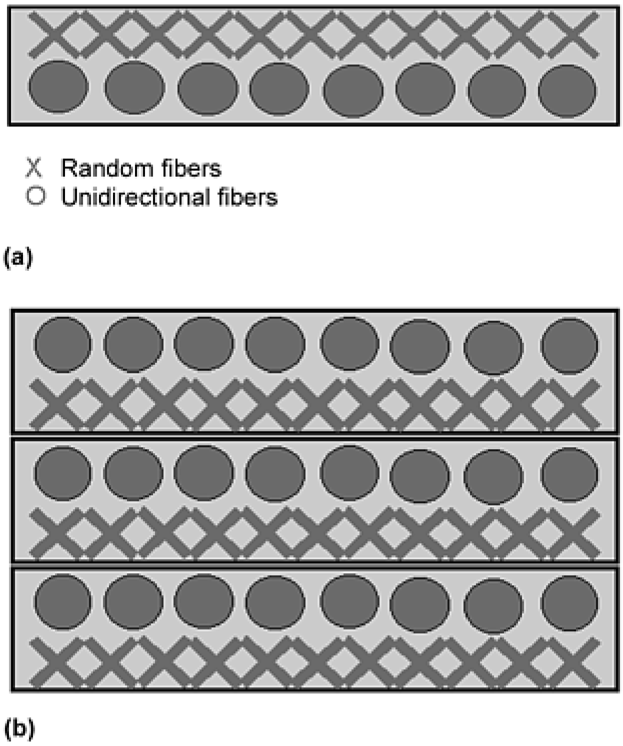

Fig. 28 High-performance SMCs with unidirectional reinforcements. (a) Asymmetric fiber structure. (b) Layering of the asymmetric structures prior to processing

The flow characteristics of SMC are influenced by the introduced fiber structures. Generally speaking, the HPC flow processes require higher compressive forces than those required for SMC with random reinforcement. Also, consideration must be given to the fact that the higher the content of reinforcing fibers, the higher the compressive forces required for the flow process.

In a comparison of SMC material with 60% by weight, randomly arranged reinforcing glass fibers with an SMC material in which 40% by weight are unidirectional, the tensile strength of the latter is more than doubled at the same overall fiber content (Fig. 29). Depending on the required strength characteristics, the overall content of reinforcing glass fibers and the share of unidirectional reinforcing-fiber strands may be freely chosen according to the requirements of the application.

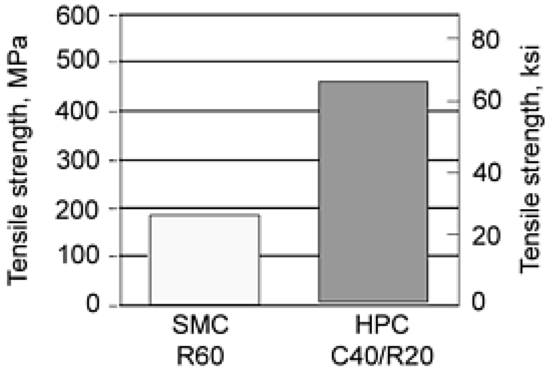

Fig. 29 Tensile strength comparison with SMC and HPC with identical content of reinforcing fibers (R, random; C, continuous)

Similar to the tensile strength, the elastic modulus also increases with an increasing unidirectional glass-fiber content (Fig. 29).

This group of material is used under the designation HPC in the manufacture of automobile bumpers and as an additional material for bumpers of vans and trucks. This application has been established for many years and has proven itself in daily use.

SMC Materials Testing

Since the resin pastes for the continual production of SMC are manufactured in batches, the constant quality level of the batches of paste is of the utmost importance. For that reason, it is necessary to inspect each batch carefully before it is processed in the SMC plant.
The following inspections have been proven in practice:

- Viscosity, through the use of a Brookfield viscometer
- Color, according to DIN 5033
- Reactive behavior, according to DIN EN ISO 12114

The following parameters should be controlled during the production of SMC:

- Belt speed
- Cutter speed
- MgO dosage
- Height of squeegee gap
- Mass per unit area substance, according to DIN EN ISO 10352
- Glass content, according to DIN EN ISO 11667
- Fiber wetting, according to ISO/DIS 17771

The following inspections are required during thickening or maturation:

- Temperature in the maturation chamber
- Viscosity by means of paste samples
- Plasticity, according to DIN EN ISO 12115

Test samples can be made from process-ready SMC in accordance with ISO/CD 1268-8. From these test samples, depending on the requirements, the materials characteristics can be determined. The essential characteristics have been recorded in a universal materials database for fiber reinforced molding compounds known as the "FUNDUS" database. The test methods adopted for all of Europe by the European Alliance for SMC, most of which are derived from ISO or EN standards, comprise all essential characteristics in order to determine the properties of the material.

SMC Form of Supply and Storage Conditions

According to DIN 16913, the standard designation for SMC (resin mat) made from rovings is UP-GMSR, and for SMC made from glass fiber mats it is UP-GMSB. However, these designations have not yet gained general acceptance.
After the impregnating process, the SMC is rolled up into coils between layers of polyethylene film or stored in zigzag layers in containers to await further processing. During the storage time, the UP resin continues to thicken with the aid of the added alkaline earth oxides or hydroxides. Depending on the formulation structure, the SMC can be stored up to six months at room temperature.

SMC Compression Molding Processing Description

The largest quantity of SMC is processed according to the compression molding method. However, processing in injection molding methods with a special, easy-flowing SMC formula is gaining importance.
SMC is processed into molded parts in heated steel molds operated by hydraulic presses (Fig. 1). The pressures used in the molding process lie between 3 and 14 MPa (30 and 140 bar) and generally depend on the formula of the SMC and the shape of the molded part. SMC-quality grades with a high content of fillers of glass fibers require high molding pressures. Parts with high sidewalls, ribs, or spigots require higher pressure than flat molded parts.
The SMC is cut into blanks for the purpose of processing. The SMC blanks are smaller than the projected surface of the molded part. In most cases, the blank size is between 40 and 70% of the size of the molded part, depending on the degree of difficulty of filling out the mold. The blank will be placed in the mold in such a way

that the flow paths to the edge of the molded part are equal in all directions, in order to prevent undesirable fiber orientations caused by change of the material flow directions. Through the calculation of the flow front and the resulting shape of the blank, it is possible to avoid weak areas caused by change of fiber orientation during the flow process in the mold.

The blanks are cut either mechanically on a cutter or manually at the press. After pulling off the separating film, several blanks are placed in layers until the input weight, corresponding to the weight of the molded part plus allowance for the flash to be trimmed off, has been reached.

The SMC blank is placed in the mold. Then, under pressure and temperature, the SMC is formed to the contours of the mold when the mold is closed. Mold temperatures of 135 to 160 °C (275 to 320 °F)—depending on the formula used—are common in this process.

The forming speed of the SMC inside the mold is selected to ensure that no damage of the glass fibers will occur. Once the cavity of the mold is filled, the full pressure is acting on the molded part. The press remains under pressure until the curing reaction is completed. The curing process can be traced through piezoelectric pressure sensors inside the mold, and the press can be opened automatically by a microprocessor control system at the end of the curing time.

Process Data Retrieval and Analysis. The technology of SMC processing is still characterized, to a large extent, by empirical studies. Analyses of defects are performed with the aid of molded parts in order to determine the cause of defects and to eliminate the cause through suitable measures by modifying the paste.

A new and decisive way for the future is to make the individual processes in the manufacture of molded parts more transparent through the observation of process signals and to use the information gathered in this way to derive a differentiated view of the technical procedures. An instrument developed for this purpose is the data retrieval system MEDAS (Ref 33), with appropriate amplification and sensors needed for the retrieval of process data.

The values to be monitored relate in particular to the function of the production plant, in which the dosage function and the forces required for this purpose are recorded. The dosage function consists of the closing motion of the press, its parallelism, as well as a possible elastic behavior of the equipment. In the further course of the molding process, it may be possible to solve shrinkage effects and other processing details.

From the retrieved data, it may be deduced whether the molding system, prior to the actual dosing procedure, may be allowed to perform its basic function undisturbed as set up, or whether new signal progressions may be observed by making changes to the process.

From the start of the molding process, the viscoelastic resistance of the material has an effect on the initiated forming process, allowing conclusions to be drawn with regard to the toughness as well as other characteristics of the molding material.

Similar information can be deduced from the observation of the cavity pressure of the mold. The closing force represents an indicative value for the overall resistance of the material, while locally measured mass pressures in the cavity may provide insights into the timing of filling as well as other local effects, which may also be taken into consideration as verification data for a simulation. By comparison of calculated local pressures and the displacement of the flow front, the plausibility of the simulation results may be verified with the aid of the measured data.

In addition, recording of interior mold pressures yields further information about the distribution of pressures during the liquid phase of the molding material as well as information on the temperature and local progress of reaction shrinkage.

Further essential information for the evaluations of the process procedures are the mold temperatures, which should be recorded and verified separately for each heating circuit. The entire sensory equipment to be used includes:

- Measuring of distances
- Measuring the force of the dosing unit
- Verification of parallelism
- Measuring the interior pressure of the mold
- Mold temperatures

In special cases, the mass temperature and the dielectric conductivity of the molding material may provide insight about the procedures in the interlacing reaction. With the use of special sensors for measuring heat flow,

values such as thermal capacity or the reactive enthalpy of molding materials can be measured under controlled technical conditions.
The software permits retrieval and data storage of signals as well as the visualization of individual or several different curves on one screen. Comparison functions enable the comparison of a measurement with a good or poor processing result as well as the ability to diagnose possible causes.
An additional software add-on permits the statistical analysis as well as the quantitative determination of process signals. This includes, for instance, pressure and temperature, heights, pressure increase speeds, and many other characteristic signal progressions.

Tool Design

Molds are either made from steel or, in the case of preproduction, from aluminum. Flat guides have proven to be best suited as mold guides for larger molds. The guide surface should be about 6 to 15% of the projected surface of the molded part, depending on the degree of difficulty of the shape of the molded part. When the parting line of both halves of the mold is joined, 75% of the guide surfaces should be in contact.
The mold can be heated using electricity, oil, water, or steam. The most widespread heating methods are steam and oil, which provide a more even temperature distribution than an electric heating system.
The temperature differences between the male and the female should not exceed 5 to 10 ºC (9 to 18 °F), depending on the SMC. The punch (male side) should have the lower temperature of the two in order to prevent any interference between the two halves of the mold.
For the purpose of easier ejection of the molded parts, the mold is equipped with ejectors, which are mechanically or hydraulically driven or designed as air ejectors. It is recommended, by means of selectively placed undercuts, to hold the molded part in one half of the mold and then lift the molded part from the mold with the aid of ejectors. This prevents damages to the molded parts caused by sticking in the mold.

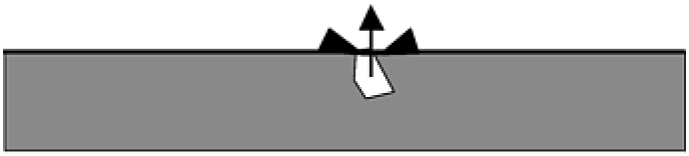
Painting of SMC Molded Parts

Painting of molded parts of automotive body panels made from SMC is generally done using the same paints and at the same furnace temperatures as used for painting of sheet metal parts. In most cases, the molded parts are primer- coated by the manufacturer of the molded parts, and later a top coat is applied either off-line or on the production line of the automobile manufacturer. During the application of the primer, defects such as craters or pores in the primer coat can be caused by inclusions of air or styrene vapor, which must be removed by reworking the molded part. Air inclusions in the SMC molded part may occur for the following reasons:

- Molding-on stops the compression molding procedure.
- Styrene vapor bubbles may form, and existing air is not compressed.
- Air inclusions in the SMC
- Air inclusions caused by deep contours of the molded parts

Air inclusions in the surface of the molded part cannot be filled with a primer applied with a conventional spray-painting method (Fig. 30a). It may be possible to cover the defective area with paint in the spray-painting process, but, in the subsequent stage of drying in the drying furnace, a defect (crater) will appear due to the expansion of the air enclosed in the painted surface (Fig. 30b).

(a)



(b)

Fig. 30 Creation of paint defects due to inhomogeneities in the SMC surface finish. (a) Air inclusion in the surface of the molded part. (b) Expansion of air in the inclusion during drying forms a crater.

The in-mold coating (IMC) method is applied in order to reduce the occurrence of defects in the painted surface (Ref 32). The coating process is performed in a second pressure cycle on the still-hot SMC molded part in the following process steps:

- An SMC blank is inserted in the hot mold (Fig. 31a).
- The mold closes and forms the SMC molded part (Fig. 31b), which cures under pressure and temperature.
- After curing of the SMC, the IMC paint is injected. The mold opens slightly for this purpose (Fig. 31c).
- The mold recloses and distributes the paint on the surface of the molded part (Fig. 31d). The IMC paint cures under pressure and temperature.
- The mold opens and the coated molded part can be removed from the mold (Fig. 31e).

Air inclusions and cracks behave neutrally after filling with IMC paint in the drying furnace, and no longer lead to defective areas.

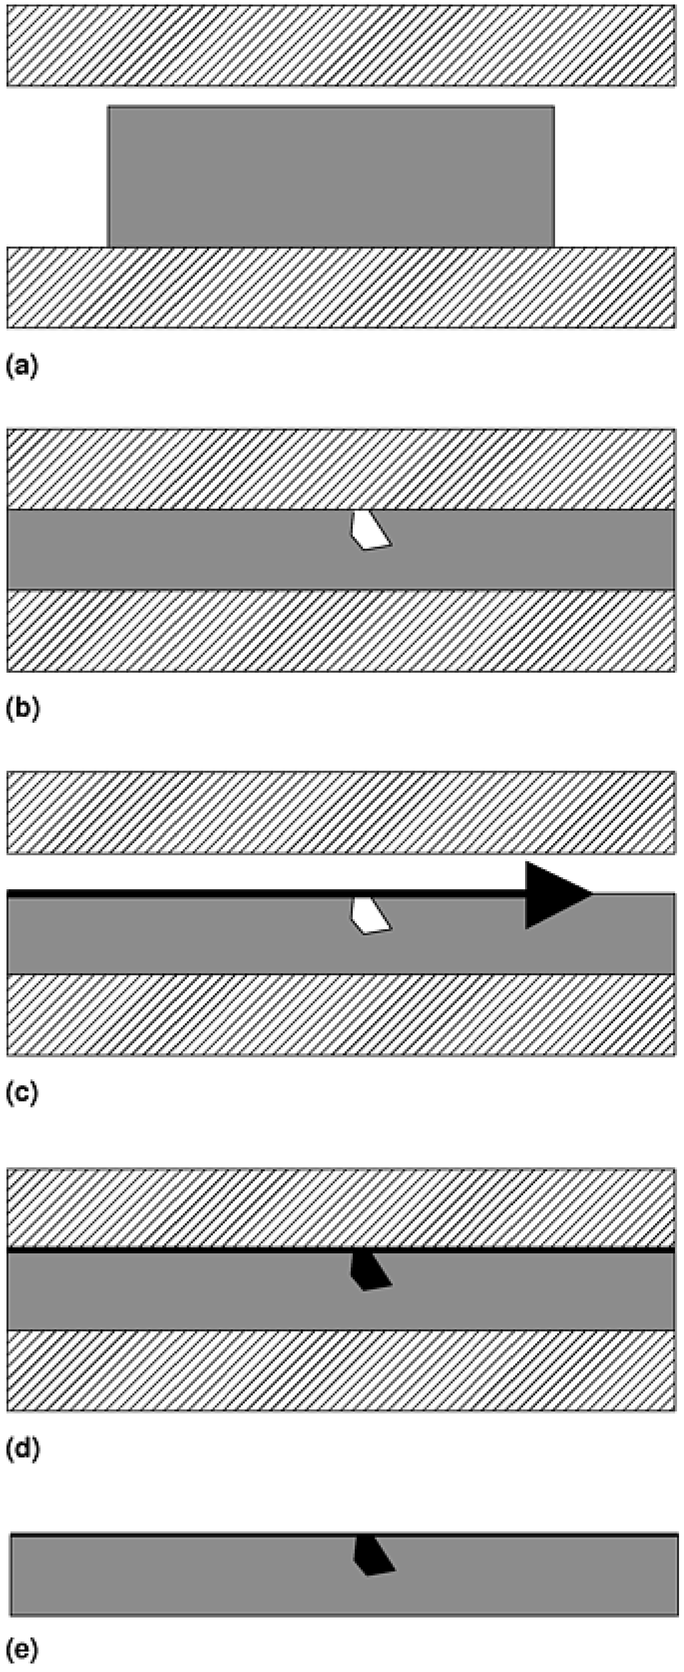


Fig. 31 Schematic diagram of the in-mold coating process. See text for description.

Applications of SMC Compression Molding

Electrical Industry. Cable and telephone branch boxes are among the oldest applications of SMC (Fig. 32). Aside from switch cabinets, millions of units of strip lighting (Fig. 33) which are used throughout every type of industry, have proven their value for more than 30 years in the electrical industry. These components have been proven for use in sanitary facilities and under wear and tear caused by aggressive media. The high technical

standards can usually only be seen when looking at the interior of the components. The illustrated base plate (Fig. 34) serves as a footing for a curved lantern pole. All functional elements (stiffeners, mounting holes, sealing lips, and opening bolts) are integrated in the component. The SMC is dyed and designed for low shrinkage, so that they do not have a tendency to warp. The grained surface finish is long-term weather resistant, even without the protection of paint.

Fig. 32 Unpainted cable and telephone boxes manufactured by SMC compression molding. The boxes, exposed to the weather for 25 years, are shown next to an old painted telephone booth.

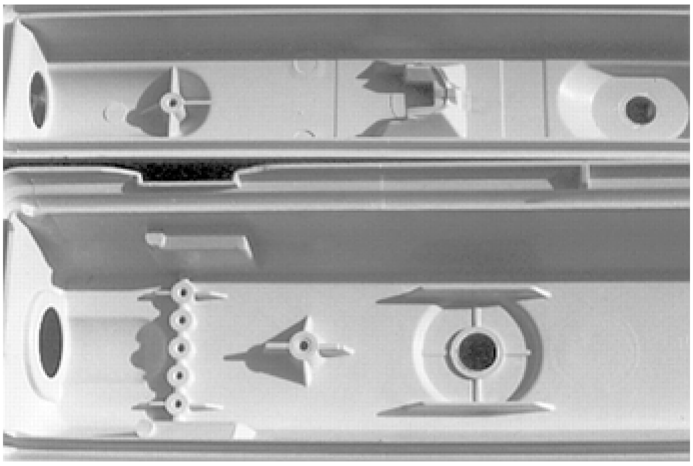

Fig. 33 Strip lighting units manufactured by SMC compression molding

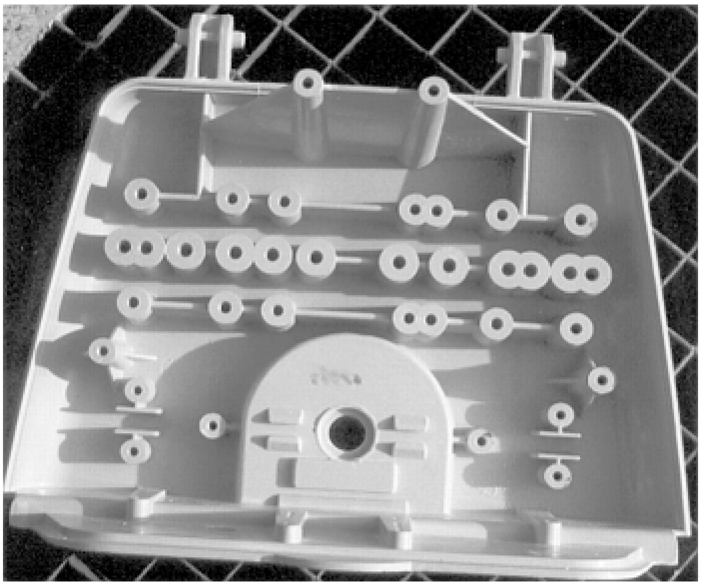

Fig. 34 Base plate for curved lantern pole. Manufactured by SMC compression molding

In the field of interior design and installations, various systems in different sizes are assembled to form complete units. The openings required for this purpose are preformed and can be cut out easily, if necessary (Fig. 35). It is important that the residual wall thickness is strong enough to guarantee the insulation, but also thin enough to permit easy cutting.

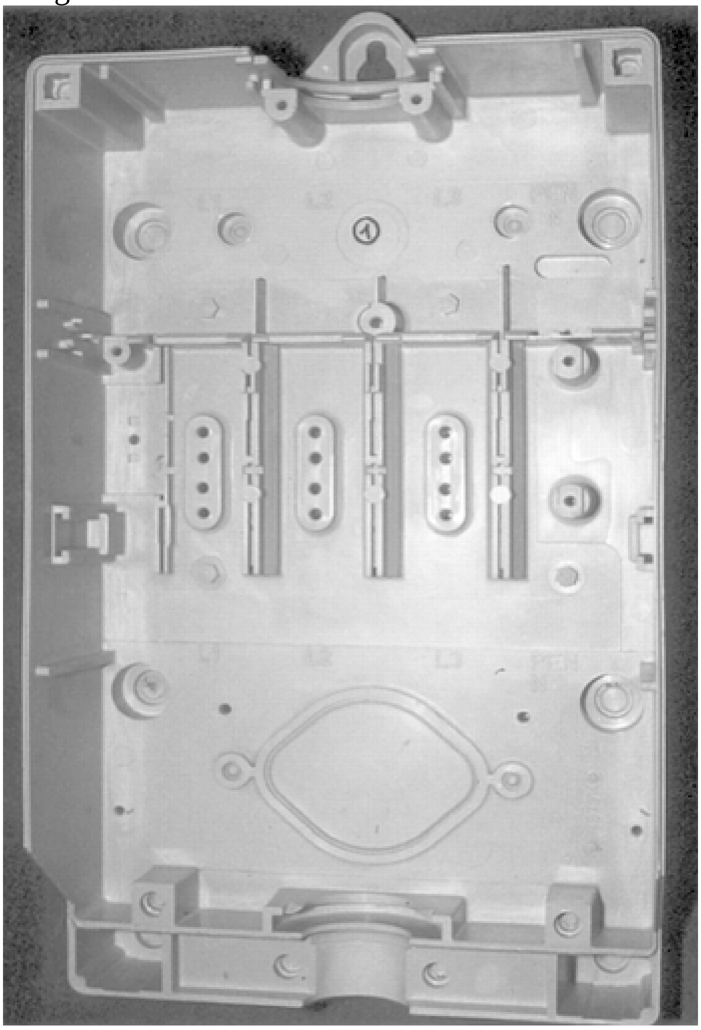

Fig. 35 Electrical switch cabinet for interior use. Manufactured by SMC compression molding

Satellite antenna manufactured by SMC compression molding gained access to sophisticated applications due to their excellent weather resistance and freedom of design, combined with outstanding dimensional stability. Their longitudinal expansion coefficient, which is close to that of steel, makes these antennas unaffected by extreme temperature fluctuations. However, a wire mesh must be embedded in the antenna dishes, because the SMC material alone does not reflect the radio waves.

Another advantage is the excellent flowability of the SMC materials, which not only allows the complete embedding of the wire mesh, but permits the inclusion of all attaching elements with reinforcing ribs at the rear.

Automobile Industry. In the field of passenger cars, bumper supports made from high- strength SMC—so-called HPC or SMC–C— have proven their worth for many years (Fig. 36). With materials characteristics approaching those of high-end composites, high-strength SMC has secured a safe niche for itself for many years. The average vehicle owner will only become aware of the SMC supports when the vehicle is disassembled, because a closed fascia usually covers them (Ref 29).

Fig. 36 Bumper support made from compression molded C-SMC

The combustion behavior of SMC is of great importance for applications in the passenger compartment. In most cases, these parts are declared to be safety-related parts subject to mandatory documentation. This applies to, for example, hatchbacks, trunk lids, doors, and so on that are connected to the interior.

Parts manufactured SMC compression molding are able to meet the demands according to ISO 3795, DIN 75200, FMVSS 302, and many other vehicle-related standards without any special fire-protection measures.

For many years, structural supports made from SMC have been in use in the manufacture of passenger cars, lately also made from long- fiber-reinforced thermoplastic. As shown in Fig. 37, the components are delivered ready-for-assembly to the system supplier. The parts support the radiator, headlights, indicators, cables, and many other installed components.

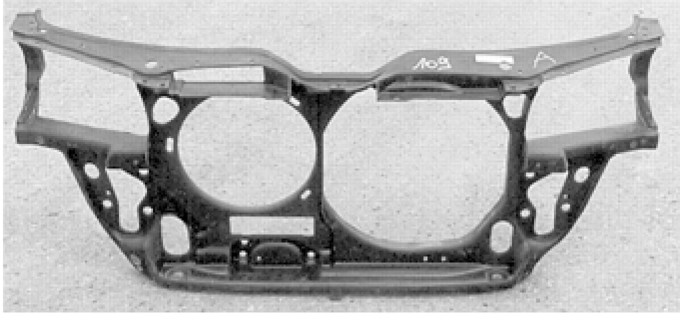

Fig. 37 Technical front end (structural support) for Ford Galaxy and Volkswagen Sharan manufactured by SMC compression molding

For many years, spoilers have been a proven design in single-shell as well as double-shell design in passenger cars (Fig. 38). High Class A demands are made on the components, resulting in the frequent use of IMC as pressed-on primer.

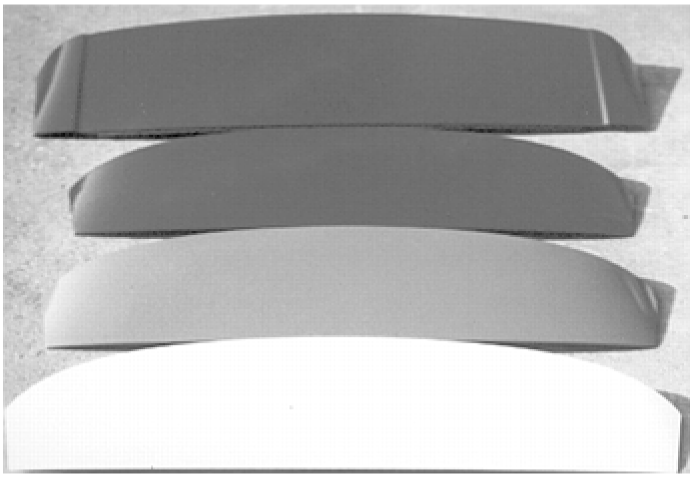

Fig. 38 Car spoilers manufactured by SMC compression molding and with the use of in-mold coating as primer for subsequent painting

Since the introduction of the Renault Espace, the first European minivan, its entire exterior body panels have been made from SMC (Fig. 39). The development of the Class A SMC can be traced through the history of this vehicle.

Fig. 39 Example of a minivan (Renault Espace) with exterior body panels made by SMC compressions molding

The particularly high demands of the German automobile industry can be met nowadays, proven by examples of trunk lids of Daimler- Chrysler cars made from SMC.

In the sector of commercial vehicles, the material has established itself due to its freedom from corrosion. The examples of the Mercedes- Benz Actros show that more than 30 SMC parts fulfill their intended functions (Fig. 40). The following components are made from SMC: bumpers, engine hood, doorsills, toolboxes and lids, fenders, top, and side covers. The side component shown in Fig. 40(b) in unfinished condition is equipped with the recesses for the headlights, flashers, fog lights, the ribbed stepping surface, all attaching elements, and the required stiffeners. High demands on strength and surface-finish quality are made on components such as side panels, toolbox lids, wheel arch, and other cover panels (Fig. 40c). Because all parts are painted together with

the driver's cab, they must be supplied in a condition ready for topcoat painting. Reworking rates of topcoat painting are tolerated only up to 1%.

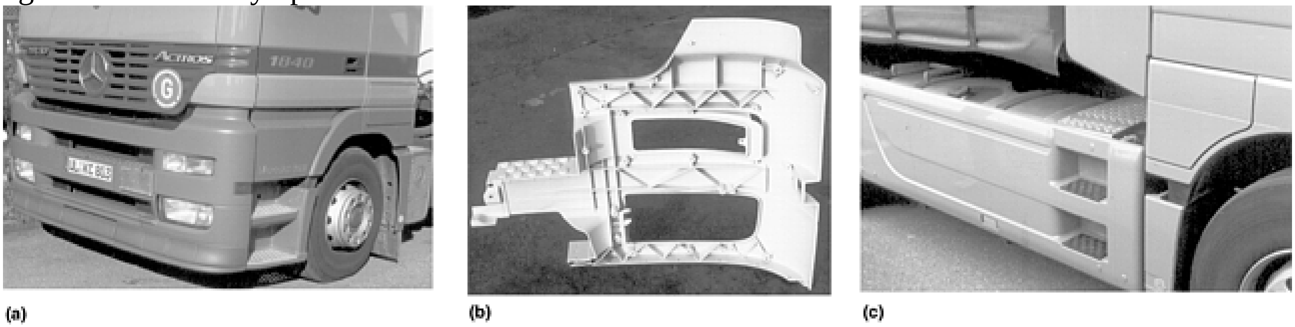

Fig. 40 Truck cab with multiple exterior components made from SMC (Mercedes-Benz Actros). (a) Front view. (b) Bumper side component. (c) Side panel with access ladder, toolbox lid wheel arch, and other parts

Other manufacturers use single-component bumpers, which are of very large dimensions due to the size of the vehicles. Battery covers of various designs and dimensions are used for various vehicle models (Fig. 41). The parts must be able to withstand persons standing on them and therefore, they are designed with pyramid-shaped, raised patterns to improve grip.

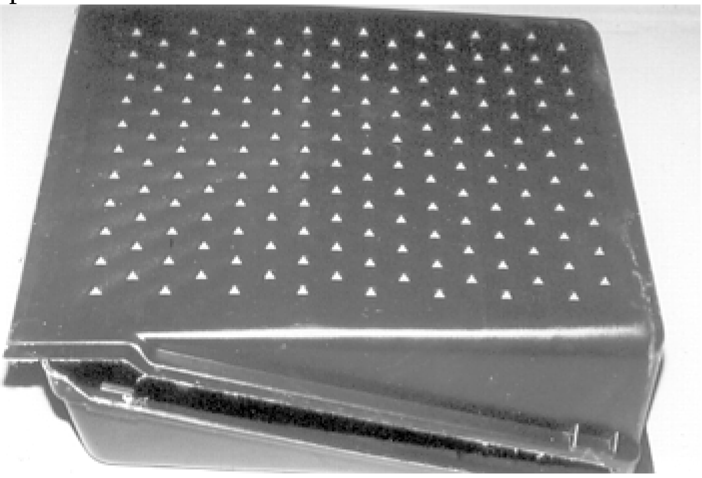

Fig. 41 Battery cover for commercial vehicles. Made from compression-molded SMC

Rail Vehicles. For many years, SMC components have made inroads, particularly as wall elements in the interior of many types of rail vehicles (Fig. 42). Most of the Interregio trains of the Deutsche Bahn (German Railway) are equipped with several different elements of self- extinguishing SMC material (Ref 32, 34).

Fig. 42 Assembly of SMC compression-molded interior wall elements in passenger rail cars

Civil Engineering. Many application examples that are immediately connected to the building industry have already been mentioned in the electrical engineering applications. When it comes to particular resistance in moist conditions and exposure to aggressive media, cable trays and sewage pumps are made from SMC, for example.

Other Applications. SMC components are also used in the medical sector. They not only serve as cover panels for various devices, but they may also be used for parts subjected to considerable loads, such as the supporting part of a dentist's chair, shown from the rear in Fig. 43.

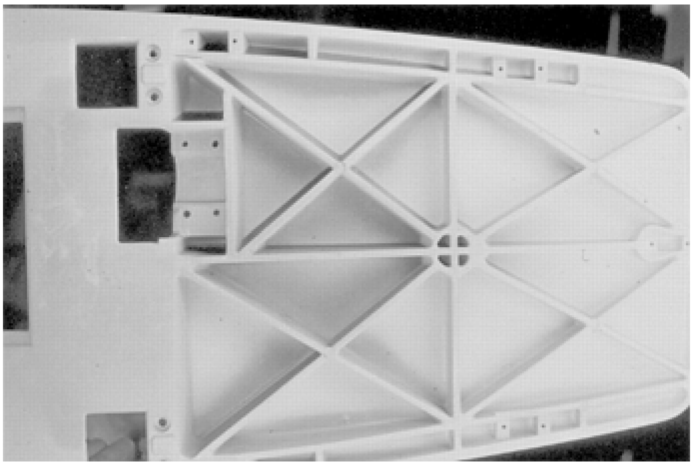

Fig. 43 Supporting part of a dentist's chair manufactured by SMC compression molding

The pleasant surface finish of the patio table shown in Fig. 44 is achieved with the incorporation of recyclate particles.

Fig. 44 SMC patio table containing recycling material (with loose recyclate shown on top of the table)

Reduction of Emissions from Molded Parts

The problem of emissions in the interior of passenger cars has become a topic of decisive importance, particularly in the last ten years. With respect to this issue, components made from SMC have captured the focal point of interest. Figure 45 shows how styrene emission occurs during the compression molding cycle.

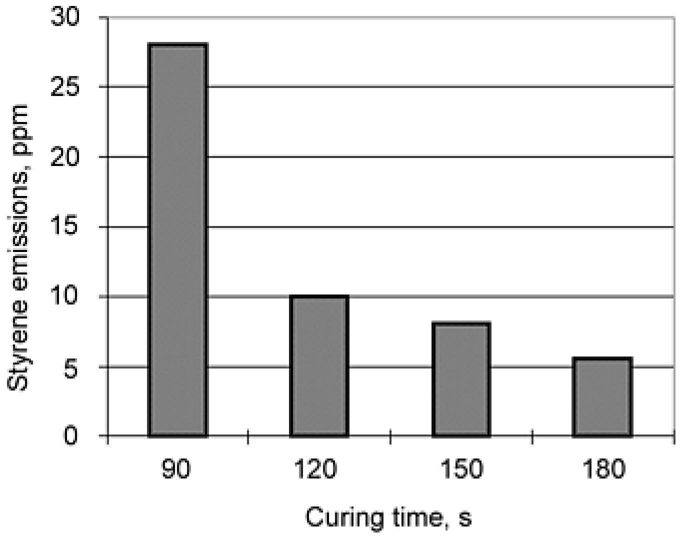

Fig. 45 Effect of curing time duration on styrene emissions from SMCs (mold temperature 160 °C, or 320 °F)

Because molding compounds are highly versatile materials with excellent materials properties, there has been a high degree of interest in finding ways to quantify and reduce emissions. Starting point initiatives were made by members of the automobile industry, who specified the first guidelines in defined test methods and limiting values (max 100 ppm).

Through the addition of suitable additives to the low-profile SMC formula, it was possible to lower toxic organic compound emissions from molded parts to the limiting value of max 100 ppm. The reduction is achieved during the curing process in the mold and requires no additional heat treatment. This method is pointing the way toward the use of molded parts without the necessity of a cost-intensive tempering process. Analyses of the emitted substances proved that no toxic substances were set free.

SMC Recycling and Reprocessing

The issue of recyclability of SMC has been addressed with particle recycling (Ref 32). The ERCOM recycling company has established particle recycling on an industrial scale. The objective was to build up a recycling concept interesting to the SMC industry, while creating material-specific advantages through the use of recycled materials. Avoiding disposal was the foremost consideration, but the declared objective was the exploitation of special characteristics of recycled materials. The aim was upcycling (creation of material with improved properties as compared with the original material); recycling (creation of material with equivalent properties) was accepted. Downcycling (creation of materials with reduced properties) was to be avoided.

The advantages of recycled SMC are:

- Reduction of density
- Substitute for new glass-fiber material
- Decorative surface finishes
- Creation of structured surfaces

The costs of recycling were, in part, recovered through the selective use of recycled materials and improvement of properties. Recycling at zero cost is not possible. With the inclusion of certain characteristics, which are only available with recycled materials, recycling costs can be quite economical. In decorative applications, for example, the special structured surfaces of molded parts can only be achieved with the use of recycled materials (Fig. 44).

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Introduction

FILAMENT WINDING is a process for fabricating a composite structure in which continuous reinforcements (filament, wire, yarn, tape, or other), either previously impregnated with a matrix material or impregnated during winding, are placed over a rotating form or mandrel in a prescribed way to meet certain stress conditions. When the required number of layers is applied, the wound form is cured and the mandrel can be removed or left as part of the structure.

High-speed, precise lay-down of continuous reinforcement in predescribed patterns is the basis of filament-winding. The filament-winding machine (Fig. 1) traverses the wind eye at speeds that are synchronized with the mandrel rotation, controlling the winding angle of the reinforcement and the fiber lay-down rate. The deposition can be controlled either by computer numerically controlled (CNC) machines or by simple mechanically controlled winders; the latter are less convenient, but require a lower capital investment. Figure 2 shows the basic six axes of the CNC machines. Figure 3 is a schematic of the optimized control systems for

efficient wet filament-winding. Usually, the mechanical machines are limited to three axes or less, whereas the CNC machines can accommodate up to seven axes.

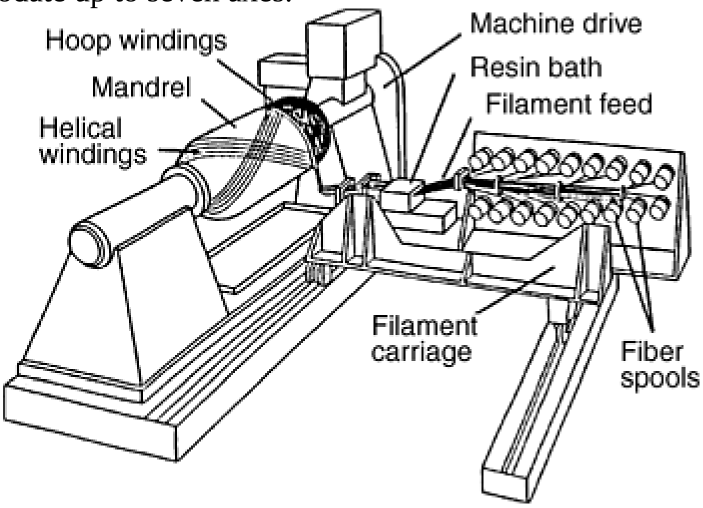

Fig. 1 Typical filament-winding machine

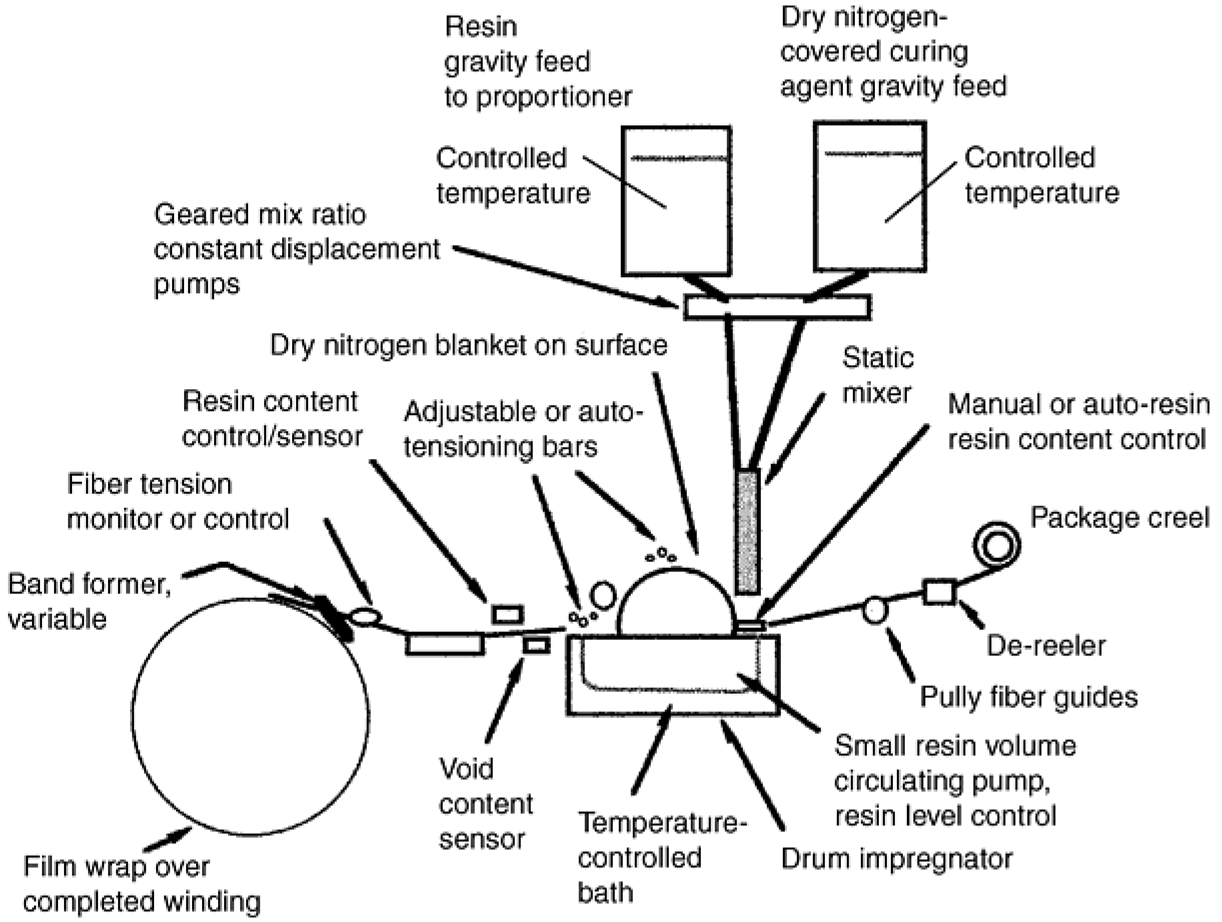

Fig. 3 Optimized controls for a wet-winding process

Thermoset resins, generally used as binders for reinforcements, can be applied to the dry roving at the time of winding, which is known as wet winding. They may also be applied prior to winding as a tow or tape prepreg and used promptly or refrigerated. Usually the cure of the filament-wound composite is conducted at elevated temperatures without vacuum bagging or autoclave compaction. Mandrel removal, trimming, and other finishing operations complete the process.

Aerospace and some other applications generally use untwisted fiber; in many commercial applications, twist is introduced by the composite manufacturer when the untensioned fiber is fed from a center pull container. The mandrel can be cylindrical, spherical, or any other shape as long as it does not have reentrant (concave) curvature—although several manufacturers have been able to incorporate complex reentrant curves in filament-wound structures (Fig. 4 and 5) (Ref 1). Large or thick-walled structures, particularly structures of revolution such as cylinders or pressure vessels, are most easily wound.

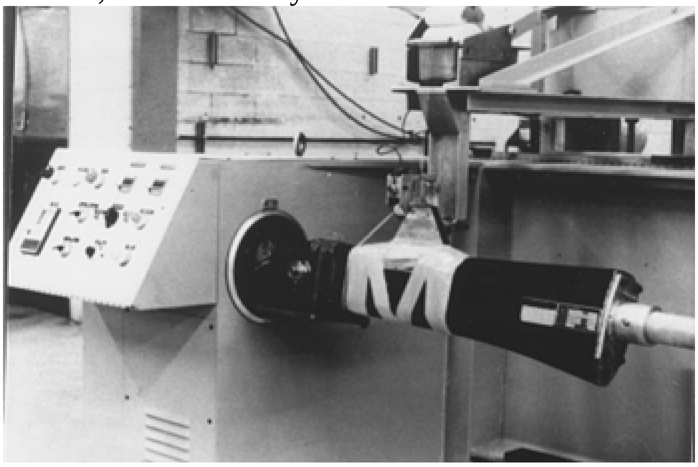

Fig. 4 Complex winding patterns for the V-22 grip assembly. Courtesy of McClean Anderson, Inc.

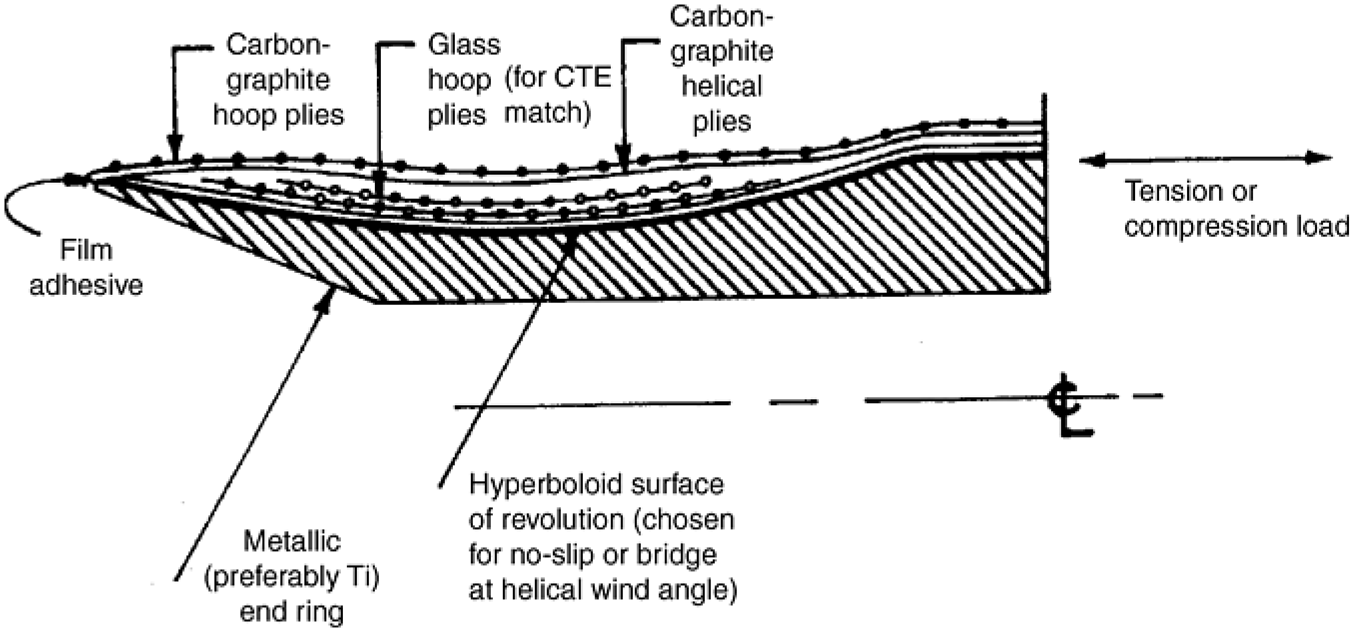

Fig. 5 In situ reentrant filament-wound joint

The reinforcement can be wrapped in adjacent bands or in repeating bands that are stepped the width of the band to eventually cover the mandrel surface. The technique, in process, looks somewhat like that shown in Fig. 6 and can be changed with both CNC and mechanical filament-winding machines to result in many different winding patterns (e.g., polar, helical, or hoop). The technique can vary winding tension, reinforcement material, wind angle, or resin content (if wet wound) in each layer until the desired thickness and resin content of composite is achieved with the required orientation. Multiple composite components can be fabricated simultaneously in the same equipment, with accurate fiber angles and good resin control. Figure 7 shows four square columns being fabricated. For small items, such as golf shafts, it is possible to wind up to 20 components simultaneously (Fig. 8).

The filament-winding industry, manufacturing processes, machines, and raw materials have undergone drastic changes during the time since the previous versions of this article (for the *Engineered Materials Handbook,* Volumes 1 and 2) were written. Many new manufacturers have emerged, primarily in the commercial and sporting goods sectors, and the emphasis has shifted from filament-winding of rocket motors to that of golf shafts, driveshafts, or drill risers. Some of the recent advancements in filament-winding include:

- The use of prepreg tows rather than impregnating the dry fibers. The change to prepreg has been driven by reductions in cost of the fibers (and the resultant prepreg), the need for minimal or no cleanup (long a problem for wet filament-winding), the reduced environmental impact, and faster wind speeds (no resin sling for hoops, no aeration of resin in impregnation bath).
- Increased strength and modulus of fibers, especially carbon-graphite fibers, versus those that were available in the 1980s
- Availability of fibers in larger tow sizes, making the process even more cost effective by increasing the speed of fiber deposition
- The evolution of new wet-winding resin systems and the increased availability of third party-formulated resins
- The evolution of cheaper towpregs, which has made their use cost-effective for many applications when compared to wet-winding resin systems
- The development of low-viscosity wet resin systems for resin transfer molding (RTM), and their subsequent adaptation for use in for filament-winding
- Improvements in filament-winding machines and controls. Seven axes of movement are commonly available, and most CNC machines feature easy-to-program software. The winding motions can now be programmed off-line much easier and faster, resulting in more cost-effective changeovers and layer modifications

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Advantages and Disadvantages

Advantages. The most important advantage of filament-winding is its low cost, which is less than the prepreg cost for most composites. The reduced costs are possible in filament-winding because a relatively expensive fiber can be combined with an inexpensive resin to yield a relatively inexpensive composite. Also, cost reductions accrue because of the high speed of fiber lay-down.
Other advantages of filament-winding compared to other compacting and curing processes are:

- Highly repetitive and accurate fiber placement (from part to part and from layer to layer). The accuracy can be superior to that of fiber placement and automated tape-laying machines.
- The capacity to use continuous fibers over the whole component area (without joints) and to orient fibers easily in the load direction. This simplifies the fabrication of structures such as aircraft fuselages and reduces numbers of joints for increased reliability and lower costs.
- Elimination of the capital expense (and size restrictions) of an autoclave and the recurring expense for inert gas. Thick-walled structures can be built that are larger than any autoclave can accommodate.
- Ability to manufacture a composite with high fiber volume
- Mandrel costs can be lower than other tooling costs because there is usually only one tool, the male mandrel, that sets the inside diameter and the inner surface finish.
- Lower cost for large numbers of components because there can be less labor than many other processes. It is possible to filament wind multiple small components, such as up to 20 golf shafts at once (Fig. 8), leading to sharply reduced costs compared to flag rolling. Costs are eliminated for bagging and disassembly of the bagging materials, as well as the recurring costs of these materials.
- Costs are relatively low for material since fiber and resin can be used in their lowest cost form rather than as prepreg.

Disadvantages of filament-winding include:

- Need for mandrel, which can be complex or expensive
- Necessity for a component shape that permits mandrel removal. Long, tubular mandrels generally do not have a taper. Unless nonuniform shapes are capable of mechanical disassembly, mandrels must be made from a dissolvable or frangible material. Different mandrel materials, because of differing thermal expansion and differing composite materials and laminate lay-up percentages of hoops versus helical plies, will demonstrate varying amounts of difficulty in removal of the part from the mandrel.
- Difficulty in winding reverse curvature
- Inability to change fiber path easily (in one lamina)
- Poor external surface finish, which may hamper aerodynamics or aesthetics

It is important to note that most of the disadvantages are application-specific and, in many cases, have been circumvented by innovative design and equipment modifications.
Several factors offset the disadvantages associated with mandrels. Usually the mandrel is less expensive than the dies or molds for forming methods other than pultrusion or RTM.

Inexpensive mandrel materials, such as cardboard and wood, have been successfully used. Fabricators of large rocket motors have been using water-soluble sand mandrels or plaster mandrels that can be stripped, reduced in size, and passed out through relatively small ports.

Even though reverse curvature generally cannot be wound, three options are available for circumventing this restriction. The first involves winding the part, bridging the concave area, and then installing a reverse curvature caul plate and applying external pressure during cure. This technique may require dropping winding tension or cutting fibers in scrap areas. A variation of this is the use of a caul plate that is removed as the fiber band crosses the depression and is replaced immediately and held until the band passes the next circuit. This method maintains the placement and tension of the fibers and eliminates the need for cutting. A second approach is to wind the exact shape on a positive dummy mandrel insert, then remove the insert and place the fiber. The third option is to wind into a reduced section area by choosing the hyperboloidal curvature of the recess in conjunction with the selection of the helical fiber angle (Ref 1).

The fiber path cannot be changed easily, but it can be done by use of pins, sawtooths, or slip of the tow. Fiber placement is the only fabrication method capable of “steering” the fiber. Commercial pinrings are available (Fig. 9).

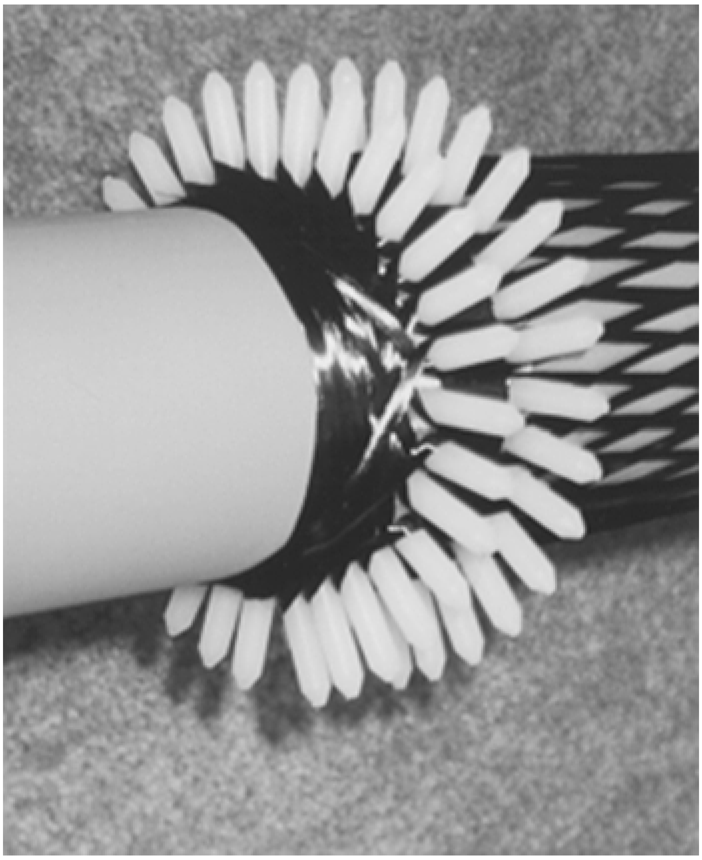

Fig. 9 Commercial preformed pinring. Courtesy of Advanced Composites, Inc.

A better outside surface can be obtained by use of outer clamshell molds. (This was the technique used for the Beech Starship, shown in Fig. 10. A bladder on the male mandrel was used to expand the part into a female mold to attain an aerodynamic finish, Ref 2.) External hoop plies or thinner tows on the last ply can be used. Uncompacted helical plies tend to be more bumpy than hoops. Another option is to use shrink tape or porous tetrafluoroethylene-glass tape overwrap. Many aerospace fabricators have used these techniques. The result is a matte surface that tends to hide flaws or blemishes while imparting some smoothing.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Effects of Fiber Tension

In filament-winding, fibers are positioned under tension. This tension can be advantageous because fibers in tension can have twice the strength of those in compression. (Structural beams of carbon-graphite may have more fiber on the compression side to offset this fact. Fibers are added on the compression side by winding at zero degrees and retained by overwinds.) However, if the fibers in a laminate are not straight, the laminate will have reduced tensile and compressive strength values. Repetitive loads and other structural performance factors are also degraded by nonstraight fibers. That is, the straight fibers in a laminate will load and fail before the relaxed fibers are fully loaded. Fiber alignment is especially important for high-modulus fibers such as carbon-graphite because of their low strain-to-failure behavior. Correct use of fiber tension during winding is the only way to achieve straight fibers in a filament-wound structure.

Because the fibers are under tension, they can move or shift when there are cut ends in the part. It is possible to retain the wound wet fibers with tensioned circumferential fibers at each place that the fiber ends (such as a cut end or a ply drop-off). When the fibers are cut outboard of these positions, the fiber tension is reduced end- to-

end of the structure, but the fibers remain straight and ready to equally assume the structural tension and compression.
It is sometimes advantageous to wind an outer hoop of dry glass at very low tension to absorb excess resin, or as material added for subsequent machining operations to avoid cutting structural fibers.
The effect of bands of fibers compressing the previously wound fibers, as the plies are placed upon one another, is to reduce the diameter of the uncured structure. The result of this reduced diameter is that the previously wound fibers are too long to remain straight and can be distorted, that is, crimped. Medium- and thick-wound walls must be wound with careful selection of tension to prevent crimping. Higher-tensioned fibers are placed on the inner plies. Since they are tight, they are resistant to further compaction. Succeeding plies have gradually reduced tension so as not to compress the inner plies.
The true fiber tension is that tension measured as the impregnated fiber exits the payout eye at the same speed in feet per minute used during winding the product. (This is called "dynamic" tension measurement.) Measuring the fiber tension at the creel is not accurate, even if all delivery contacts between creel and winding surface are via pulleys.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Materials

The filament-winding process allows choices in the selection of fibers, resins, and materials form (or delivery system)—that is, wet, prepreg tow, or prepreg tape.

Fibers

Fiberglass. The most widely used fiber for commercial filament-winding is fiberglass, which has been used in several grades in the United States for many years. Glass fibers used for filament-wound structures include types "E,""R,""S," and "C" (see the article "Glass Fibers" in this Volume). Fiberglass is used extensively where dimensional stability, corrosion resistance, and low-cost materials and processing are required.
Aramid fibers, specifically Kevlar 29, 49, and 149 (i.e., Du Pont de Nemours & Co., Inc., Wilmington, DE), exhibit exceptionally high strength-to-density and modulus-to-density ratios (known as specific strength and specific modulus). They also show great consistency with a low coefficient of strength variation, allowing high design allowables. Aramid composites have relatively poor shear and compression properties because of the fibrillar nature of the filaments, but find extensive use in pressure vessels and nonprimary loaded structures. Additional information is available in the article "Aramid Fibers" in this Volume.
Carbon/graphite fibers exhibit the largest range of available fiber mechanical properties. Constant improvements in fiber modulus, tensile strength, strain to failure, and surface finish have made handling for filament-winding easier. Although the modulus and tensile strength of graphite fibers have been dramatically improved over the past few years, increases in modulus have generally resulted in a decrease in tensile strength, and vice versa. The intermediate fibers have been the only exception. Increases in the amount of fiber graphitization result in increased modulus, which in turn results in increases in thermal and electrical conductivity. The cost of the fiber also increases, primarily because of lower demand for the high-modulus fibers and higher energy costs, and because large-scale production economies have not yet been imposed. All fibers, except ultrahigh-modulus pitch and extremely high-modulus pitch, have been successfully filament-wound. Additional information is available in the article "Carbon Fibers" in this Volume.

Resins

The resin system in a filament-wound composite serves the same functions as it does in composite structures fabricated by other means, namely:

- Retaining the filaments in the proper position and orientation
- Transferring the load from filament to filament and ply to ply
- Protecting the filaments from abrasion (during winding and in the composite)
- Controlling electrical and chemical properties
- Providing the interlaminar shear strength

There are several handling criteria for a wet resin system that are unique to filament-winding:

- Viscosity should be 2 Pa · s (20 P) or lower
- Pot life should be as long as possible (preferably more than 6 h)
- Toxicity should be low

Important resin-matrix properties in the cured structure are adhesive strength, heat resistance, fatigue strength, chemical resistance, high strain to failure, and moisture resistance.

The introduction of aramid fiber in the early 1970s spurred new investigations into resin systems. Many resin systems that had worked well with glass were not appropriate for use with the new fibers. New types of resin systems were subsequently developed to address low-temperature cure, long pot life, high heat deflection, high elongation or strain to failure, and low toxicity. These five factors are somewhat exclusive, that is, a low-temperature cure does not usually result in high heat deflection properties, and high heat- deflection generally lowers strain capability.

Long pot life resin systems were developed to allow fabrication of large structures with an extended gel time and minimum exotherm. Generally, anhydride-cured systems have long pot lives, coupled with high-temperature cures and high heat-deflection temperatures. The high- temperature resin systems generally have higher cure temperatures and lower strain-to-failure capability.

Composite structure toughness is a concern for aircraft and all other long service life, impact- sensitive structures. Filament-wound aircraft structures, attractive because of the potential for large cost savings, must exhibit damage tolerance. Toughness can be incorporated into a composite structure by any of several methods:

- Introducing elastomer or thermoplastic particles
- Blending to result in an interpenetrating network
- Interleaving with thermoplastic film
- Decreasing cross-linking density
- Using special fiber orientations (including through-the-thickness reinforcement)
- Using a thermoplastic matrix

All toughened wet filament-winding resin systems depend on the addition of a prereacted epoxy resin and carboxy-terminated polybutadiene acrylonitrile rubber polymer to achieve toughness without shortening pot life. Generally, the addition of rubber also increases the viscosity of the resin system, which may be unacceptable from a processing standpoint. The toughened, long pot life and flexible formulations have lower heat-deflection temperatures (or glass transition temperatures) than do the high-temperature resin systems.

Another technique for increasing the fracture toughness of a filament-wound composite has been to use thermoplastic resins, because they offer outstanding interlaminar fracture toughness (G_{Ic}) and good compression strength after impact testing.

Delivery Systems

The three different impregnation methods commonly used are preimpregnated roving (prepreg), wet rerolled, and wet winding.

Prepregs. Preimpregnated rovings offer excellent quality control and reproducibility in resin content, uniformity, and band width control. These parameters can be determined well in advance of the filament-winding process; not on the factory floor where many of the quality control tests must be done for wet winding. Many high-performance resins that can only be impregnated using special processes, such as hot- melt, can be employed; however, the resin must be modified to reduce the adhesion between the resin-covered tow layers on the delivery package (usually tangential letoff rolls) because separator plies are not used for prepreg tows.

Most commercial prepregs may also use solvents or preservatives to extend storage life. These additives change the resin system from that which retains the same name but may be marketed for other applications that may enjoy broad qualification approval. Thus the filament- winding resin, because of the necessary minor modifications, may have to undergo detailed qualification testing. Some newer resin systems have been optimized for long out time, and some are marketed with essentially infinite storage time at room temperature, rather than in freezers.
Prepreg filament-winding resins are commonly thought to possess the following as advantages:

- Better resin-content control
- Encapsulation of carbon-graphite fibers (prevents small, airborne, graphite-fiber interference with electrical motors)
- Minimal fiber damage due to the protection offered by the resin and the use of roller redirects
- Better stability on a nongeodesic path
- More consistent composite properties

The commonly quoted disadvantages of prepreg tow are:

- Poor fiber availability. This is a result of adding another step to the manufacturing process.
- Requirement, generally, for refrigerated storage and control of out time
- Higher cost
- No room-temperature cures are possible.

Wet Rerolled. With wet-rerolled “prepreg,” a controlled volume of resin is impregnated on fiber reinforcement and then respooled. Quality control can be performed away from the winding operation. Preservatives or solvents are not required, because the roving is either used immediately or stored in a freezer for future use. This can be a very cost-effective method for obtaining preimpregnated roving at the plant of the winder.
Wet Winding. The lowest-cost materials for composite processing are those that are brought together at the process by the composite manufacturer. Thus, if the design requirements allow wet filament-winding, it will always be less expensive than winding with prepreg, but the manufacturer must make some choices in terms of safety, cleanliness, and so on, before production. When a prepreg is used, there will be some limitations on the choice of fiber/resin; with wet impregnation the choices are unlimited.
Wet impregnation of fiber can be accomplished by either pulling the reinforcement through a resin bath or directly over a roller that contains a metered volume of resin controlled by a doctor blade. This low-cost system is widely used in commercial applications with polyester and epoxy resins. The resin content is affected by several parameters (most of which are interrelated): resin viscosity, the doctor blade setting, the interface pressure at the mandrel surface, winding tension, the number of layers, and the mandrel diameter.
Delivery systems for prepreg and wet-rerolled rovings are similar. Each includes a winding comb (or series of rollers) that is designed to collimate the several strands of roving into a single band width for delivery to the mandrel. Wet winding differs primarily in that the dry fiber roving passes from a creel (or tensioner) into a bath containing the winding resin and passes over a large drum that has a doctor blade that controls the thickness of the resin. Alternately, the roving passes through a series of rollers or rods that are submerged in the resin bath and are designed to flatten the roving strand and force resin into the fiber bundle. After leaving this type of bath, the band usually passes under a wiper or doctor blade to remove the excess resin. Next, the wet-out roving progresses to the winding eye, where it is deposited on the mandrel.
Often, the advantage of one delivery system over another is either lower cost or better resin content control. A major drawback of wet winding is that it is usually limited to horizontal winding operations.
Fiber Volume. Typical fiber volume fractions for several types of fibers in wet-wound composites are shown in Table 1. It can also be seen that the typical fiber volumes are similar to those for composites made by other methods, and that the fiber volume for helical and hoop fibers can be different. Fiber volume, for wet winding, can be changed by the composite manufacturer by resin content control and by more precise side- by-side fiber and fiber band lay-down than is possible with prepreg.

Table 1 Typical fiber volume fractions for helical winding and hoop winding

Fiber	Typical fiber volume fraction (V_f)	
	Helical winding	Hoop winding
Glass	0.55–0.60	**0.65–0.70**
Para aramid (Kevlar)	0.55–0.60	**0.65–0.70**
Carbon-graphite	**0.50–0.55**	**0.60–0.65**

Void content for most wet-wound composites, unless special precautions are taken, are in the range of 3 to 6%. This has been of little concern to pressure vessel manufacturers who seek a composite that only experiences tension in the fibers at minimum weight, but it is of concern if the structure is to experience compression, bending, or shear.

Figures 11 and 12 and Table 2 provide some guidelines for choosing appropriate fibers, resins, and the form of starting materials.

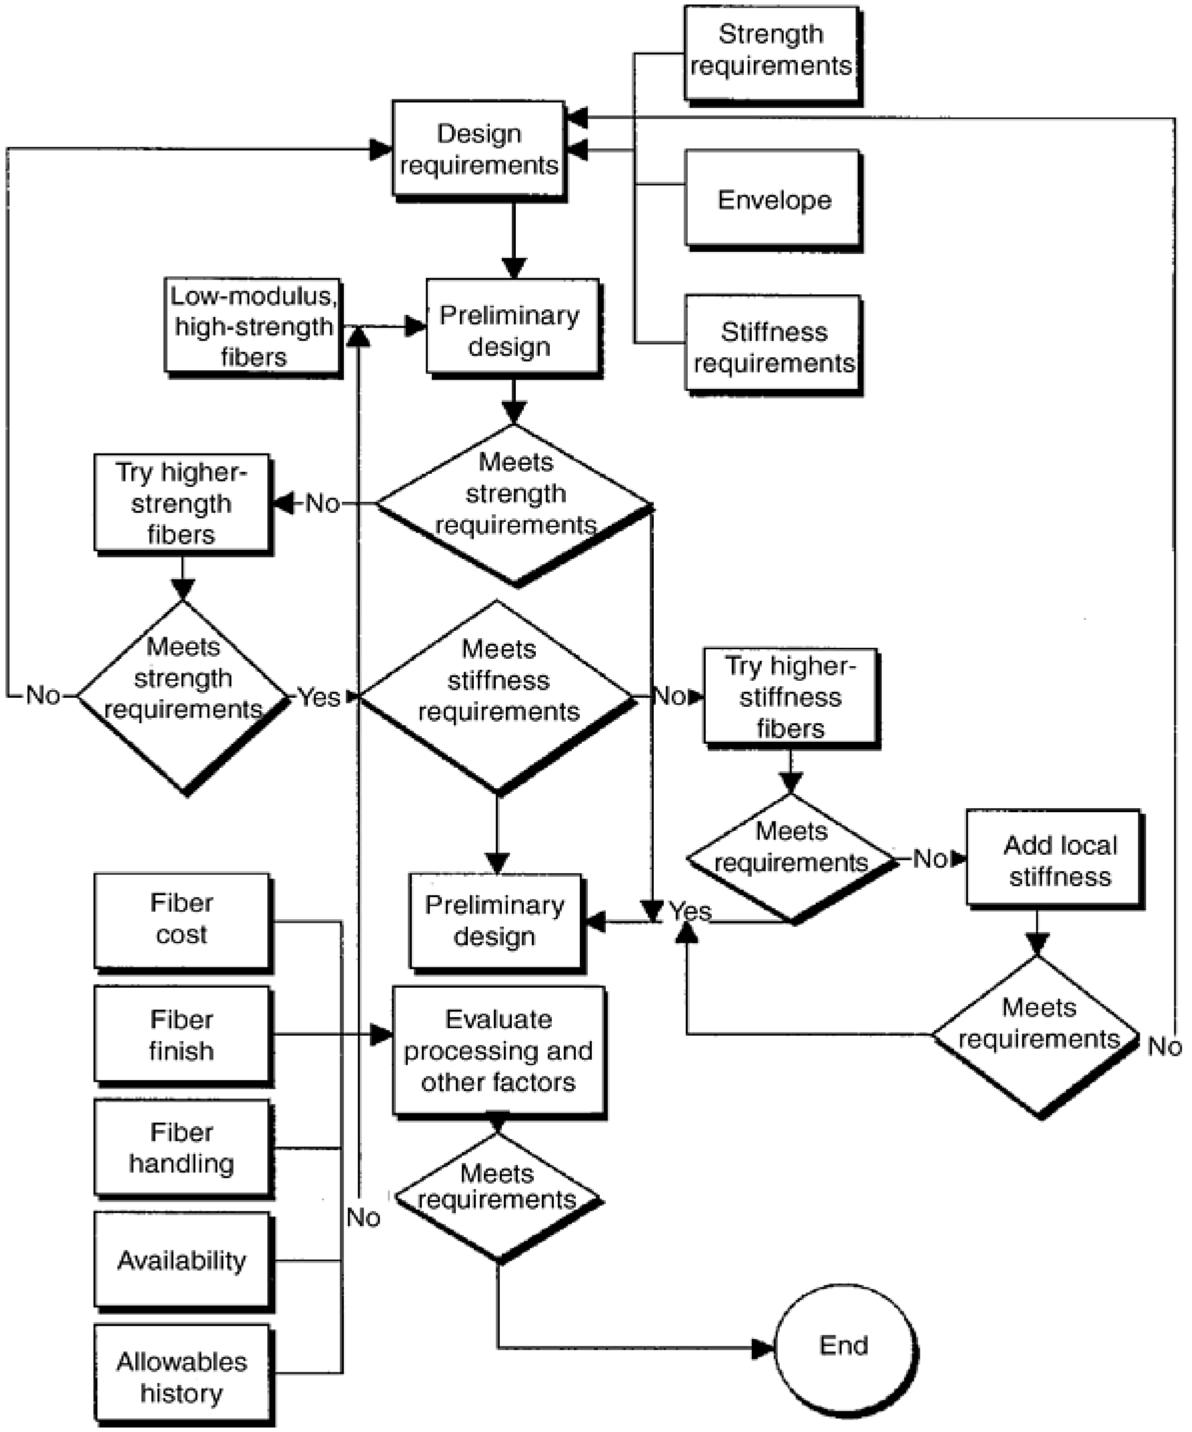

Fig. 11 Iterative process for selecting reinforcing fiber

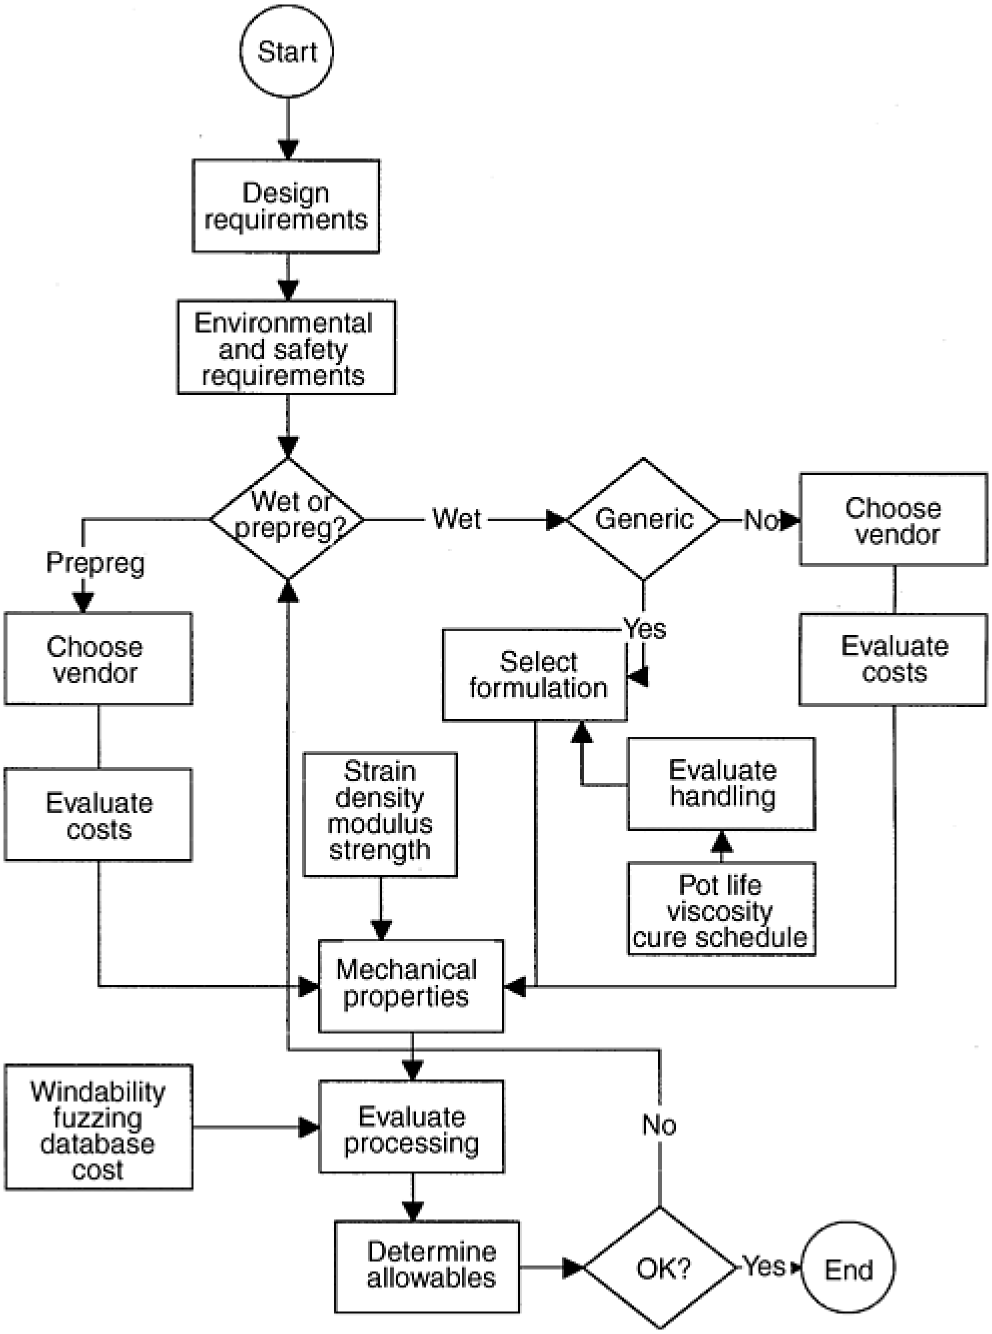

Fig. 12 Selection process for resin component

Table 2 Comparison of prepreg, wet winding, and wet-rerolled filament-winding materials systems

Parameter	**Prepreg**	**Wet winding**	Wet rerolled
Cleanliness	Best	Worst	**Almost equal to prepreg. Mess is away from winder**
Safety	Best; fibers and resin contained	Worst	**Little better than wet. Impregnation can be done where it is convenient and safe.**
Fiber availability	Poor; not all fibers available, some are special order	Best; any fiber that system can handle	**Best; all fibers**
Control of resin	Best; constant speed	Poor; speed of mandrel and resin	**Better; process is away**

content	and viscosity	viscosity varies	**from winder and is faster; little viscosity change**
Quality assurance	Highest; can be done in advance	Worst; imposes quality procedures onto factory floor and can lead to errors	**Good; can be done ahead**
Complex resin systems	Can use; hot melts are available	Very difficult; requires complex impregnators to remove solvents or liquefy hot melts	**Difficult; still requires complex impregnators**
Large data base systems	Yes	Commercial prepreg resin systems generally not available as liquids. Wet systems with large data bases are likely to be proprietary.	**Same as wet winding**
Graphite fibers encapsulated (to prevent electronic short circuits nearby)	Yes	No	**They are not released at winder.**
Storage	Must be refrigerated and storage records maintained	Easy mix at winder. Dry fibers have long shelf life.	**Must be stored like prepreg, but for shorter time. Records must be kept**
Pot life	Longest; can be adjusted	Short, not controllable	**Same as wet**
Cycle time	Adjustable; can be shortest	Limited control	**Limited control**
Fiber damage	Depends on impregnator; can be the least; fiber is handled twice	May require special equipment. Potentially the least, but seldom is	**All handling of fiber is under control of the user.**
Cost	Highest	Lowest	**Above wet, but requires capital equipment for impregnation equipment**
Large roving package	Depends on impregnator	Whatever is available dry from fiber sources	**Same as wet**
Room-temperature cure	Not possible	Possible	**Possible**
Simple resin formulation	Possible	Necessary	**Necessary**
Winding speed	Highest; resin throw and wetting are not factors	Lowest speed	**Intermediate; resin can be staged to reduce resin throw**
Stability on nongeodesic path	Highest possible	Lowest; wet resin may cause slippage	**Intermediate; resin can be staged**
Composite property variations	Least	Largest variations	**Intermediate**
Catenary	Not a problem	Dry fiber to impregnator may have catenary	**Catenary would probably be found previously**
Differential slip (e.g., to slip around or over pins)	**Very difficult to have once the band is formed**	**Easy**	**Easy**

Shapes

Filament-wound shapes generally include cylindrical, spherical, conical, or dome-end configurations. These bodies of revolution best exploit the advantages of high-speed winding. Any part with an axis of symmetry and without a concave surface can be filament-wound with state-of-the- art equipment. Cylindrical shapes with domes (or other provisions for turnaround) are ideal for winding. Additional information about typical shapes and components manufactured by filament-winding is provided in the section "Applications" in this article.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Winding Patterns

The three basic filament-winding patterns are helical, polar (or planar), and hoop (see Fig. 13).

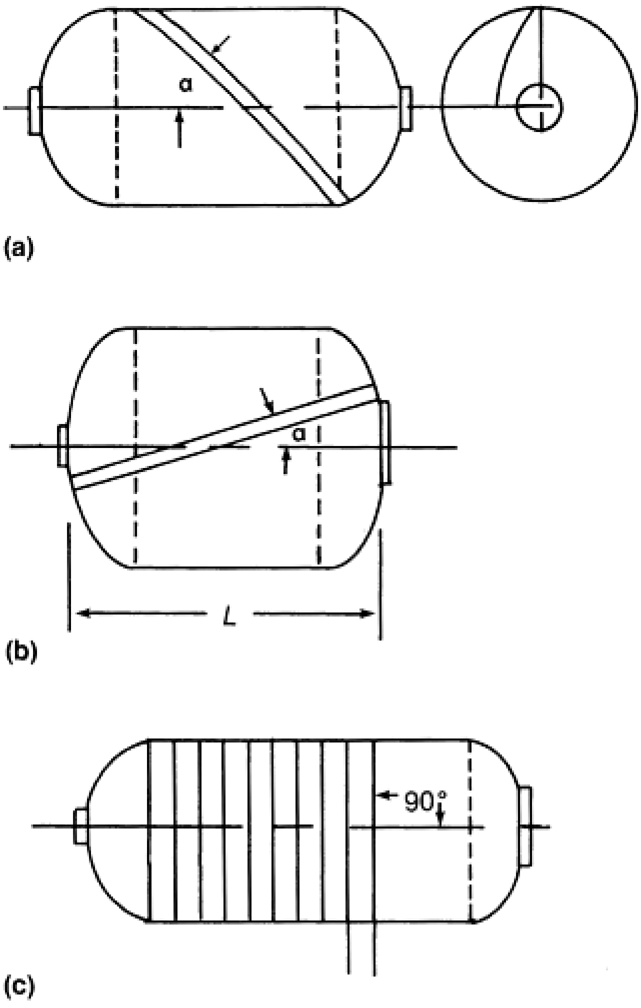

Fig. 13 Basic filament-winding modes. (a) Helical. (b) Polar. (c) Hoop. *α*, wind angle

In helical winding, the mandrel rotates more or less continuously while the fiber feed carriage traverses back and forth at a speed regulated to generate the desired helical angle. The normal winding pattern provides a multicircuit helical. After the first circuit, the applied fibers may not be adjacent. If adjacent, it is called a one-circuit pattern. If three circuits are required to have the fiber band next to the starting fibers, it is a three- circuit pattern. The helical pattern is characterized by fiber crossovers at certain points along the mandrel. The quantity of crossovers increases with the number of circuits per pattern. A layer is made up of a two-ply plus-and-minus angle-balanced laminate. The mandrel revolutions per circuit vary with the winding angle, band width, end dwell, and overall length of the vessel.

Winding of angle plies, if done with a helical program that does not completely cover the mandrel surface with each pass, results in a two-ply layer in which the two angles are interspersed. A polar-wind technique can apply laminate layers in a similar fashion, but the fiber is not deposited on a curved surface in the shortest length. This can cause increased tendency for fiber slippage and, possibly, reduced ultimate loads.

The advantage of helical winding is greater versatility. Almost any combination of diameter and length can be wound by trading-off wind angle and circuits to close the pattern. Minor adjustments can be made by changes in band width, wind angle, and dwell.

In polar winding, the fiber passes tangentially to the polar opening at one end of the chamber, reverses direction, and passes tangentially to the opposite side of the polar opening at the other end. A one-circuit pattern is inherent to polar winding. The windings are delivered by an arm while describing a great circle, and the laid-down pattern is planar. Because the mandrel is regulated to advance one band width for each rotation, succeeding band widths will lie adjacent to one another.

The main advantage of polar (or planar) winding is its simplicity. There is no carriage reversal, and an even winding speed can be maintained. However, because the fiber path is not a helix, it is not the shortest fiber distance between points. This can result in fiber slipping during wet winding and lower ultimate values in pressure vessels.

Hoop patterns are also known as girth, 90°, or circumferential (circ) winding. Strictly speaking, hoop winding is a high-angle helical winding that approaches an angle of 90°. Each full rotation of the mandrel advances the band delivery one full band width. The winding machine is much like a lathe in that the spindle speed is much more rapid than the carriage travel. Hoop windings are generally combined with longitudinal windings (helical or polar) to produce a balanced-stress structure. Hoop patterns are applied to the cylindrical section of a closed-end vessel, while helical and polar patterns reinforce both the cylinder and the domes.

Crossovers. One of the major differences between filament-wound composite laminates and those manufactured by other methods is the presence of crossovers. When a structure is helically wound with bands of fibers of a width such that in traversing from one end to the other the object is not covered completely, crossovers will result. Helical filament-winding patterns, rather than polar, are chosen for all structures where the length-to-diameter ratio equals or exceeds two, because polar-wind patterns can be expected to slip during fabrication and when cured and under load. The quantity of crossovers depends upon the width of the band and upon the number of circuits per pattern. The analysis for design of composites with crossovers is more involved than that for discrete layers.

When pressure vessels are loaded at very high rates (a matter of 10 to 20 microseconds from earth atmospheric to burst), they generally fail at the crossovers. There is some evidence that the cyclic fatigue resistance is reduced slightly when crossovers are used. Values when layers are five- to ten-thousandths of an inch thick are very close to those of structures having discrete layers.

In some evaluations, such as short beam shear tests, the crossovers appear to be of value in increasing the apparent shear stress to force the desired failure mode. In small rocket launch tubes, crossovers provide an additional benefit. If they are on the inner surface, they can prevent band or tows from unwinding or stripping from one end of the tube to the other. In parts that do not have crossovers, this is likely to happen, especially when individual fibers have not been completely attached to the resin matrix.

Also, a helical-wound tube without crossovers can fail under a tensile stress on the tube by transverse fiber pullout. Some have recommended an interior hoop layer to avoid this failure mode. Because the two helical layers that form each angle ply are interlaced at the crossovers, there is some degree of enhanced fracture toughness, at least between the angle plies.

Bands of tows can conform to extreme shapes without distortion or buckling or without having been strained (stretched). This is because each tow in a band can be any length relative to the others and can be free to slip, at least in wet- winding systems and in some prepreg when heated.

It is possible in filament-winding to have two bands, for example, that when they cross, the total thickness at the crossing may be less than the total thickness of the two bands, or less than the thickness of one band, due to the possibility of spreading. Of course, the band width at the nodes will be larger, related to the reduction in thickness. This technique can be used advantageously to build a practical structure such as an isogrid, without a complex grooved mandrel and without any additional fiber buildup at the nodes.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Tooling and Equipment

One of the big advantages of filament-winding over other composite manufacturing methods is the simplicity of tooling. The mandrel, which provides the part with accurate internal geometry, is generally the only major tool. Equipment and facilities required are usually simple and often consist of just a winding machine and curing oven.

Mandrel design can be as simple or as complex as the part requires. The factors that must be considered are production reusability, tolerances required, thermal expansion control, weight (equipment limitations), deflections (sagging), part removal from mandrel, and cost.

Low-cost mandrel materials such as cardboard or wood can often be used when winding routine parts. At the other end of the use spectrum, where critical parts require close tolerances, expensive steel mandrels designed

for long-term use may be required. For high-temperature cure (315 °C, or 600 °F), graphite mandrels with low thermal expansion are advantageous. Gas-containment pressure vessels often require metal or plastic liners because composites are porous at high pressures; metal liners can also serve as mandrels.

Mandrel Types. Descriptions of the principal mandrel types used in the filament-winding industry are given below.

Water-soluble mandrels are primarily used in rocket motor cases and pressure vessels where mandrel removal through small openings is desired. The sand is cast into female molds that use preassembled components, such as insulation, wind axis, lightening tubes, and polar bosses. The sand is cured, and two mandrel ends are assembled and bonded. Two binder systems commonly used are polyvinyl alcohol and sodium silicate. The advantage of water-soluble sand mandrels is low cost for small production quantities and excellent dimensional reproducibility. The disadvantage is a high initial tooling cost.

Spider/plaster mandrels are often used to provide a high-tolerance mandrel surface in which a plaster sweep is used over removable or collapsible tooling. The plaster is cured, then overwrapped with a synthetic fluorine-containing resin tape or some other separator film. Following cure, tooling is removed, the plaster is chipped or washed out, and the release tape is removed, leaving the desired inside contour. Metal-supported plaster is generally used for relatively large parts (3 to 6 m, or 10 to 20 ft). For any larger size, the mandrel may be limited by torque or bearing strength of the wind-axis attachments.

Segmented-collapsible mandrels are specialized and expensive, but the advantages of their reusability and the continuous winding process renders expensive tooling worthwhile for high- production applications.

Cylindrical (tubular) steel mandrels are used to fabricate composites that are stripped (pushed or pulled) off the surface after curing. These tools must be of high quality for trouble-free usage. Chrome-plated, anodized, or hardened and polished surfaces assist in easy mandrel removal. A slight taper along the length of the mandrel also is beneficial. The tube mandrel may be as complex or as simple as economy dictates. Its size is limited only by the length of the winding machine bed.

Nonremovable liners in pressure vessels provide a lightweight pressure container that combines the high strength-to-density of composites with a thin, impermeable metal or plastic liner to contain high-pressure gas, such as helium, hydrogen, or oxygen (Fig. 14). Metal liners can be designed to carry either a large or small portion of the internal pressure, but in all cases the liner, which initially served as the winding mandrel, becomes a vital part of the pressure vessel.

Fig. 14 Metal-lined filament-wound oxygen bottle. Courtesy of SCI, Astro Division of Harsco Corporation

Specialized mandrels include inflatable rubber (elastomeric) or plastic mandrels. These are limited by the explosive properties of the inflating medium. One approach is to fill the mandrel with a material such as sand and then draw a vacuum on it.

Winding Machines. In most winding machines, the mandrel is suspended horizontally between a head stock and a tail stock, much like a lathe (Fig. 1). The carriage travels lengthwise at speeds synchronized with the mandrel rotation to deliver the roving from a wind eye at various winding angles for the selected winding pattern. There is a great variety of winding equipment commercially available to wind helical, polar, or hoop patterns (refer to the Section “Winding Patterns” in this article). The bulk of production filament-winding is still performed using the mechanical gear-driven machines that evolved during the late 1950s. These machines will continue to be

used because of their low cost. Polar winders with only two axes of rotation (mandrel and winding arm) still produce rocket motor cases and spherical pressure vessels in great numbers.
Helical winders have progressed from two- to seven-axes machines (and some suppliers have promised eight-axes equipment). Helical winders may be either horizontal or vertical; the latter of which can be much simpler, because the load goes through the axis of rotation, minimizing mandrel deflections. Also, handling operations are simplified if the mandrel does not require horizontal-to-vertical rotation for installation of tooling or for B-staging (of rocket motor skirts).
Tensioners. Because most reinforcements are packaged on rolls, tension can be introduced at the roll. Magnetic or friction brakes, electronic rewind, and rotating scissor bars are the tension devices used. Because they rewind, the latter two allow the overtravel past the domes to be taken up, thus winding of low-angle patterns around end domes is possible.
The tensioners are often mounted on creels that are either remote to the winder or part of the carriage that actually travels with the delivery system. The tensioning devices should have as many of the following features as possible: variable but controlled tension levels, easily adjusted tensions, rewind capability to prevent fiber slacking, and uniform tension regardless of the size of the roll.
Ovens. The fabrication of the composite portion of the assembly is completed by the curing operation, although some resin systems are room-temperature cured and do not require an oven. Several equipment options for oven curing are available. The most commonly used are ovens (gas-fired, microwave, or electric) or autoclaves.
Most epoxy resin systems are cured in gas- fired ovens heated with either air or inert gas, without supplemental pressure. The use of vacuum bags and bleeder cloths has been implemented by some manufacturers, and the system is reported to produce void-free laminates with improved compaction. Autoclaves are commonly used with the more exotic resins, such as bismaleimides and polyimides. Bismaleimides require special considerations because of the high degree of compaction required to promote resin flow, while polyimides necessitate the removal of a high volume of volatile materials produced during cure. Generally, autoclaves are not used for pressure vessels such as pipes and tanks. If an autoclave is to be used for pressure vessels, care must be exercised to not bleed the resin too much. Excess bleed causes the filaments to relax and can even cause wrinkles, disturbing the load- carrying effectiveness of the filaments. Autoclaves are the state of the art for nonwound components, such as skins and panels for aircraft applications, for which the interface pressure between the continuous fibers and the thermally expanding mandrel may not otherwise develop during cure.
Microwave oven curing requires a high initial investment but provides life-cycle savings by dramatically reduced energy costs and significantly reduced cure times. However, special heating supplements, such as induction heaters, are often required at the composite-metal interfaces, and microwave cure works best with nonconductive fibers.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Applications

Pressure vessels have been the most demanding and pervasive application for the technique. Filament-winding is the only fabrication technique for high-performance pressure vessels. The recent advances in increasing the strength of carbon-graphite and organic fibers have resulted in carbon-graphite fibers with a strength of almost 7000 MPa, or 1000 ksi (for example, Toray T-1000, [Toray Industries, Japan], 6370 MPa, or 924 ksi), and an organic fiber (PBO, manufactured under the trade name Zylon [Toyobo Co., Ltd., Japan]) has tensile strengths and moduli almost double those of p-aramid fibers. The performance factor of the fiber (fiber strength divided by density) using values quoted by the vendor shows the PBO fiber about 3% less efficient than T-1000 carbon-graphite fiber.
Rocket Motors. All new booster rocket motors manufactured in the United States are strong candidates for filament-winding. The Titan IV strap-on booster is now a filament–wound carbon-graphite-epoxy composite that has replaced the high-strength steel cases (Fig. 15). Strap-on boosters for Atlas and Delta rockets are also

filament-wound. There are still no aircraft- launched tactical composite rocket motors in the United States in spite of their advantage of greater munitions insensitivity. Ground- launched tactical rocket motors have been in continuous production since the late 1970s when the Viper rocket motor concept was introduced. This was a glass-fiber reinforced structure with a 100% aft opening for introduction of a preformed propellant grain. The aft opening was closed with a closure that had removable pins inserted into the specially reinforced case end (Fig 16).

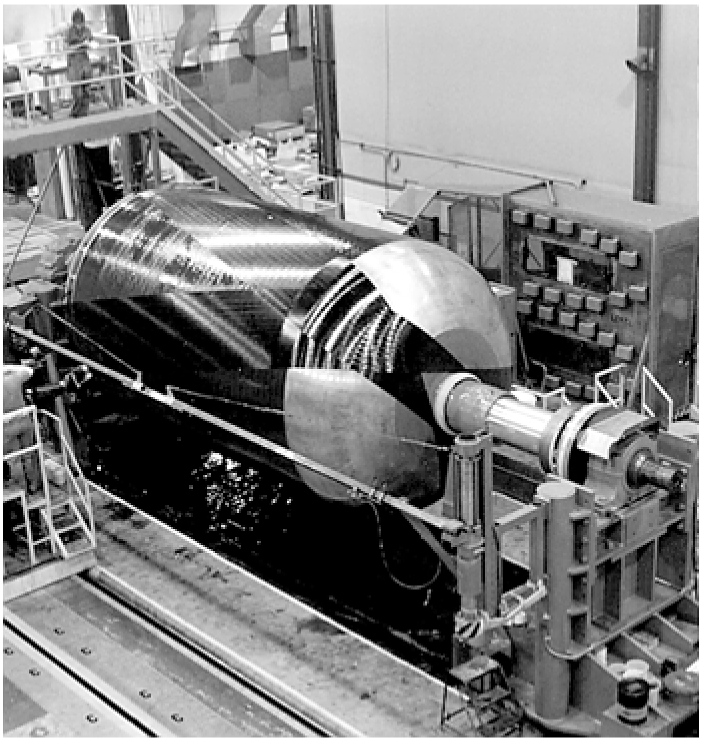

Fig. 15 Large winding for the Titan IV rocket motor. Courtesy of Alliant Techsystems, Inc.

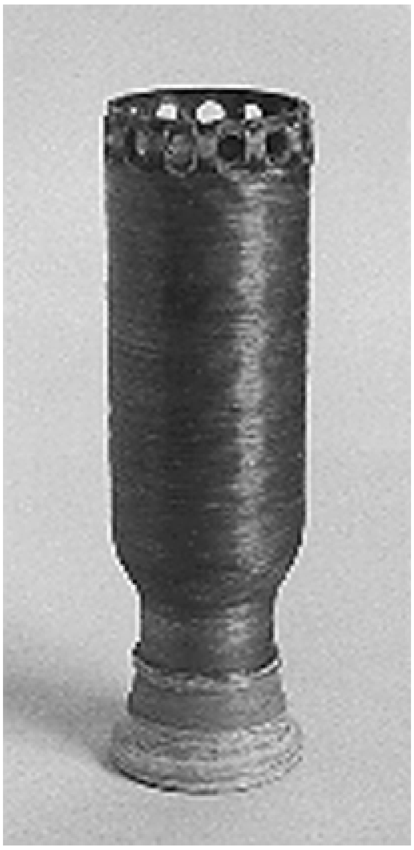

Fig. 16 Viper tactical rocket case with wound-in pin joint. Courtesy of Brunswick Defense Division (now Lincoln Composites)

Natural Gas Vehicle (NGV) Tanks. A large market exists for composite-overwrapped NGV pressure vessels for mass and individual transportation. These vessels have used thick and thin steel and aluminum liners as well as thermoplastic liners. The fibers have been carbon- graphite and/or fiberglass with a variety of epoxy matrices (Fig. 17). The pressure vessels have performed well in service except for a very few problems. In 1985 there was an in-service failure of a hoop-wrapped high-pressure cylinder that necessitated recall and reinforcement of the dome-closure area. This was a metal failure. Only the cylindrical portion of this tank was filament-wound. Wound tanks use a process called autofrettage to expand the metal past yielding and place tension in the fibers. Without internal pressure, the steel is under compression and the fibers under tension. Under service pressure, the steel undergoes low tensile loading as the fibers sustain the high values.

Fig. 17 Typical natural gas vehicle tanks. Courtesy of Lincoln Composites, Inc.

Power Transmission Shafts and Rollers. The filament-wound power transmission shaft industry started because of corrosion problems with metallic shafts and poor durability in the corrosive atmosphere of water cooling towers. Also, composite shafts could be made longer, replacing two shafts with one composite shaft, eliminating the intermediate support and universal coupling with lower vibration concerns. Replacing of steel rollers (for slack take-up in paper mills and similar industries) resulted in higher throughput because of lower inertia in the roller (Fig. 18).

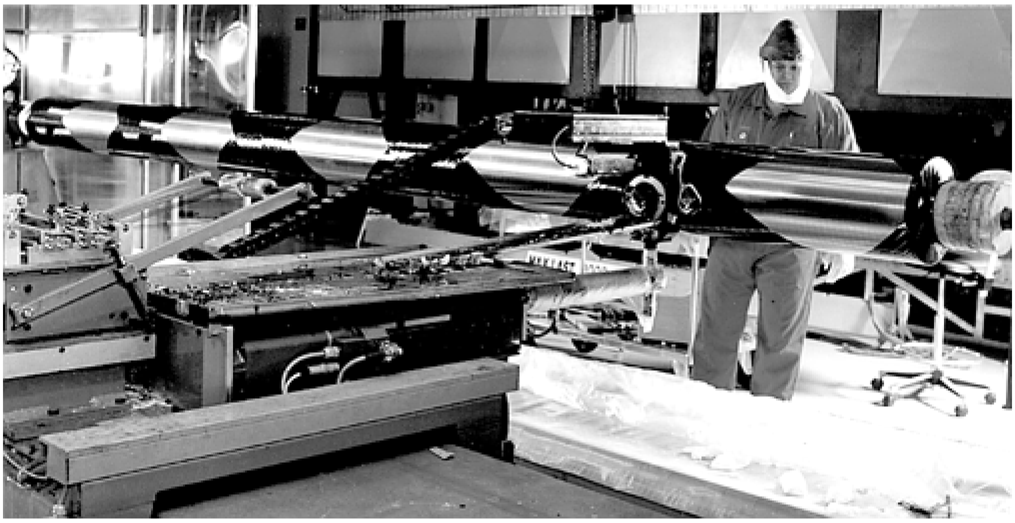

Fig. 18 Commercial roller filament-winding. Courtesy of Applied Composites AB, Celsius Group

Sporting Goods. The effect on sporting goods of filament-wound composites has been immense. Virtually all tennis rackets are manufactured from composites. Many are made from a filament-wound preform (Fig. 19). The bulk of products are made from filament-wound broadgoods that are folded to result in a stacked prepreg with the desired fiber angles.

Fig. 19 Filament-wound carbon-epoxy tennis racket. Courtesy of Wilson Sporting Goods Co.

Boats. Most of the attempts to introduce filament-winding into the boating industry have been unsuccessful. Filament-winding was attempted as a technology by two contractors for large craft such as minesweepers, but failed because of fiber slip (Ref 3). However, the process has been successful for smaller craft.

A historical perspective on the applicability of filament-winding for diverse uses is illustrated by a small boat (Fig. 20) filament-wound in the 1950s. The boat has been in continuous use in rivers and lakes in the United States and Canada. It has never had to be repaired and has never leaked. The floor has recently increased its deflection. This may be due to the partial failure of the balsa bonded to the wound fibers or to the deterioration of the balsa. The many years of water transfer due to rain and time in water plus hull-bottom flexing are probably the significant factors.

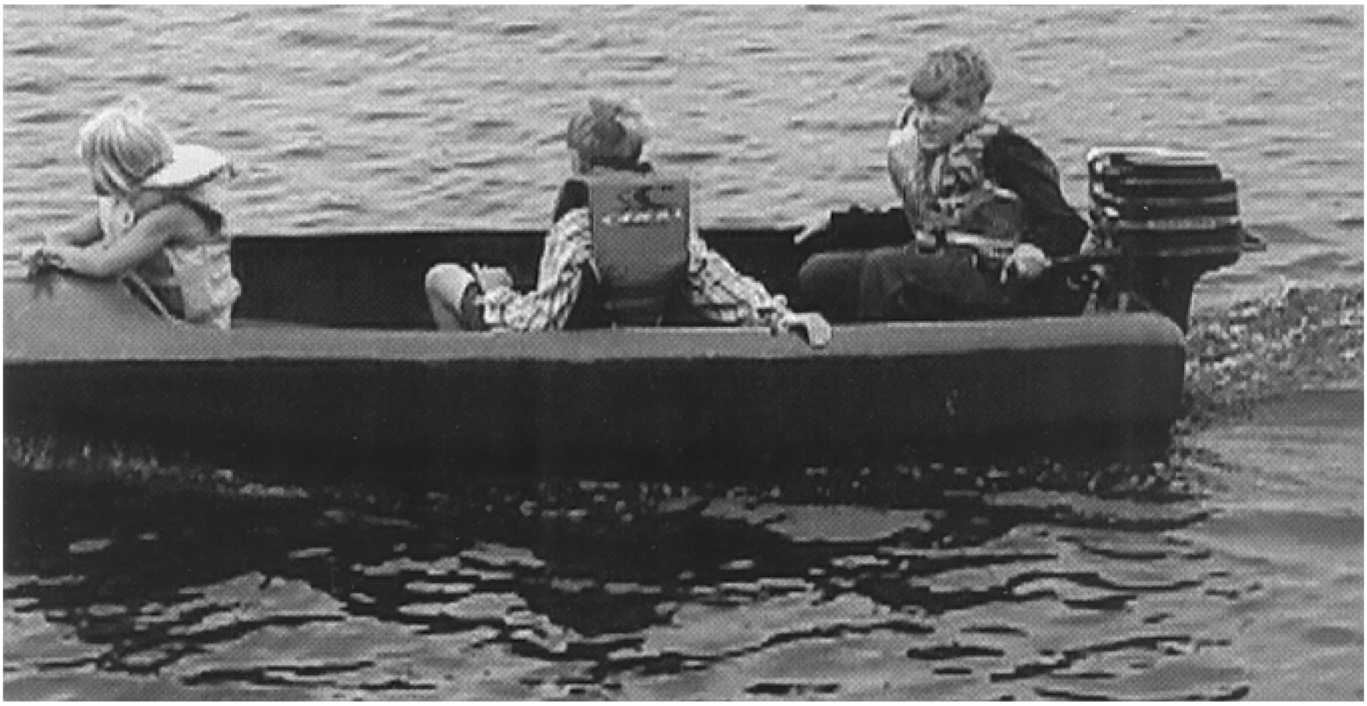

Fig. 20 Filament-wound car-top boat

The principal feature of this boat is the use of filament-wound material for molding complex shapes, that is, early preforms. The added feature was to combine this molding material with filament-winding to create an all filament-wound structure for any configuration.

The materials used were 250-yield glass rovings, epoxy resin, an epoxy curing agent, and three parts of green pigment. No other ultraviolet light protection was used. The war surplus end- core balsa varied between 140 and 220 g/cm^3 (5 and 8 lb/ft^3). No paint was used. Oarlock fittings and forward rope attachments were bronze.

The tooling consisted of hull-shaped boxes bolted together around a three inch steel tube. The boxes were small enough to be removed through the open section above the seats. Pockets were placed in the boxes as an internal detail for the seat supports. Materials needed for molding were filament-wound on a 0.9 m (3 ft) diameter mandrel. The mandrel surface had 1.6 mm (1/16 in.) deep circumferential grooves by using a plastic floor runner. This surface was for ease of materials removal without fiber displacement. Seat mandrels were of solid 25 mm (1 in.) balsa that were overwound at ±65° and remained as part of the structure.

The winding pattern for the molding filament- wound material was ±65° for two reasons. The fibers did not slip at end reversal. When used as a molding material, the ±65° fiber orientation could be rotated to change the ± value. For example, the ±65° would be ±25° when rotated 90° and placed on the boat hull mandrel. During winding of the hull, fiber band placement was always on a nonslipping path. There were no circumferentials or longitudinals. The placement was based upon a design that should be flexible, that would have small changes in wind angle between the very few plies available, and would effectively distribute the load of the passenger and cargo within the hull and load on the outer hull due to beaching and to smooth rocks in shallow streams.

Representative Component Properties

Because most filament winders can use wet resin systems along with prepregs and preformulated wet resin systems, there is a need to verify the properties of the individual components of the composite as well as the fiber-resin combination and the cured component. Table 3 shows the test methods to verify the fiber-resin components.

Source: Ref 4

There are several reasons that filament-wound composites are not tested in the same manner as composites fabricated by other means. It is always preferable to test a laminate that has the same manufacturing method and lay-up as the component. This is relatively easy for common composites that generally have a flat surface that may replicate a surface of the component.

Filament-wound composites are generally surfaces of revolution, that is, curved, so that usually a portion of the composite will be impossible to test without bending. If the laminate could be wound onto a flat surface, if helical plies are used, the laminate can be expected to warp upon cure due to the lack of symmetry in a single-laminate wall. A further problem arises with flat filament-wound structures; the flat laminate is not adequately compacted across the flat surface, and the laminate center bulges during the winding. If it is desirable to wind a flat laminate that replicates the actual laminate, then that test part will have to be wound using a polar pattern for the angle plies to avoid distortion of the laminate on cure and will probably have to be compacted by alternate means, depending on the thickness of the laminate. In either case, the manufacturing method is not representative of the actual part, and thus the properties are not representative.

To test a filament-wound structure, the general procedure has been to burst test a subscale bottle of the same laminate design and lay-up, because the bulk of filament-wound products have been pressure vessels. The raw materials can be tested as filaments, rings, and cylinders (Fig. 21). The filament or tow test results in somewhat higher values than those obtained by vessel testing. The ring-test specimen can also be cut up for short beam shear tests. These are for comparative shear values only and are not a true engineering shear. These shear values can be misleading with carbon/graphite fiber composites because of edge effects in a narrow ring and the nonuniformity of ply-to-ply strain. The ring tests are useful to develop ultimate tensile values, but not moduli. Three test methods have been adopted to evaluate unidirectional ply properties. These are transverse tension, compression, and in- plane shear. Table 4 shows these tests and a summary of the consensus standards for testing and evaluation of filament-wound components.

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Design Guidelines (Ref 6)

The design process for any composite involves both laminate design and component design and must also include considerations of manufacturing process and eventual environmental exposure. These steps are all interdependent with composites, and the most efficient design must involve true concurrent engineering. These recommendations are directed towards the filament-winding design/manufacturing process. Other articles in this Volume address general design recommendations and those that relate to specific manufacturing methods. Basic design guidelines include:

- Use the most appropriate fabrication method or methods for the part. Combine methods if necessary. Particularly for large structures, the relative cost of filament-winding is less than one-fourth that of hand lay-up and less than one-half that of tape laying.
- Choose the most appropriate starting material form. Use a wet resin, if appropriate and safe for the process, to further reduce the cost of manufacture.
- Consider fabrication requirements during preliminary design. Avoid designs that are technically elegant but cannot be built consistently or reliably.
- Design “net” parts. Reduce machining to a minimum. Try to incorporate composite-to- metal in situ joints in the winding process. *In situ* refers to a co-cured joint with possible failure-safe design. One joint technique (Ref 1) uses a reduced section to join a composite cylinder to an end fitting. The reduced section ensures that the joint is not totally dependent on the adhesive qualities of the bond and adds a measure of fail-safe performance because, without the adhesive, the components will remain joined. Whenever possible, co-cure adhesive-bonded assemblies and build in stiffeners.
- Take advantage of the flexibility of the filament-winding process. Ply thicknesses are not predetermined, as with unidirectional tape or woven fabric. They are a function, primarily, of the band width, the cross-sectional area of the filaments, the resin content, the filament count of the tow, and the number of tows. Some computer analysis programs, designed primarily for use with tape reinforcements, may only accommodate predetermined ply thicknesses in their included ply data tables. The user must know the techniques of circumventing these limitations or must use another analysis process.
- Select the simplest design to manufacture. If there is a hard choice between ease of analysis and ease of manufacture, choose the latter.
- Design for an entire composite structure rather than using composite as a substitute for a metal.
- Consider the possibilities of different fiber angles versus fabrication. If the design calls for very low angle helicals, but they would bridge or slip, consider absorbing a slight weight penalty by designing with higher angle helicals to simplify fabrication.

Detailed design recommendations involve taking advantage of the orthotropic nature of the fiber composite ply:

- To carry in-plane tensile or compressive loads, align the fibers in the directions of these loads.
- For in-plane shear loads, align most fibers at ±45° to these shear loads.
- For combined normal and shear in-plane loading, provide multiple or intermediate ply angles for a combined load capability. Use resins that have the strain-to-failure values to match the fiber and fiber orientations and intra- and interlaminar forces. Intersperse the ply orientations. If a design requires a laminate with 16 plies at ±45°, 16 plies at 0°, and 16 plies at 90°, use the interspersed design $[90_2/\pm45_2/0_2]_{4S}$ rather than $[90_8/\pm45_8/0_8]_S$. Concentrating plies at nearly the same angle (0° and 90° in the previous example) provides the opportunity for large matrix cracks to form. These produce lower laminate allowables, probably because large cracks are more injurious to the fibers and more readily form delaminations than the finer cracks occurring in interspersed laminates. The preceding comments are true for most composite applications regardless of the fabrication method. Because of the (usually) axisymmetric nature of filament-winding, the resultant structure does not have to be symmetric with respect to the wall centerline unless more than one helical winding angle is used.
- Avoid extreme angle changes from ply to ply. It is recommended to step from 15º to 45º to 60º to 85º rather than directly from 15º to 85º.
- If a design requires all 0° plies, some 90° plies (and perhaps some off-angle plies) should be interspersed in the laminate to provide some biaxial strength and stability and to accommodate unplanned loads. This improves handling characteristics and serves to prevent large matrix cracks from forming. Use softening strips of lower-modulus fiber (such as cloth) at structure ends and in joints to reduce end stresses.
- Locally reinforce with fabric or mat in areas of concentrated loading. (This technique is used to locally reinforce pressure vessel domes.)
- Use fabric, particularly fiberglass or Kevlar, as a surface ply to restrict surface (handling) damage.
- Select the lay-up to avoid mismatch of properties of the laminate with those of the adjoining structures, or provide a shear/separator ply.
- Consider Poisson's ratio. If the transverse strain of a laminate greatly differs from that of adjoining structure, large interlaminar stresses are produced under load.
- Consider coefficient of thermal expansion. Temperature change can produce large interlaminar stresses if coefficient of thermal expansion of the laminate differs greatly from that of adjoining structure.
- The ply layer adjacent to most metal-to-composite bonded joints should not have fibers perpendicular to the direction of loading. Do not thicken the composite in the joint area. The essential stiffness (EI, where E is modulus of elasticity and I is moment of inertia) of all elements of the joint should not have abrupt changes. Glass fiber in carbon structures as well as various carbon fiber orientations can be used to achieve smooth transitions.
- Use multiple ply angles. Typical composite laminates are constructed from multiple unidirectional or fabric layers that are positioned at angular orientations in a specified stacking sequence. From many choices, experience suggests a rather narrow range of practical construction from which the final laminate configuration is usually selected. The multiple layers are usually oriented in at least two different angles, and possibly three or four (±θ°, 0°/±θ°, or 0°/±θ°/90° covers most applications, with θ between 30 and 60°). Unidirectional laminates are rarely used except when the basic composite material is only mildly orthotropic (e.g., certain metal-matrix applications), or when the load path is absolutely known or carefully oriented parallel to the reinforcement (e.g. stiffener caps, chain links and springs).

Fabrication Recommendations

This Section addresses the delivery and handling of the tow during filament-winding and was adapted from Ref 7. With only a small amount of attention and rudimentary engineering, carbon-graphite fiber tow can readily be spread evenly to its maximum width or any desired intermediate width. For a wet wound 12K tow, nominal width is about 3 mm (0.125 in.); for a 48 to 50K tow, it is 25 to 30 mm (1.00 to 1.25 in.). Good practice in fiber handling will result in wider band widths with resultant better control of layer thicknesses.

The tube package must be positioned horizontally, with the tube axis perpendicular to the direction of fiber feed. Fiber should never be pulled off the end because each revolution of feed introduces one twist. Twist is not acceptable for high-performance fibers because it decreases fiber volume and reduces some mechanical properties.

It is basically a matter of choice as to whether the fiber feed is taken from the top or bottom of the package unless a de-reeler is used to eliminate all tension. In that case it is better to have the fiber off the bottom to reduce the opportunity for material to slip off the package ends and become entangled on the support shaft. The de- reeler uses slack for its operation and uses vertical side deflectors to eliminate end spill.

For guides, eyelets, and orifices that contact the tow:

- The bore diameter must not be less than 9 mm (0.375 in.).
- The entry and departure angles of the fiber through the guide should be minimized, never more than 20° from the normal. This prevents acute fiber abrasion.
- Ceramic guides are an excellent choice, but steel may be used (as in a “pigtail,” for example) only if the guide is very well polished. Pigtail guides should not be of fine diameter and not used for carbon-graphite fiber. Pigtail guides allow the winder to move the fiber from one guide to the other without cutting fiber. Figure 22 shows some typical guides.
- Roller redirects, not guides or pigtails, should be used for prepreg. The best materials are Teflon (i.e., Du Pont de Nemours & Co., Inc., Wilmington, DE) or polyethylene (high-density polyethylene or ultrahigh molecular weight polyethylene). Radially grooved rollers of these materials have been found to be acceptable
- The first guide or pick-up point should be at least 400 mm (16 in.) from the package surface. If the guide is too close and a de-reeler is not used, the fiber scuffs laterally across the outer package surface, generally abrading and causing loose fiber. Additionally, if there are not vertical side restrictions, the first guide should be on the horizontal centerline of the package to prevent fall-off of wraps at the edges and to minimize scuffing.
- Try to eliminate as many redirects (guides) as possible. The ideal fiber handling is zero touches between the creel to the wind eye, but this is generally impossible. The reason for reducing the number of redirects is that each redirect adds friction to the fiber with a multiplying effect. If fiber packages are tensioned, the control that should be exercised at the creel may not be possible.
- If the first guide from the package is shifted to either side of the centerline, the departure angle becomes more acute for material coming from the far end of the spool, which results in lateral slippage as it unwinds, scuffing the underlying fiber. This is especially prevalent with creel-tensioned fibers.
- Excessive tension, until the fibers have been wet with resin, should be avoided for a number of reasons. There is the possibility of increased self-abrasion over the roll surface and guides and possible breakage of the tow. The tow may imbed itself in underlying windings, producing a tangle that is unacceptable in a structure. Highest tension should be on the inner plies, with gradually decreased tension each ply until completion. This will prevent the outer plies from crimping the inner plies and making them ineffective in both tensile and compression loadings. The diameter or curvature of the product being wound and the winding angle determine the packing force normal to the surface; that is, use the lowest fiber tension that will assure straight fibers in the completed structure.

- If flat sheet is used as an orifice/guide plate, choices of materials should be limited to polytetrafluoroethylene (Teflon), high-density polyethylene, or nylon.
- The bore length of a guide is of little or no concern: It is the condition of the entry to the guide that determines success in handling.
- Carbon-graphite is a high modulus, and therefore a brittle and frangible material. There will always be some minor degree of fiber buildup at the guides and/or contact points. The essence of successful processing is what might be called “preventative housekeeping practices.” In periods as short as 10 minutes elapsed processing time, any extraneous loose fiber buildup should be removed. If a small problem remains unattended, it will escalate very quickly into a serious problem, possibly resulting in tow breakage. Other fibers such as glass and aramid do not abrade or “fuzz up” as badly.
- Typically, loose fiber build-up problems are exacerbated with resin-wetted tow after it exits the resin bath, if tension is applied at the creel. Somewhat closer attention to “housekeeping” is demanded in this circumstance.
- Tube-packaged fiber is provided twist-free. However, “false twist” can occur. Typically, if the path length from the creel to the first process point is adequate (2.5 to 3 m, or 8 to 10 ft), especially with prepreg where false twist cannot be tolerated, the false twist will fall out.

Fig. 22 Typical pigtail and ceramic guides. Courtesy of Texkimp, Ltd.

Guidelines for spreading the fiber:

- Moving the fiber over a rolling surface does not increase spreading nearly as much as passing it over static surfaces. However, in either case, the surface should be polished to a surface roughness of 16 root mean square (rms) or better (comparable to drill rod stock, which may be used).
- The fiber bundle will assume a near-circular cross section 15 to 30 cm (6 to 12 in.) from band flattening. The distance shortens with tension. A wet fiber band should be deposited on the winding surface within a few inches of band forming.
- The lower the tension level on the tow, the wider the spread width will be. Ideally, only enough tension should be placed on the tow to prevent roving overruns when winding is stopped. For wet winding, a nonreversing mechanism on the impregnation roller or on the creel will prevent excessive spill problems with rewind tensioners when there are broken tows or lengthy reversals that drag the impregnated tow back over the roller.
- Diameters of static bars for band flattening should be no less than 12 mm (0.5 in.); 12 to 24 mm (0.5 to 1.0 in.) is a good working range. Usually, the larger the radius and the distance that the fiber passes over, the greater the spread of the fiber, although friction is increased.

- An “S” wrap, consisting of two static bars placed one over the other, is a very effective way to spread the fiber. The pair can be rotated as a unit to minimize or maximize the fiber contact or to provide tension in the fiber.
- The longer the fiber is in contact with the surface (residence time) on the static rods, the greater the spread width will be.
- Running speed has little or no effect on the spread width.
- The higher the back tension on the fiber, the more critical the sweep angle on unwinding becomes.
- If the package is mounted with a spring, washers, and nut arrangement (for tension control) on a shaft, the package should rotate in the direction that loosens the nut. (Otherwise, it will tighten the nut until the package is literally seized.)

Filament Winding

S.T. Peters, Process Research; J. Lowrie McLarty

Outlook

Technology. Filament-winding technology will shift to more dedicated equipment as the demand for more filament-wound products increases. Now, dedicated equipment is being used for filament-wound golf shafts, oil and water pipe, electrical fuses and interrupter tubes, commercial gas pressure vessels, chain links, transmission couplings, drive shafts and rotors, small spacers, and auto leaf springs.

Technology will be developed for maintaining the high structural strength values of the virgin fibers, such as carbon-graphite. For example, there will be increased use of de-reelers to eliminate tension at the creel, and tension will be applied only after fiber impregnation and will be controlled after band forming. New resin content sensors and controls will be developed.

The development will continue of apparatuses and processes to allow the dropping and starting of fibers in a wound structure (thereby allowing band widths and thicknesses to be changed).

Varying wall thickness and side-by-side fiber combinations can increase the number of products that can be economically wound, and will enable existing structures, such as bridge components, to use less material.

Prepreg tows and bands will become commercially available in thicknesses as small as 0.08 to 0.10 mm (0.003 to 0.004 in.). However, use of fibers this thin is not possible in wet winding. The very thin plies will increase the quantity of plies and strength of many structures. Many spacecraft structures use very thin plies for modulus-dominated quasi-isotropic structures.

Sensors and devices for controlling the resin content of wet-impregnated fibers will become more common. Use of these devices will reduce the resin waste and clean up now prevalent.

The use of wound material as a molding compound and as a primary bonded adjunct to filament-wound products is starting to be adopted for container corners and rotor bodies.

Applications. It is expected that filament- winding will be used increasingly to manufacture components in the following areas:

- *Transportation:* Railroad floor beams, door frames, pressure vessels, bus wheel wells (to prevent personnel injury from blown tires), over-the-road tankers for various liquids (in Europe and South America, not the United States), bridge beams, building columns
- *Springs.* In addition to leaf springs for autos and trucks, a spiral-wound spring is used for an aircraft door. Circular concave-wound disks are used in series as a shock absorber for glider landing gears.

- *Automobile Driveshafts:* When it was discovered that a composite driveshaft for an automotive application (the GMT-400 pickup truck) could be cost-competitive with its metallic counterpart, the effort was to find more applications on vehicles. Now many disparate vehicles, from garbage trucks to racecars, use filament-wound driveshafts (Fig. 23). In the future, these applications will transition more frequently to filament-winding, rather than other competing processes, because of the inherent cost-effectiveness of the process and because a more reliable joint technology exists for filament-wound shafts than for pultruded shafts.
- *NGV Tanks:* The trend has been to outfit more buses with the filament-wound tanks to comply with environmental restrictions. Automotive uses will increase greatly due to the recent qualification of type 2 cylinders (hoop-wrapped carbon-graphite fiber-epoxy over aluminum alloy 6061 high-pressure cylinders) for use in taxis and minivans. This is just the start of large-scale usage in automotive applications.
- *Automobile Flywheels:* As yet, the cost picture for employment of flywheels in automotive applications is not positive. More likely is the use of large composite flywheels for power plant storage of energy during off- peak hours. This concept is a great deal cheaper than building new power plants and would not encounter the environmental resistance that a new power plant would.

Pultrusion

Joseph E. Sumerak, Creative Pultrusions Inc.; Jeffrey D. Martin, Martin Pultrusion Group

Introduction

PULTRUSION is a cost-effective automated process for manufacturing continuous, constant cross-section composite profiles. Though developed in the early 1950s, pultrusion has gained a market and technical position of prominence in the 1980s and is now recognized as one of the most versatile of the composite production methods.

Pultrusion refers to both the final product and the process. Most simply, it refers to a method of manufacture wherein a collection of reinforcements saturated with reactive resin is pulled through a heated die that imparts the final geometry to the composite profile. In virtually every case, the continuous reinforcing fiber choices are integral to the processibility and the finished product properties. The resin matrix used is typically a liquid thermosetting resin, which reacts exothermically when heat is introduced to create a cross-linked polymer with exceptional engineering properties. The resulting thermoset composite profile cannot be reshaped or otherwise altered within its operating temperature range. In contrast, the extrusion of aluminum and thermoplastic materials generally involves unreinforced (homogeneous) materials that are heated and pushed through a die, then allowed to cool into the final solid shape. These materials may be reheated and reshaped numerous times with little loss of basic properties. Although a body of technology exists for thermoplastic pultrusion processing that enables post-pultrusion reshaping, it has not yet reached a position of commercial significance.

Despite the surge of commercial activity and study, there is still a significant amount of unpublished art in combining the continuous reinforcements and resins in a continuous operation that has kept the processor base small. During the 1980s, there was a dramatic increase in market acceptance, technology development, and pultrusion industry sophistication. In the 1990s, the number of technically competent personnel in pultrusion processing, materials supply, end use, and academia on a global basis has developed to the point where additional dramatic growth can occur. This coupled with increased awareness of the cost-competitive advantages of pultruded products and the availability of design standards and application specifications will enable pultruded composites to become a traditional material alongside steel, wood, and aluminum in the 21st century.

Pultrusion

Joseph E. Sumerak, Creative Pultrusions Inc.; Jeffrey D. Martin, Martin Pultrusion Group

Technique Characteristics

Of the six basic elements in the pultrusion process, the three that precede the pultrusion machine are the reinforcement handling system (referred to as roving and mat creels), the resin impregnation station, and the material forming (or preforming) area. The pultrusion machine consists of component equipment that heats the input materials, cures the reactive resin, pulls the product through the die, and cuts the finished profile to a desired length.

The process begins when reinforcing fibers are pulled from a series of creels. The fibers are directed in a specific path through a resin bath, where they are impregnated with formulated resin. The resin-impregnated fibers are formed to the shape of the profile to be produced with excess resin being stripped from the fibers at this point. This consolidated material is then drawn into a heated steel die that has been precision- machined to the final shape of the part to be manufactured. The heated die initiates an exothermic reaction in the thermosetting resin matrix. The profile is continuously pulled and exits the mold as a hot, fully cured, constant

cross-sectional area profile at a rate determined by the resin reactivity. Upon exiting the die, the profile cools in ambient or forced air, or is assisted by water spray, as it is continuously pulled by a mechanism that simultaneously clamps and pulls. The product emerges from the puller mechanism and is cut to the desired length by an automatic, flying cutoff saw. Either manual or automated part removal clears the product from the line for further value-added operations or for inspection and packaging. Very little additional cosmetic finishing is required for a properly processed pultruded profile.

Although pultrusion machines are available that can operate at rates that range from 25 mm/ min to 5 m/min (1 in./min to 15 ft/min), typical production line speeds today are in the range of 0.6 to 1.5 m/min (2–5 ft/min). Higher effective output can readily be achieved by producing multiple streams (cavities) within one machine. Nearly 100% of the input raw materials exits the die as usable product. Pultrusion of high volume products can be executed with less than 2% raw material and finished product scrap.

Two general categories of pultruded products are: solid rod and bar stock produced from uniaxial reinforcements (0° orientation with respect to the machine direction), which deliver the highest axial tensile strength and stiffness, and structural profiles, which use a combination of uniaxial fibers and multidirectional fiber mats or fabrics to create a set of properties that meet the requirements of the application in the transverse (90°), off-axis (plus and minus angles other than 0 and 90°) and longitudinal (0°) directions.

More than 75% of all pultruded products are based on fiberglass reinforced polyester resin. When better corrosion resistance is required, vinyl ester resins are used and represent the next largest product segment. Both of these resin types are also available as flame-retardant versions. When a combination of superior mechanical and electrical properties is required, especially at elevated temperatures, epoxy resin is used. When applications require both high continuous-use temperature resistance and the highest mechanical properties, the use of epoxy resins reinforced with carbon or aramid fibers is the necessary option. Improved flame retardance, smoke suppression, and low toxicity can be achieved with selection of highly filled acrylic resin. The best overall flame, smoke, and toxicity performance coupled with high-temperature property retention is achieved with phenolic resin matrices. Toughness properties can be achieved with high elongation vinyl esters or thermoset polyurethane as well as with thermoplastic resins of various types. Each of the material selections has some processing expertise that must be well understood by the pultruder to make quality products.

Joseph E. Sumerak, Creative Pultrusions Inc.; Jeffrey D. Martin, Martin Pultrusion Group

Process Advantages

Pultruded composites exhibit all of the features found in products produced by other composite processes, such as high strength-to-weight ratio, corrosion resistance, electrical insulation, and dimensional stability. Additional advantages are derived from the process characteristics. One advantage is that the continuous nature of pultruded composites allows any transportable length to be produced. An example of such a product is the 1 to 3 mm (0.04–0.12 in.) diameter fiber-optic cable strength member rods that are pultruded in lengths of 2.2 km (1.4 miles) long and wound on a spool directly after the pultrusion gripper unit.

Another advantage is that complex, thin-wall shapes, such as those extruded in aluminum or polyvinyl chloride (PVC), are now possible because of recent process technology advances. Parts with multiple hollow sections can be produced using cantilevered steel mandrels and sophisticated forming guides. In addition to constant wall thickness profiles, which are always easier to pultrude, variable wall thickness in a constant cross section can be pultruded as well, providing a great deal of design flexibility. No other composite fabrication process can match the profile complexity possible with pultrusion.

Wire, wood, or foam inserts can be encapsulated on a continuous basis in pultruded products. In fact, any continuous feedstock may be encapsulated as long as sufficient bonding strength is present between the composite skin and the encapsulant in the application environment so as to prevent delamination.

A less obvious process advantage is the ability to use the widest variety of reinforcement types, forms, and styles with a broad selection of thermosetting resins and fillers. Virtually no other composite process offers as

much materials versatility as pultrusion. Reinforcements can be placed precisely where they are needed for mechanical strength and consistency.

In addition, pultruded shapes can be made as large as required because equipment can be built in virtually any size. A corollary advantage of larger equipment is its ability to produce multiple cavities of the same or dissimilar profiles, which enables pultrusion to compete with traditional materials because of a relatively low resultant labor cost. Capital equipment costs of pultrusion and supporting equipment is low relative to aluminum or thermoplastic extrusion equipment. The cost of tooling for pultruded shapes is also low compared to other composite processes.

Pultrusion

---

Applications

The versatility of the process has enabled pultrusions to penetrate such market areas as road and rail transportation, construction, infrastructure, marine, corrosion-resistant equipment, electrical/electronic, consumer, appliances/business equipment, aircraft, and specialty. With the newest forming technology, pultrusion can produce nearly any constant cross-sectional shape that can be extruded. Aluminum extrusions account for approximately 15% of all of the aluminum consumed, while pultrusions account for only 5% of all reinforced plastics produced; thus, pultrusion has much growth potential. However, pultrusions are rarely cost competitive based solely on shape replication since adjustments in strength factors usually require a wall thickness increase. There are several markets in which pultruded profiles have made a significant penetration that is not tied to just price competitiveness. Pultruded products are most successful when they provide corollary advantages that are not available with traditional competitive materials as previously described.

Two categories of pultruded shapes distinguish a processor's business focus. The first category, standard structural shapes, includes channels, tubes (round, square, and rectangular), I-beams, and wide-flange beams and solid bar stock that are produced for inventory in a variety of performance grades. Fabricators apply these standard shapes in designs for structures such as cooling towers, walkways, stairs and numerous other applications. A collection of standard structural shapes is shown in Fig. 1.

Fig. 1 Pultruded standard structural shapes. Courtesy of Creative Pultrusions, Inc.

The second general category is custom profiles, where a pultruder assists the end user in designing a profile that suits a specific need and may be a consolidation of design functions replacing several parts or fabrication steps required with conventional materials. Custom shapes are generally not offered for sale to the general market because they are the proprietary property of the end user. A custom shape can also be a symmetrical geometry like a standard profile but may have special dimensions defined by the end user. Custom shapes are often nonsymmetrical and quite complex when the full potential for design consolidation is realized. Examples of custom pultruded profiles are shown in Fig. 2.

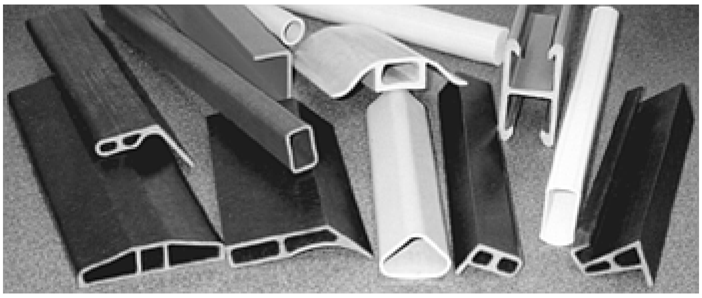

Fig. 2 Custom pultruded profiles. Courtesy of Creative Pultrusions, Inc.

The highest-volume application of pultrusion at this time is the fabrication of nonconductive ladder rails for in-plant and communication and power utility use. The 1990s saw expansion of this product into the consumer market as well. Similarly, fiberglass tool handles, which were restricted to industrial use, now proliferate in retail outlets for garden and construction tools.

In highly corrosive environments, pultruded grating systems have become the standard because of their excellent mechanical properties and durability, replacing steel, aluminum, and even stainless steel systems. They are also used in elevated walkways and on steps where the supports are structural profiles, such as I-beams, channels, angles, and tubular shapes, that are often made to the same dimensions as steel or aluminum supports for ease of substitution of traditional materials. Cable trays of steel are being replaced by pultruded composite cable trays because of their superior corrosion resistance and better electrical insulation values. Corrosion-resistant fiberglass sucker rods have replaced steel in the extraction of oil.

Pultruded solid rectangular and square bars are being used in transformers, one of the oldest applications, to separate the windings and to permit air circulation. Utility market applications include guy strain insulators, standoff insulators, hot-line maintenance tools, and booms for electrical bucket trucks. Other electrical applications include high-voltage maintenance tool handles, bus bar insulator supports, fuse tubes, lighting poles, and cross-arms. Utility power poles up to 20 m (65 ft) in length are finding a competitive niche where traditional materials become cost prohibitive. High-voltage electrical power transmission towers as well as cellular communication towers are being introduced as low-maintenance designs for power companies. The digital communication revolution, which relies on high-speed fiber-optic cables for data transmission, also relies on pultruded cable tension members; the high tensile strength of these members ensures the strength of the cable and shields the fragile communication fibers from stress.

Dunnage bars that separate and isolate loads in trucks and railcars have been made from pultruded lineals for many years. The back doors that roll into the roof of the truck are also pultruded, as are the structural Z-sections between the inner and outer walls of a refrigerated truck trailer. Complete over-the-road trailers as well as rail cars have recently been produced using composite materials with a heavy content of pultruded profiles. One manufacturer has successfully tested a complete truck chassis as a pultruded beam fabrication with improved performance compared to steel.

Construction of residential and commercial buildings has successfully applied pultruded composite window and door framing, taking advantage of the superior thermal insulation, thermal expansion, and dimensional stability properties. Introduction of complete construction systems that include foam-filled or cellular paneling and functional connectors enable low-cost transport and assembly of structures for outbuildings as well as low-cost emergency relief dwellings.

Flame-retardant pultruded composites have captured business in underground transit systems where low flame, smoke, and toxicity protect passengers in the event of fire. The Channel Tunnel, or Chunnel, project (connecting England and France under the English Channel) utilized a tremendous amount of pultruded product for electrical cable support systems and other structural applications. Offshore oil production platforms rely on flame-retardant phenolic pultruded gratings and structural shapes to provide corrosion resistance, structural function, and personnel protection.

In many buses, the luggage rack is pultruded. Hollow sections within the rack allow air to be passed for heating or cooling. Because of its continuous nature, the pultrusion process produces the rack in one piece to span the entire length of the bus. In another transit application, long lengths of electrically insulating coverboard are pultruded to cover the current-carrying third rail on rapid transit systems. Because of the design flexibility of composite profiles, the shape is designed to snap over the rail and yet support a load dropped from above or a

railroad workman. On the highway, pultruded delineator posts that deflect without permanent deformation are now most often used instead of rigid rolled steel posts with plastic reflectors.

The recognition of the longevity potential of composites has opened vast new opportunities in the infrastructure market. Bridge decking to replace steel reinforced concrete is under intense study with many demonstration projects well into service-evaluation stages. Steel rebar is being challenged by composite rebar produced by hybrid pultrusion processes. Dowel bars that connect poured concrete slabs are also being tested as pultruded replacements for steel with much promise of greater durability. Highway guardrails are another very large potential where composites and specifically pultrusions are currently being evaluated. In all such applications, the higher initial cost of composites must be weighed against the life-cycle cost benefits afforded by the improved durability of the materials.

Pultrusion

Joseph E. Sumerak, Creative Pultrusions Inc.; Jeffrey D. Martin, Martin Pultrusion Group

Key Technology Areas

There are three critical technology areas of equal importance: product composition, material forming, and control of process temperature.

Product Composition. Resin formulation and reinforcement selection determine composite properties that satisfy application needs. Reinforcements are selected to meet desired mechanical properties. The electrical insulation and the corrosion resistance of the composite are affected by the amount and type of reinforcement used. In many applications, compromise is required to meet all of the desired properties.

Pultrusion is a composite process that allows selective reinforcement of profile sections using different materials. This can be accomplished on a continuous basis with good consistency and repeatability. Base resin selection is important because the resin governs mechanical characteristics, operating temperature range, electrical insulation, corrosion resistance, and the flame and smoke properties of the profile. In addition, it governs process speed by its reactivity and can significantly control product aesthetics and tolerance capability. The resin matrix can be altered by chemical additives and fillers, which enhance its ability to handle higher temperatures; provide better electrical insulation, corrosion resistance, and dimensional stability; and lessen flame and smoke propagation. It is essential to the success of any pultruded profile that the polymer matrix be correctly engineered to meet the desired end- use properties and still provide those processing characteristics that are necessary to fulfill the economic goals of the application. This balance requires significant interaction between the end user and the pultruder.

Material Forming. The material-forming area usually comes after the reinforcements have been impregnated with resin. Reinforcements are precisely positioned using porcelain bushings, metal forms, or plastic guides that have been machined to allow axial and multidirectional reinforcements to pass from one to the next before entering the heated die. These guides, if properly designed, can ensure the consistent placement of the different reinforcement types. These forming guides can become very complex and interactive on large profiles and hollow sections. This necessitates engineering the reinforcements, their path, and their forming sequence. However, even with a fair understanding of materials, the techniques required to produce these forming systems can take years to develop. Even with experience, considerable on-line process engineering is required to fine-tune the material delivery and forming systems. This technology is fundamental to the consistency and optimization of mechanical properties and tolerances and is the most difficult aspect encountered by the beginning and novice pultruder.

Control of Process Temperature. With thermoset resins, it is important to control the rate and level at which heat is added to the matrix or removed from the profile. If too little heat is put into the die, the composite material will not reach its desired exotherm temperature, resulting in an incomplete cure and less than optimal properties in the finished profile. Too high a temperature can induce thermal stress cracking as the profile cools, resulting in a material that exhibits poor electrical insulation or corrosion-resistance properties.

The following discussion provides additional details of processing equipment and tooling, material composition, and process control essential for a basic understanding of the pultrusion process.

Joseph E. Sumerak, Creative Pultrusions Inc.; Jeffrey D. Martin, Martin Pultrusion Group

Process Equipment

The pultrusion process is depicted in Fig. 3. The basic elements of all pultrusion machines are very similar, but there are differences in the selection of heating components, power transmission, clamping devices, and cutoff saws. A full range of hardware as well as process control features are available from commercial machinery suppliers. These features designed from years of process insight help to bridge the gap between the art and experience of the established pultruders and the new companies entering the field. A pultruder must strive for a common denominator in establishing the processing system and its corresponding process control in a multimachine production facility.

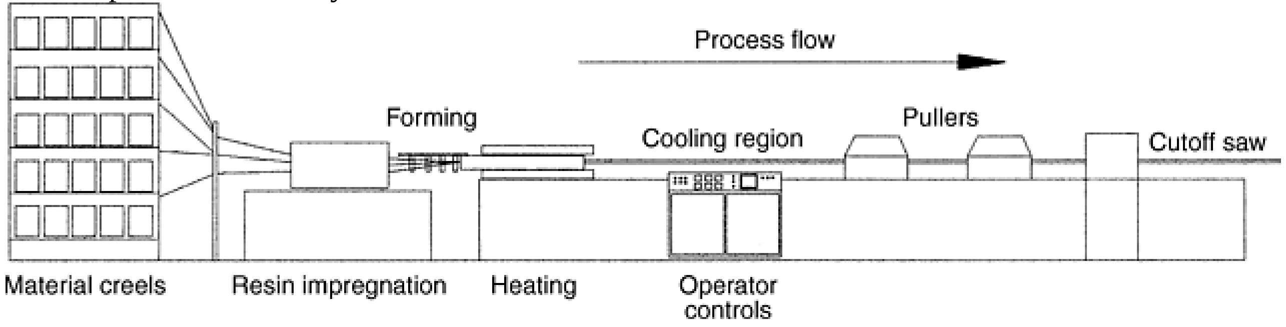

Fig. 3 Schematic of pultrusion process

Material In-Feed. Reinforcements are provided in packages designed for the best continuous runout of its material form. The continuous fiber creels are usually the first station on a process line. Continuous glass rovings are provided in center-pull packages that weigh 15 to 25 kg (33–55 lb) and are designed for a bookshelf-style creel. Creels of 100 or more packages are common and may be stationary or mobile. The glass roving is usually drawn from the package through a series of ceramic textile thread guides or drilled carding plates of steel or plastic. This allows them to be pulled to the front of the creel while maintaining alignment and minimizing fiber damage. Some creel designs allow multiple guide eyes (bushings) or guide bars to tailor the tension on each roving. The ease of servicing or replacing roving packages must be considered in selecting a creel design and package capacity since the process is never interrupted for material replacement.

While most center-pull rovings have a small twist useful for package formation, some fiberglass rovings are available as center-pull twistless; that is, the natural twist as a consequence of winding has been offset by a built-in reverse twist. As an alternative, continuous fibers of glass, carbon, and organic polymers can also be supplied on packages with cardboard cores designed for outside payout to avoid twist. This style of package dictates the use of a multiple spindle creel design in which the packages are oriented horizontally. Ceramic bushings are again used to guide and protect fibers as they are delivered to the front of the creel. With this style creel, an additional consideration of package rotation and the resulting tension necessitates the use of a spindle bearing to provide uniform tension regardless of package size. Because packages in this configuration are usually smaller in diameter and weight, a greater number of packages may be found on such a creel design. It is not common to find both style creels used in the same facility due to the desire to standardize inventory and methods.

Directly after the roving creels is a creel designed to accommodate rolls of continuous strand mat, engineered fabric or surfacing veil. The roll materials are usually supplied in diameters between 305 and 610 mm (12 and 24 in.) with cores of 75 or 100 mm (3 or 4 in.) inside diameter. The creel must be able to accommodate both the size of the roll and the inside diameter of the core, along with appropriate spindle spacing and core bushings. The ability to lock the position of the roll in the desired lateral position will ensure consistent delivery of the

material to the desired location in the profile. In many cases, it is also necessary to provide for the payout of web material in a vertical, rather than a horizontal, format. This requires independent roll stands with a vertical roll spindle and a roll support plate to support the material as the material pays off the roll.

As materials travel forward toward the impregnation area, it is necessary to control the alignment to prevent twisting, knotting, and damage to the reinforcements. This can be accomplished by using machined creel cards that have predefined specific locations for each material strand or ply. In some cases, these cards can be used for only one specific profile. An alternative approach uses a general-format creel card for roving and web locations that can be utilized and easily adapted for a variety of common profiles. While this is a less expensive approach, it requires more operator attention in order to confirm proper material input over the production period.

Resin Impregnation and Material Forming. The impregnation of reinforcements with liquid resin is basic to nearly every pultrusion process. The point at which resin is supplied and the manner in which it is delivered can take many different forms. A dip bath is most commonly used where fibers enter and exit a contained volume of resin with open top access only. With this design, fibers are passed over and under wet-out bars while immersed below the resin level, which causes the fiber bundles to spread and accept resin. This is suitable for products that are of an all-roving construction or for products that are easily formed from the resulting flat ply that exits the wet-out bath. In cases where it is impractical to dip materials into a bath, such as when vertical mats are required or hollow profiles are made, materials can pass directly into a “straight-through” resin bath. This design has entry-end and exit-end plates that have been machined for both passage and alignment of fibers as they pass through the resin. This alternative method provides the necessary impregnation without the need to move the reinforcements outside of their intended forming path. Since this type of bath has an open top as well as end plates that have a degree of resin leakage, a resin drip collection system and recirculation pump are necessary with this design. Due to recent attention to both industrial exposure limits to styrene for plant personnel as well as environmental volatile organic compound (VOC) emission regulations, emphasis has been placed on minimizing bath size, controlling airflow, and enclosing bath areas.

An alternative approach employing direct resin injection into the die is being used by many pultruders, but has substantial technical limitations regarding fiber permeability and maximum filler content as well as substantial hardware investment. This area of technology requires additional study before widespread use is possible.

Forming of reinforcing materials is usually accomplished directly after impregnation, although some initial steps can be carried out during the impregnation process as well. Forming guides are usually attached to the pultrusion die to ensure positive alignment of the formed materials with the die cavity. Forming is always accomplished progressively with consideration of continuous support for materials while maintaining operator accessibility for service. Sizing of the forming guide slots and holes and clearances between forming plates must be designed to prevent excess tension on the relatively weak and wet materials, but must allow for sufficient resin removal to prevent excessive hydraulic force at the die entrance.

In the case of tubular pultruded products, a mandrel support is necessary to extend the mandrel in a cantilevered fashion through the pultrusion die while securing it to resist the forward drag on the mandrel during processing. The mandrel support is typically attached to the die to achieve positive registration to the cavity and provide a platform for mounting forming guides. Materials must form sequentially around the mandrel in an alternating fashion to prevent weak areas due to ply overlap joints.

In the case of direct die injection, the reinforcements are formed dry and are fully compacted inside the die at the time of resin injection. Although this technique minimizes the problems associated with the wet bath systems, some limitations exist in the areas of wet-out, air entrapment, and maximum filler content. An alternative method pumps resin into a forming card prior to the die entrance and can be done at multiple forming stages to achieve better wet-out while minimizing exposed resin and the volume of resin committed to the process as compared to a bath system. A combination of techniques may be the answer for a specific profile, depending on its complexity, and each case requires special forming guide and impregnation consideration.

The materials commonly used for forming guides include fluoropolymers, ultrahigh molecular weight polyethylene, chrome-plated steel, and various sheet steel alloys. The pultrusion processor must employ a craftsman capable of converting sheet metal and plastic stock into forming guides with precise control to be most successful in processing complex shapes. Of all of the technologies employed by pultruders, the forming techniques and fabrication methods are perhaps the most proprietary and remain an unpublished art.

Die Heating. A number of different methods can be used to position and anchor the pultrusion die in the machine and to apply the heat necessary to initiate the reaction. The use of an open die bed with a yoke arrangement that allows the die to be fastened to the frame is the simplest arrangement. In all die-holding designs, the thrust that develops as material is pulled through the die must be transferred to the frame without allowing movement of the die or deflection of the frame. With this open-bed design, heating jackets that use hot oil or individual electrical resistance strip or plate heaters are positioned around the die at desired locations. Thermocouples are placed in the die to control the level of heat applied. Multiple individually controlled zones can be configured in this manner to achieve the greatest flexibility in heating design. This is the preferred method for complex nonsymmetrical profiles that have nonsymmetrical heating demands to achieve temperature uniformity around the cross section. This approach is well suited to single-cavity setups, but becomes more complex when the number of dies used simultaneously increases, since each die requires multiple heat sources and control thermocouple feedback provisions. To help alleviate this limitation, standardized wide heating jackets or wide heating plates can be designed to accommodate multiple dies.

Another popular die station design uses heated platens that have fixed zones of heating control with thermocouple feedback from within the platen rather than the die. The advantage of this method is that all dies can be heated uniformly with reduced-temperature cycling, because changes in temperature are detected early at the source of heat rather than at the load. In the same respect, however, a significant temperature drop will be common between the platen set point and the actual die temperature. Use of die monitor thermocouples identifies the differential and an appropriate controller set point can be established. When provided with the means to separate the platens automatically, the advantage of quick setup and replacement of dies can lead to increased productivity through reduced downtime with this heating design approach. A die mount height adjustment feature, found on many commercial open-bed and platen-based machines, allows the processor to exactly align the die centerline with the pulling mechanism to eliminate any product distortion associated with misalignment.

A source of cooling water or air is essential in the entry end of the die at start-up and during temporary shutdown periods to prevent premature gelation of the resin at the tapered or radiused die entrance. While the first section of the die is typically unheated to allow for some amount of natural cooling through convection, additional forced cooling is often applied by coring the die for fluid circulation, by using a detachable cooling jacket, or by utilizing the self- contained cooling zone within the heating platen. Such cooling is especially useful when high initial die temperatures are required, as with epoxy resins.

The most critical pultrusion process control parameter is the die-heating profile because it determines the rate of reaction, the position of reaction within the die, and the magnitude of the peak exotherm. Improperly cured materials will exhibit poor physical and mechanical properties, yet may appear visually identical to adequately cured products. Excess heat input may result in products with thermal cracks or crazes, which destroy the electrical, corrosion-resistance, and mechanical properties of the composite. Heat- sinking zones at the end of the die or auxiliary cooling may be necessary to remove exotherm heat prior to exit of the product from the die. The dynamics of the heat demands and reaction energy release have recently been modeled mathematically, empirically, and with the use of finite element analysis (FEA) methods, and graphical predictions of heat transfer balance can be used to guide the processor to optimal process conditions.

To increase process rates and to reduce temperature differentials between the die and the material that contribute to thermal cracking in large mass products, it is often desirable to preheat material before it enters the die. This may be accomplished by radio frequency, induction, or conventional conductive heating methods. Such heating devices are best applied as stand- alone devices that can be positioned before the die entrance when required.

The use of a process optimization instrument that allows tracking of external die temperature profiles and internal product temperatures as a function of die position during the curing process is highly desirable and a well-accepted test method. The data collected in a graphic format at a specific process speed represent a “snapshot” of steady-state process conditions that can be used for production troubleshooting, process engineering, and quality assurance documentation. There is a need for further process control developments of this nature that will provide improved process capability and production efficiency.

Clamping and Pulling Provisions. A physical separation of 3 m (10 ft) or more between the die exit and the pulling device is typically provided in order to allow the hot pultruded product to cool in the atmosphere or in a forced- water or air-cooling stream. This allows the product to develop adequate strength to resist the clamping forces required to grip the product and pull it through the die. The pulling mechanisms are varied in design

among the hundreds of machines built by entrepreneurs or supplied by commercial machinery firms. Three general categories of pulling mechanisms that are used to distinguish pultrusion machines are the intermittent-pull single reciprocating clamp, continuous-pull dual reciprocating clamps, and continuous belt or cleated-chain puller.

The earliest pultrusion machines used a single clamp, which was hydraulically operated to grip the part between contoured pads. A carriage containing this clamping unit was then pulled by a continuous chain, which was driven by a variable-speed reversible drive train for a stroke of 3 to 4 m (10 to 13 ft). At the end of the stroke, the clamp released and the clamping carriage returned to its starting point. During this return interval, the product remained stationary until the clamping and pulling cycle could be reinitiated. Because of this pull-pause sequence, this style became known as an intermittent-pull machine. Variations of this design are still found in the industry, including multiple clamping heads for multiple-cavity production.

The continuous-pull reciprocating dual clamp machine has become the most popular style machine due to its versatility. Its alternating clamping, extension, and retraction cycles are synchronized between two pullers to provide a continuous pulling motion to the product. The value of using the intermittent-pull cycle with slow-cure materials or for purging die buildups is reflected in the fact that commercial reciprocating clamp machines also have selectable intermittent-pull sequences. Subtle variations exist in the use of different drive methods, such as direct-acting hydraulic cylinders, hydraulic motor driven chain drives or electrically powered recirculating mechanical ball screws. Methods of clamping can be hydraulic, pneumatic, or a mechanical wedge action. The basic prerequisite is that sufficient clamping pressure be available on the contoured puller block that is held within the clamping envelope. The longer the clamping unit, the lower the unit pressure on the pultrusion required to prevent slippage. Clamping units are available with lengths of 300 to 900 mm (12–36 in.). In addition, sufficient thrust must be provided to the clamping unit to overcome the pulling resistance and to maintain a uniform pulling speed. An advantage of the reciprocating clamp system is its need for only two matched puller pads to maintain a continuous pulling motion. These pads are easily changed and are generally fabricated of durable polyurethane for long life and mar resistance and are mounted on steel or aluminum bases.

Continuous-belt pullers have evolved from thermoplastic extrusion take-off pullers, but have been modified for higher pulling loads of pultrusion. These pullers are suitable for single- cavity or multiple-cavity production when all profiles are of the same physical size. Even with this restriction, uneven belt wear can result in slippage of adjacent cavities. As an advantage, the contact area of the belted puller is generally longer than that found with the reciprocating clamp pullers, which allows lower unit pressures on the pultrusion. A more flexible version of the continuous-belt machine is the cleated-chain (or caterpillar) puller, which has many individually contoured puller pads attached to chain ears along the chain length. This modification allows the production of complex shapes and multiple cavities by providing the necessary contoured pads. The number of individually contoured puller pads can vary widely, depending on the complexity of the part and the machine design. However, it is not uncommon to have several hundred contoured pads on a machine of this type, which makes the initial cost as well as the production setup time and cost substantial.

The space available within the gripper unit that determines the maximum possible size of profile is referred to as the machine envelope. Standard pultrusion equipment is available with production envelope sizes of 200 mm (8 in.) wide by 100 mm (4 in.) high to 1270 mm (50 in.) wide by 380 mm (15 in.) high. However, several machines have already been placed in production that can produce parts up to 2540 mm (100 in.) wide. More than 90% of all profiles can be produced on machines that have envelopes 760 mm (30 in.) wide and 305 mm (12 in.) high. Larger machines must have more power to pull the raw materials through the process. Power is especially important when the resin matrix begins its gel transition to final curing and the resultant part shrinkage occurs. The larger the surface area of the part and the lower the volumetric shrinkage, the more power is needed in the equipment. Standard pulling forces are in the range of 49 to 147 kN (5.5–17 tonf), but some machines are capable of up to 441 kN (50 tonf) of power.

One of the limitations to shape size within a given machine envelope is related to the forming area upstream of the die. When forming the raw materials for hollow shapes and especially for multicell hollow shapes, the size of the forming area is quite large. As wall thickness increases, this problem intensifies because there is more mat and roving material to deal with. The result is that the creel space width requirement at times may be far wider than the basic machine, limiting the machine product size capacity.

Cutoff Station. Every continuous pultrusion line requires a means of cutting product to length. Many systems employ radial arm or pivot saws on a table that moves downstream with the product flow and are activated manually when a length-limit switch activates a cutoff alarm. More sophisticated automatic cutoff saws are

found on commercial machines, eliminating the need for operator attention. Both dry-cut and wet-cut saws are available, but regardless of design, a continuous-grit carbide or diamond- edged blade is used to cut pultruded products. Aramid-reinforced products present a special cutoff problem because of the toughness of the fiber. The use of conventional blades results in jagged edges and delamination. While water-jet cutting is satisfactory, a suitable cost-effective alternative is still being sought for these composites.

Pultrusion

Process Tooling

Pultrusion tooling has two areas of consideration that are distinct, yet inseparable:

- The primary die, which is the precision-machined component that yields the final profile dimensions
- The devices required to align and form the input materials prior to entering the die as well as those required to clamp and draw the product through the die and to align the product during cutoff

All of the elements needed to produce a specific profile in addition to the primary die are referred to as secondary tooling items.

Primary Tooling. The pultrusion die is typically made from tool steel that can be purchased in an annealed condition or prehardened to 30 HRC. Pultrusion dies are usually multiple pieces that are machined and bolted together to form the desired profile cavity. Die pieces must be squared, rough machined, and then stress relieved to form the approximate cavity size. Each die component is then ground on a linear profile grinder to the finished dimension, with an as- ground finish of 0.50 to 0.65 μm. The die components are then aligned to form the finished cavity, and the pieces are doweled for positive parallel alignment within 0.025 mm (0.001 in.). Alternatively, an integral alignment groove can be provided along the length of the die near the parting line for a separate or integral key. The pieces are then drilled and tapped for bolts that are used to hold the die together against the internal pressure developed during processing.

After positive alignment and fastening, the exterior of the die is again ground flat. The die entrances are tapered or radiused to relieve pressures on the material as it enters the die and to decrease wear associated with fiber compaction at the entrance. The cavity surfaces are then polished to a 0.25 μm finish with buffing wheels and polishing compounds. The polished die is then plated with hard chrome to 0.025 to 0.038 mm (0.001–0.0015 in.) at 68 to 72 HRC hardness. Depending on profile complexity, additional grinding may be desirable after chrome plating on both the parting lines and the cavity.

An alternative to the softer steels described previously is the use of air- or oil-hardened steel, which can be heat treated to provide a 60 HRC hardness and does not require chromium plating if noncorrosive resin systems are processed. With resins of acidic pH, hard chrome may still be desirable on top of the hardened substrate to provide corrosion resistance, lubricity, and release characteristics. Also, with these steels, an allowance must be made for distortion upon heat treating prior to finish grinding. It is more difficult to modify a hardened tool after heat treating if additional tapped holes or grinding is required. The hardened tool is more prone to fracture at areas of stress or impact damage. The softer steel dies provide a tougher substrate resistant to brittle fracture and easily repaired. If chrome is the primary means of wear resistance, chrome- plated dies must be inspected frequently for complete surface coverage, because wear will proceed rapidly on the softer substrate steel once the chrome is removed.

It is difficult to predict die life, but a production quantity of 15,000 to 30,000 m (50,000–100,000 ft) is not uncommon for chrome-plated dies, which may be replated as necessary to extend their service lives. An equivalent or superior service life can be expected with hardened steel dies without chrome (if their design minimizes stress cracking and corrosion). Case hardening, ion implantation, and ceramic-base die alternatives have all been used with some success in an attempt to improve die life. Die lengths typically range from 610 to

1525 mm (24–60 in.), depending on the size, complexity, and tolerances required as well as the sensitivity to initial tooling cost, which increases rapidly for the longer die lengths.

Secondary Tooling. Forming technology is an art that develops over years of experience and is the most guarded area of processing technology. Improper execution will cause problems with chipping, cracking, poor reinforcement distribution, and frequent breakouts, all of which make continuous, economical processing very difficult. Properly executed, the constant, controlled delivery of material will in turn ensure reproducible quality and profitable production.

Various methods are used, such as step-sequence forms that are machined into steel or plastic plates that gradually collimate, align, and form the input materials. Continuous sheet metal forms can be used as an alternative or in conjunction with forming plates. Individual location guide eyelets and forming rods, tubes, or blades help to guide fiber to areas that are difficult to fill by other means. The guides that are used within the resin pan and on the creels are also considered part of secondary tooling if they are designed specifically for one profile. Although it is relatively easy to find a toolmaker who can manufacture a precision-machined pultrusion die, it is nearly impossible to find one with a pultrusion process insight that allows him to develop secondary tooling. Consequently, the design of secondary tooling is based on process experience with many forming system optimization trials, and fabrication is most often executed by the pultruder.

Clamping devices depend on the style of puller used. The continuous-belt cleat-style puller requires numerous custom urethane pads to conform to a complex profile. Reciprocating clamp-style pullers also require contoured puller blocks, but only for two clamping units. In either case, the design of clamping pads is such that adequate pressure can be applied to the product surface without cracking the profile. Consideration of shrinkage, angularity, and heat dissipation is often necessary in designing the clamping hardware.

Fixtures must also be provided at the cutoff saw to allow clamping before and after the blade to produce a quality cut. Insufficient guiding in this area can result in poor tolerances related to length and squareness as well as gouges caused by part movement relative to the blade.

Materials

One of the greatest advantages of the pultrusion process is that a wide range of materials can be used to provide a broad spectrum of composite properties. Given a specific profile geometry, the design engineer has a virtually unlimited supply of material options from which to construct a composite. The engineer must consider the intended function of the finished product, as well as the effects of temperature, atmosphere, environment, and time. Every selection, of course, carries an economic impact, and the optimal cost/performance options can be derived only with a proper understanding of the needs of the application and the available raw materials.

A composite is, by definition, a combination of reinforcement surrounded by a stress-transferring medium, or matrix, that allows the development of the full properties of the reinforcing fibers. The level of properties developed within a volume can be described approximately by the rule of mixtures, which, simply stated, predicts the resultant properties displayed in any direction to be proportional to the volume fraction of fibers aligned in that direction. Factors that influence composite property development include:

- The type of reinforcement fiber and its ultimate strength capability
- The form and style of reinforcement as it pertains to orientation of fibers
- The proportion of the selected reinforcement relative to the whole volume

In pultrusion, great versatility is possible with all three of these factors.

Reinforcement Types. The most widely used reinforcement has been and will continue to be glass fibers, because of ready availability and low cost. Electrical grade E-glass fibers are most commonly used, exhibiting a fiber tensile strength of approximately 3450 MPa (500 ksi) and a tensile modulus of 72 GPa (10.5×10^6 psi),

but have relatively low elongation. Elongation of glass bundles ranges from 1.5 to 2%, while that of single strand is 3%. These properties of glass fiber result in composites with high strength and low elongation, with virtually no yield up to ultimate failure, which is by brittle fracture. A variety of fiber diameters and yields are available for specific applications. Recently, boron-free glass compositions have been developed for superior electrical and corrosion properties. A-glass compositions are also used, though primarily in continuous strand mat form. Higher tensile strengths can be achieved with S- glass fibers, which were developed for high-performance applications. These fibers exhibit a tensile strength of 4600 MPa (665 ksi) and a tensile modulus of 86 GPa (12.5×10^6 psi). Glass fiber surface sizing chemistry has been developed over many years to provide optimal wet- out and chemical bonding between the fibers and matrix resins, thus ensuring maximum strength development and retention.

Far greater stiffness can be achieved by using carbon fibers when their conductive nature would not be detrimental to the application. Carbon fibers are produced from a process of continuous graphitizing and stretching of a textile thread, such as polyacrylonitrile (PAN). The resultant fiber exhibits tensile strength from 2070 to 5500 MPa (300–800 ksi) and tensile modulus from 206 to 690 GPa ($30–100 \times 10^6$ psi) with elongation of 0.5 to 1.5%. Normally, if high tensile strength is chosen, a lower tensile modulus must be accepted, and conversely. In addition to the mechanical properties cited, these fibers deliver unique properties, such as electrical conductivity, slightly negative thermal coefficient of expansion, high lubricity, and low specific gravity (1.8 versus 2.55 for E-glass). The price of carbon fibers is often the only limitation to their widespread use; however, recent advances in technology and production volume have dramatically reduced the price of commodity fibers (210 GPa modulus) to a reasonable level for many commercial applications. Carbon fibers do present some processing challenges as well, which limits the number of pultruders participating in this market segment.

High-modulus organic fibers, such as aramid fiber, are an attractive option for providing high tensile strength and modulus of 2750 MPa (400 ksi) and up to 131 GPa (19×10^6 psi), respectively, with elongation of up to 4%. The use of this fiber results in very tough composites that exhibit good flexural and impact strengths, which are well suited to ballistic applications and wherever energy absorption is necessary. The low specific gravity (1.45) of these fibers gives them one of the highest strength-to-weight ratios of any reinforcement available. Deficiencies in compressive strength and interlaminar shear strength are being addressed through improved surface chemistry and fiber treatment.

Other organic fibers have recently become available for use in pultrusion. Heat-stabilized and oriented polyester and nylon fibers with appropriate binders have been used as a replacement for glass in applications that would benefit from increased toughness and impact resistance, but where tensile and flexural strengths can be sacrificed. These fibers provide a low-modulus capability to composites, thus bridging the gap between thermoplastics and glass reinforced thermosets. With low specific gravity and only a moderate cost premium over glass, these fibers are well suited for certain commercial and industrial applications. A highly oriented polyethylene fiber geared toward higher specific strengths (high properties with low specific gravity) can also compete with the aramids in applications requiring stiffness, toughness, and light weight. All of the synthetic fibers have a lower use temperature capability than the inorganic fiber forms.

Reinforcement Styles. Once the fiber type has been selected, the next most important consideration is the ability to orient the fiber in the desired direction to utilize its properties most advantageously. A common denominator for all materials used in pultrusion is that they must be available in a continuous form to provide reasonably long payout lengths without defects, splices, or changes in cross-sectional volume.

The most common and lowest-cost form of continuous reinforcement is roving, which consists of continuous axial filaments in single and multiple-strand configurations. Glass rovings are designated by their yield, which is defined by the number of yards per pound of material or by the international designation, TEX, in grams per 1000 m. The two most commonly used yields are 4400 TEX (113 yd/lb) and 8800 TEX (56 yd/ lb), the latter of which is the larger size tow of the two products. The rovings are typically supplied in 18 kg (40 lb) hollow cylindrical packages with a center payout that allows them to be stacked on a multiple-shelf (bookshelf) creel configuration. A similar package is available for the organic fibers previously described. Carbon fiber rovings, however, are provided in sizes designated by the number of filaments per tow, with the most common being 3K, 6K, and 12K, with K equal to 1000 filaments. The carbon tow areas are considerably smaller than the glass roving tow, and the package weights are 0.9 to 2.3 kg (2–5 lb), with an outside payout designed for a spindle-style creel system. This difference in material form, although of no consequence in the end product, does present some limitations to the processor with regard to creel style and capacity, splicing frequency, and

product size limitations. Recently, larger tow options of 24K, 40K, 160K, and 320K, as well as assembled unidirectional webs held together with scrim or adhesive, reduce the creel limitations, allowing much larger parts to be manufactured.

The roving form allows maximum packing of fibers within a volume to yield the highest possible properties along the product axis, referred to as the longitudinal or machine direction. Maximum axial property development may be diminished by such factors as incomplete wet-out, improper fiber alignment, fiber damage due to creel or forming fixtures, and catenary (uneven fiber-to-fiber tension resulting in loops or nonparallel strands). Given near-perfect alignment, fiber fractions of 65 vol% are achieved (80 wt% for glass fibers). In such a product, there are no fibers oriented in the transverse direction (90^o to the longitudinal axis), and the strengths exhibited by the composite in this direction reflect the strength of the matrix resin only.

To overcome this transverse strength deficiency, reinforcing fibers aligned in the transverse direction must be provided. Continuous- strand mat, which has fibers oriented randomly in all directions, is most commonly used to provide some level of transverse properties. These fibers are held together with a thermoset resin binder, which allows the mat to have sufficient tensile strength for processing.

Several mat styles can be used, but the most common is an E-glass mat that has fairly coarse fibers in an open or porous construction yet provides high overall structural efficiency. This mat is used on exterior surfaces and as a center ply to build a laminate with substantially improved transverse physical properties. The porous construction, however, results in a potential for composite surface porosity and provides a very noticeable fiber pattern on the finished product due to shrinkage of the large resin domains. When this is unacceptable, a fine-filament A-glass mat (or veil) is used as surfacing ply to bring more resin to the surface and to achieve a dense, aesthetic surface appearance. Recent strength improvements in fine-filament A-glass mats have allowed their use throughout the composite. Regardless of mat style, the processor depends on the mat manufacturer to provide control over fiber distribution, binder content and distribution, and defects that may have a serious impact on processing efficiency.

Random-fiber mats are generally used in weights of 150 to 600 g/m^2 (0.5 to 2.0 oz/ft^2). To accommodate the volume required by this lower bulk density type of reinforcement, it is necessary to remove fibers from the longitudinal direction. The resultant composite will have a slightly lower overall fiber content by volume because more resin is consumed to fill the open- structure mat described. As a result, the resultant increase in transverse and off-axis strengths is accompanied by a decrease in longitudinal properties. It is here that the engineer can exercise control over fiber proportions to achieve the properties necessary for the specific application. One restriction dictated by the nature of composites is the need to provide a symmetrical composite ply structure relative to the centerline of the thickness. This practice will prevent dimensional problems resulting from differential shrinkage of the plies of different reinforcement forms and styles.

Within the limits of design, glass mat and roving based pultrusions are the most common structural compositions, with typically 50 wt% fiber. By exercising control of the relative proportions, and the use of inorganic fillers, the overall fiber weight content can be varied between 40 and 80%. Mat construction is also available with carbon fibers having a fine-filament construction. Other mat-type products are produced by paper processing methods and can incorporate a variety of filament types for tailored properties.

Although the random-fiber orientation of a mat provides fiber orientation in all directions, a specific volume of fibers can be oriented transverse to the axis by means of biaxial fabric reinforcement. The traditional material used had been woven roving; however, problems associated with weave stability, wet-out, and ply edge fiber retention limited the effectiveness of this material in pultrusion. In addition, woven materials do not provide optimal properties due to fiber kink stresses during loading. The introduction of nonwoven biaxial fabrics employing fibers stitched or knitted together at the interstices has provided an effective solution to the problems mentioned above. The stitched fabrics can be supplied with any proportion of longitudinal- to-transverse orientation—even to the point of having a 100% transverse fiber continuous ply with only longitudinal stitch fibers. These materials are available from a large number of suppliers employing various techniques to ensure fiber directional stability, ply integrity, and thickness and weight control.

The biaxial fabrics are generally introduced as internal plies and used in conjunction with a mat as exterior plies. Although not impossible to apply, the use of these materials as exterior plies is somewhat limited because of the tendency for the transverse fibers to be distorted by friction at the die surface. This can be resolved to an extent by stitching a continuous strand mat to the biaxial fabric to create a stabilized three-ply fiber form referred to as a “complex” material. Multiaxis fabrics typically employing 0^o, 90^o, and ±45° orientations have also become available and provide additional direction strength as well as an improved level of fabric stability.

Double- bias fabrics of ±45° without some amount of longitudinal fiber orientation for pulling strength and stability are impractical for pultrusion unless used strictly as an interior ply. Additional problems of splicing and fabric skewing make the use of these material forms more of a challenge to the pultruder.

In all of these multidirectional fabric styles, the supplier has the versatility of using every fiber type previously described (glass, carbon, or synthetic) in any or all of the directions possible or in an alternating fashion to provide hybrid composites with tailored properties. The challenge to the pultrusion design engineer becomes the identification of the most cost-effective style of reinforcement to use in an application not satisfied by the conventional mat/roving construction.

Because of the tendency toward ultraviolet degradation of the resin on surfaces of composites used outdoors, a condition known as fiber bloom will occur over time. This term refers to the exposure of fibers at the surface, which can be an irritant to human contact as well as an aesthetic detraction. To resolve this problem, surfacing fabrics of organic fiber composition, primarily polyester and nylon, are being used. The surfacing fabrics are available in a variety of weights and constructions and provide a corollary advantage of contributing to the impact strength and toughness of the composite. They also help the processor from the standpoint of providing a tough material to assist in carrying materials through the die while also protecting the die wall from the abrasive glass. The ability to provide a smooth resin-rich surface appearance without fiber patterns and the ability to be screen or roll printed with company logos, information, or wood grains make this surfacing material option an important element in many pultrusion composite designs.

Matrix Resins. Although the fiber type, form, and style determine the ultimate mechanical strength potential, the matrix resin determines the actual level of properties realized through effective coupling and stress transfer efficiency. There are composite properties, however, that are determined exclusively by the properties of the matrix resin. Among these are high-temperature performance, corrosion resistance, dielectric properties, flammability, and thermal conductivity. Selection of the resin, as well as formulation chemistry, becomes an important consideration that must be addressed very early in the design process.

Unsaturated polyester resins are most commonly used in pultrusion. Orthophthalic, isophthalic, and terephthalic acids or anhydrides, in combination with maleic anhydride and various glycols, are the basic backbone ingredients of polyester resins. The isophthalic polyester has dominated the supply by virtue of its well-rounded physical properties and economics. By adjusting the ratio of backbone chemical units, a variety of strength and elongation characteristics, as well as reactivity levels, can be achieved. A necessary characteristic of a pultrusion polyester is the ability to gel and cure rapidly to form the strong gel structure needed for adequate release at the die wall. Styrene monomer serves as a resin diluent and a reactive cross-linking agent necessary to form a thermoset polymer. Viscosities of 0.5 Pa · s (500 cP) are typical for highly diluted resins, or higher-viscosity, low-monomer versions can be blended at a later time with additional styrene to suit the processing need. The styrene level must be properly chosen to achieve good cross-link structure without leaving residual (unreacted) styrene in the finished composite. The final structure of the fully cured polyester resin is thermoset, resulting in the associated stability of the finished product to many adverse conditions.

Polyester resin properties differ based on their backbone compositions; the following generalizations can be made:

- Polyester resins exhibit good corrosion resistance to environments of aliphatic hydrocarbons, water, salts, and dilute acids and bases. They do not perform well when exposed to aromatic hydrocarbons and some concentrated acids. Corrosion-resistance guides provided by the resin supplier should be consulted for information on suitability to a specific chemical exposure.
- Because of the high unsaturation of the polyester chain and the resultant high cross-link density, polyesters exhibit volumetric shrinkage of up to 7%. This level can be reduced by using fillers and low-profile (thermoplastic) additives, which also help to control microcrack development and shrinkage-related sink marks.
- Polyester resins have glass transition temperatures ranging from 80 to 120 °C (175–250 °F). Exceeding this temperature threshold is accompanied by a rapid reduction in mechanical properties because of molecular chain movement. The actual continuous-use temperature must be defined in the context of the desired performance characteristics. Composites based on polyesters, for example, can be approved for continuous use at 150, 180, and even 200 °C (300, 355, and 390 °F) while retaining a high percentage of their electrical insulation properties, even though their ability to support mechanical stress decreases

rapidly above the glass transition temperature. Chemical decomposition of polyesters will begin to occur at temperatures above 300 °C (570 °F).

- Polyester resins can be brittle or tough, depending on the backbone chemistry and the cross-link density. However, maximum elongation is in the 5% range; therefore, impact properties will depend greatly on fiber orientation, fiber type, and impact-modifying additives.
- Polyesters will support combustion without modification. Through the use of additives or molecular backbone bromination, the flammability and smoke-generation properties of polyesters can be greatly improved in order to satisfy many flammability codes.
- The electrical properties of polyesters make them suitable for use as primary insulators in many high-voltage applications. Secondary insulation applications abound for polyester- base composites. Retention of electrical properties at elevated temperatures has made polyester insulators the cost-effective material of choice in many applications.
- The weatherability of polyesters is fair to good, depending again on molecular backbone composition. Additional weatherability protection is usually sought through a variety of ultraviolet absorption additives, the use of polyester surface veils, and weather-resistant paints, such as polyurethane, applied in-line or as a secondary processing step.

Vinyl Ester Resins. When additional performance is required in the areas of corrosion resistance and elevated-temperature mechanical properties, vinyl esters are available as an alternative to polyesters. The chemical structure of vinyl ester resins is such that the reaction sites are at the end of each polymer chain rather than along the chain length, as with polyesters. This structure results in a thermoset resin that has a lower cross-link density and exhibits greater toughness properties, such as interlaminar shear and impact strength. In addition, there are fewer sites available for chemical decomposition along the vinyl ester molecule. The use of rigid molecular segments (like bisphenol A epoxy) along the polymer backbone results in the high-temperature capability of these materials.

In addition to being approximately 75 to 100% more expensive than polyesters, an added cost due to lower process speed is characteristic of vinyl esters used in pultrusion. This results from the slower reaction rate associated with its lower cross-link density. In every other respect, the processing of vinyl esters is very similar to that of polyester. Both resins require high-temperature initiation of catalysts to begin the reaction. The room-temperature pot life of these resins is usually 24 to 72 h.

Epoxy resins are used when physical properties of the highest level, as well as elevated-temperature property retention, are required, which is often the case in military and aerospace applications. Although they have increased continuous-use temperatures to about 150 °C (300 °F), composites made with epoxy resin are known for the poor toughness caused by their rigid structure. Much of this deficiency can be overcome with proper selection of reinforcements to provide impact strength. Epoxy resins do provide increased flexural strengths and interlaminar shear strengths greater than polyester and vinyl ester systems. In addition, their excellent electrical properties and corrosion-resistance also qualifies them for use in many commercial and industrial applications requiring superior performance.

Epoxy resins are expensive materials in a number of respects. The resins are three to six times more costly than polyesters and have a number of process-related costs not found with polyesters. Because they are cured by a stepwise reaction rather than an addition reaction, as with polyester resins, their reaction rate is very slow. The gelation of epoxy resins occurs at a later stage of reaction, and it is critical that the exotherm developed be contained within the die to avoid cracking. This dictates a slow process rate, which results in a higher labor and burden allocation to the product being produced. Unlike polyesters or vinyl esters, epoxy resin begins to react slowly as soon as it is mixed, resulting in a pot life measured in hours rather than days as viscosity begins to increase. The resin scrap rate is potentially higher if viscosity buildup affects wet-out to the extent that the bath must be recharged. The die temperature profiles used for epoxy are typically hotter than for polyesters in order to achieve reasonable pultrusion rates, and the resulting hot resin drip-off at the die entrance must often be discarded rather than recirculated to the resin bath to avoid bath gelation. Because of the tendency for the epoxy resin to bond strongly to the die wall, epoxy products often display surface defects, such as exposed fibers, chipping, or loss of dimension, all of which increase finished-product scrap rates. These additional material and processing costs place epoxy products in a class in which the end-use requirements must justify the high price and processing difficulty.

Much effort has been directed at developing more processible epoxy systems by using viscosity-modifying fillers, improved internal mold releases, and hybrid epoxy/vinyl ester structures. Some processors use slip sheets or release plies between the epoxy resin and the die wall to prevent bonding and to improve surface quality. Ultrasonic vibration of the die is one experimental method evaluated to reduce the adhesion tendency of epoxy resins. With improved methods, including selection of die materials and surface treatments, epoxy processing is now considered routine and cost competitive in high-performance applications.

Other resins in addition to the traditional three mentioned previously have achieved commercial significance. Resins based on methyl methacrylate and vinyl ester are quite attractive because they offer the advantages of higher physical properties, high filler loading due to very low viscosity, rapid processing speeds, smooth low-profile surfaces, and improved flame-retardant and weathering characteristics. Although the heat resin costs twice as much as polyesters, these resins have found use in applications that exploit their special properties. Most notably, methacrylate vinyl ester resins were used exclusively in the pultrusions produced for use in the Channel Tunnel project and other underground transit installations. The methacrylate resins are quite reactive and provide excellent processing speeds. Thus, the net cost premium is moderated, making these systems competitive with polyesters in many applications.

Phenolic resins have achieved a level of acceptance in applications where the highest level of flame, smoke, and toxicity performance are required. Another unique feature must be dealt with when processing these resin systems. Unlike any of the previous resins, which are 100% reactive with no reaction by-products, phenolic resins of the resole type are water and solvent diluted to provide workable viscosity and generate additional water as a reaction by-product during processing. As a result, phenolic products have a higher level of voids and a significantly lower mechanical property level than the previously mentioned resin systems. In addition, in order to achieve maximum strength potential, phenolic compatible roving and mat products must be used. Both acid-catalyzed and temperature-activated phenolics have now been processed successfully at rates that are comparable to vinyl ester resins. One of the very important considerations in processing these materials is the new demands on industrial hygiene and environmental emissions created by the presence of carrier solvent and phenol and formaldehyde components of the resin that are evolved during processing. As a result of all of these special needs, phenolic cannot be processed interchangeably by most pultruders and a fairly narrow supply base will exist for the near term.

Composite toughness has been a deficiency with the brittle matrices of polyester, vinyl ester acrylic, epoxy, and phenolic. While some high- elongation vinyl esters have been introduced, it is often with a sacrifice in reactivity, which affects process speed. Recent activity in two-component thermoset polyurethane pultrusion shows promise to increase elongation and toughness by a factor of two to five times that of polyester. Once again, the special equipment for meter-mix delivery of the reactive system along with special direct die injection hardware will limit this alternative to specialty processors or original equipment manufacturers (OEMs) with a specific product line that merits this investment.

A great deal of interest has developed in recent years in using thermoplastic resins as the matrix for pultruded profiles. The major driving force also comes from the desire for improved toughness as well as the additional benefit of postprocessing reformability. In addition, several of the engineering thermoplastic resins provide heat distortion properties that are superior to those of the epoxy systems currently used, making them very attractive for advanced composite applications. The technology for impregnating fibers with thermoplastic resins has been developed using a variety of methods, including hot-melt application, solvent solution impregnation, and fluidized bed particle application. Most of the success reported to date has been limited to the preparation of thin tapes or small-diameter rods, which are then used as molding materials in subsequent processing methods, such as compression molding. Limited success has been achieved with fairly simple shapes, but the surface quality and dimensional control is inferior to thermoset products at this time. Interest in this area is growing, however, and the advantages of these materials will undoubtedly result in the development of a viable pultrusion process. Recent new activity includes thermoplastic polyurethane as well as low-viscosity in situ polymerization of thermoplastic resins employing ring-opening chemistry. All thermoplastic approaches tout the substantially higher processing rates theoretically possible by eliminating the cure dependency of the thermoset polymerization reactions. In addition, pressures to provide recycling options by composite end users clearly favor thermoplastic systems.

Additives are used in all liquid resin systems to provide specific tailored performance. Although the thermoplastic processor often receives precompounded materials, the pultruder develops his own formulation and prepares it on- site for his own use. Resin suppliers have developed recommended formulations that are

available to the general market, but the resin formulation is also a well-guarded secret of the pultruder and is often considered to be a competitive edge in cost or performance.

Fillers often constitute the greatest proportion of a formulation, second to the base resin. The most commonly used fillers are calcium carbonate, alumina silicate (clay), and alumina trihydrate. Calcium carbonate is primarily used as a volume extender to provide the lowest cost resin formulation in applications where performance is not critical. The clay fillers are used where improved corrosion-resistance and electrical properties are required. They also impart a superior surface finish to the pultruded product. Alumina trihydrate is a filler that is used for its ability to suppress flame and smoke generation and provide electrical-arc and track resistance. It is used in many applications to satisfy consumer or governmental flammability codes for product safety. Other fillers, such as mica, talc, calcium sulfate, and various glass beads and bubbles are used by the pultruder for their specific property modification qualities, although they represent a small portion of total use.

Fillers can be incorporated into the resins in quantities up to 50% of the total resin formulation by weight (100 parts filler to 100 parts resin). The usual volume limitation is based on the development of processing viscosity, which also depends on the particle size and the characteristics of the resin. The low-viscosity acrylic resin, for example, can incorporate an additional 50 parts of filler beyond the polyester resin levels while maintaining processibility. Wetting agents have been developed that enable incorporation of a greater filler volume without increasing formula viscosity. These wetting agents and other surface modification agents can be added to the filler by the supplier or introduced as an additive by the pultruder. Air release agents are added to provide more efficient packing by reducing entrapped air in the liquid resin and void content in the finished product.

Another important category of materials in resin formulation are the initiators required to cure the thermosetting resins. The polyester, vinyl ester, and methacrylate systems are all cured by the elevated-temperature decomposition of organic peroxide catalysts. A variety of initiators that provide different levels of activation temperature are available. Pultrusion formulations typically employ a multiple-initiator system to provide rapid low-temperature initiation, followed by midrange acceleration and high-temperature reaction completion. This combination, which delivers the fastest processing speed, can also reduce resin pot life, especially in high ambient temperatures. The use of reaction inhibitors and the selection of catalyst type and quantity become important considerations in controlling resin scrap due to premature gelation of formulated resin. Catalysts for epoxy systems which are amine or anhydride cured, are usually supplied as a component that is matched in specific proportion to the epoxy resin system obtained from the supplier.

Mold releases are important in the development of adequate dynamic release of the curing material from the die wall to provide smooth surfaces and low processing friction. The mold release cannot leave a surface residual that interferes with bonding if subsequent painting or fabrication is necessary. These releases are added to the resin and are typically metallic stearates or organic phosphate esters suitable for high- temperature use.

Other special-purpose additives would include ultraviolet radiation inhibitor for improved weatherability, antimony oxide for flame retardance (used in combination with halogenated resins), pigments for coloration, and low-profile agents for surface smoothness and crack suppression characteristics. A variety of options are available in each of these material categories as well.

Pultrusion

Properties of Pultruded Products

Mechanical Properties. The great amount of latitude that exists in selecting reinforcement type, form, style, and proportion allows a broad spectrum of mechanical properties. As noted, the directional strength in a pultruded composite can be greatly influenced by substituting longitudinal reinforcement for random mat or directional fabrics. A product with only longitudinal reinforcement will typically exhibit mechanical properties that are at least ten times greater than the same property measured transverse to the longitudinal fibers. In this type of composite, the properties of the fiber dominate the axial properties, but the properties of the resin dominate the transverse properties. As the volume fraction of fibers in the off-axis direction is increased, the longitudinal

volume fraction, by necessity, must decrease; thus, the transverse properties are increased at the expense of longitudinal properties. This substitution method can be used to move the directionality of strength deliberately toward a one-to-one ratio, or even to the extent of achieving higher transverse properties when using some of the weft transverse orientation fabrics available. Accordingly, when evaluating pultruded product property data it is necessary to be aware that both lengthwise (LW or 0°) and cross-wise (CW or 90°) properties must be reported for an accurate representation of these nonisotropic materials. The magnitudes of typical properties for glass reinforced pultrusions from one supplier are given in Table 1 to illustrate the effect of orientation on property levels.

Table 1 General properties of fiberglass-reinforced pultruded products

Material	Property(a)																	
	Specific gravity	**Tensile strength**		**Tensile modulus**		**Flexural strength**		**Compressive strength, axial**		**Dielectric strength, parallel**		**Thermal conductivity**		**Coefficient of thermal expansion, 10^{-6}/K**	Water absorption, wt%

Table 2 indicates the effect on selected ultimate properties in the lengthening direction at an equal volume fraction of alternative continuous fibers. The specific contributions of fiber type become very apparent in the properties selected to illustrate this point. Because so many options exist, even among the unidirectional reinforcements, it is difficult to provide an all-inclusive list of properties. The designer must learn to exploit the specific fiber characteristics to achieve the desired performance properties, along with exercising the orientation options available from raw material suppliers. The end user must be aware that published values from any pultruder do not necessarily represent the limits of achievable properties.

Frequently, the decision to be made by an end user relates to the application of composite material as an alternative to such traditional materials as steel, aluminum, or wood. Selected relative properties of common alternative materials are listed in Table 4. Although Table 4 compares various materials in terms of absolute strength or stiffness, it is often desirable to determine the thickness of fiberglass reinforced plastic (FRP) necessary to achieve strength or rigidity equivalent to that of the traditional material. Such an analysis is shown in Table 5, using the data of Table 4 and contributions of section geometry to strength and stiffness ultimate values. When the application does not require property equivalency, the product thickness can be reduced accordingly to yield savings in material and processing costs. A similar analysis can be conducted for the alternative fiber types to determine equivalent thickness factors for the high- strength high-modulus materials. The relative costs per unit volume can then be readily determined.

Table 4 Material property comparison of FRP versus alternative materials

Material	Property					
	Tensile strength		**Tensile modulus**		Flexural strength

Physical Properties. The thermal conductivity of pultruded composites reflects both matrix and fiber characteristics. Generally, the fiberglass reinforced composites are excellent insulators for thermal and electrical environments. This is also true of the organic fiber composites, regardless of the matrix employed. The use of conductive carbon fibers, however, results in composites that exhibit greater thermal and electrical conductivity. This reduces their potential as insulators but creates new opportunities because of their static and heat dissipation characteristics.

Although fiberglass reinforced composites display a modest positive coefficient of thermal expansion, both aramid and carbon reinforced composites display a slightly negative coefficient of thermal expansion. This characteristic can be used to advantage in aerospace structures and in producing very tight tolerance parts. The thermal expansion characteristics can result in molded-in stresses in multidirectional reinforcement systems when dissimilar fiber types (hybrids) are used in the profile. Upon exiting the die, residual stress is relieved in the form of dimensional distortion that can be either cross sectional (angularity or flatness) or axial (warp, twist, or bow). Carbon reinforced composites are also noted for their lubricity and wear resistance, which makes them suitable for use as bearing materials. Their capacity for heat dissipation is advantageous in this application.

Specific gravity is a key consideration when strength-to-weight ratios are important, as in aircraft and aerospace applications. The specific strength of carbon and aramid reinforced composites excel because of their low specific gravity and high strength and stiffness characteristics. High-modulus polyethylene fibers also have very low specific gravity and high strength and stiffness properties at room temperature and have the potential to provide the highest specific strength available at lowest cost.

The impact resistance of organic fiber reinforced composites is quite high, making them suitable for energy-absorption applications, such as ballistic shielding. The impact resistance of carbon fibers is generally low, and advanced composites that use carbon rely on the tough resin matrix for impact properties. Fiberglass reinforced composites are also relatively poor in impact performance compared to the organic fibers, but are superior to carbon reinforced composites. The fatigue resistance of graphite reinforced composites is superior to that of the fiberglass reinforced composites, particularly when used with epoxy resins.

Chemical and corrosion-resistance characteristics of pultruded composites are predominantly attributed to the resin matrix. In considering a particular resin system for an intended environment, the degree of exposure, the concentration of the corrosive element, and the temperature of the environment must be known. Resin companies servicing the corrosion markets generally publish a list of chemical environments tested at various concentrations and temperatures, as well as recommendations for the use of their resins. The areas of suitability for polyester, vinyl ester, and epoxy resins are described in the section “Matrix Resins” in this article.

Chemical and corrosion attack can occur at the product surface or at the end of the profile. The presence of a resin-rich barrier layer on the surface can provide a greater degree of corrosion- resistance. Although this is readily achievable in the wet lay-up or filament-winding process, the nature of the pultrusion process requires a high fiber volume and significant internal pressure to fill the die volume and to minimize porosity. To achieve a resin-rich surface, a synthetic veil or mat that is typically of polyester fiber is used on the surface of the product when pultruded. The layer can range from 0.15 to 1.0 mm (0.005–0.040 in.) thick, depending on the barrier thickness required. In pultrusion, therefore, a resin- rich layer does not mean a fiber-free layer, it means that the fibers in the surface layer are organic fibers rather than inorganic reinforcing fibers.

The end cut of the profile is particularly vulnerable to corrosion because fibers are exposed to the corrosive agent. Any matrix crazing or resin-fiber debonding in this area will promote wicking of the chemical along the fiber surface. Therefore, it is a common practice to dip or brush coat the end cuts of pultruded profiles (as well as any fabricated holes along the product length) with resin to seal them from corrosive attack. If this is not done, the corrosion resistance of the fiber itself becomes an important consideration because the resin does not effectively protect the fiber from attack along the fiber/resin interface in damaged or machined areas.

As previously stated, of the glass fibers available, C-glass is by far the best in all-around chemical resistance, while ECR glass (modified E-glass) is excellent in most acids. Standard E- glass is relatively inferior in concentrated acidic and alkaline environments, and A-glass is poor in water resistance. Standard E-glass is the most popular and is available in pultrusion rovings and mats, while A-glass and C-glass veil is generally utilized for surface coverage. Aramid fibers are resistant to fuels, solvents, and lubricants and are superior to glass fibers in many strong acids and bases. Carbon fibers are resistant to alkaline and salt solutions, but are subject to attack by strong oxidizing agents and halogenated chemicals, particularly at elevated temperatures. It is important, therefore, to consider the chemical resistance aspects of both the reinforcement and the matrix when considering the application of any composite material in corrosive environments.

Design Guidelines

The design of any pultruded profile requires a thorough understanding of the material and processing contributions that affect the product design. Although many material options exist for use in pultrusion, some limit the configuration of the resulting profile. The primary characteristics of a pultruded product and process are listed in Table 6.

Table 6 Pultrusion product characteristics

Size	**Equipment pulling envelope and forming guide width influence size on specific machinery**
Shape	**Constant cross-section, straight profiles; hybrid processes allow some curvature and local variable cross-section features**
Length	**Only limited by transportation limits. Flexible product can be coiled in very long lengths, e.g., 1 kilometer 2 mm diam fiber-optic strength member rods**
Reinforcements	**Fiberglass, carbon, aramid, thermoplastic polyester, polyethylene, and nylon, natural fibers—jute, flax, sisal**
Reinforcement content, wt%	**All roving from 40–80% by weight, mat and roving from 35–65% by weight, roving/mat/fabric to 70% by weight**
Resin systems	**Polyester, vinyl ester, epoxy acrylic, phenolic, polyurethane, and thermoplastic matrices**
Mechanical properties	**Anisotropic for all unidirectional, near-isotropic with multiaxial reinforcements including engineered fabrics**
Labor content	**Low to medium depending on the number of streams and machines tended by one operator. Also product size and speed dependent**
Production rates	**Typically 0.5–1.5 m/min (1.5–5 ft/min), depends on thickness and resin type**
Tooling costs	**Low to medium depending on part complexity and forming guide complexity**
Equipment costs	**Medium to high depending on product size. Typically less than extrusion or injection equipment. Also depends on control sophistication**

Table 7 shows many of the geometry guidelines for designing pultruded products. The pultrusion process can produce virtually any shape that can be extruded. The part must be consistent in cross section over its length. Tapered shapes cannot be produced. Some moderately curved shapes have been developed, but generally, the equipment required for this activity differs from a standard pultrusion machine and commercial success has been limited. Any length can be produced that can be transported.

Table 7 Pultrusion design guidelines

Minimum inside radius		**0.79 mm roving shapes, 1.6 mm mat shapes**
Molded-in holes		**No**
Trimmed-in mold		**Yes**
Core pull and slides		**Yes**
Undercuts		**Yes**
Minimum recommended draft		**No limitation**
Minimum practical thickness		**Roving, 1.0 mm. Mat, 1.5 mm**
Maximum practical thickness		**Roving, 75 mm. Mat, 25 mm**
Normal thickness variation		**As required**
Maximum thickness buildup		**As required**
Corrugated sections		**Yes, longitudinal**
Metal inserts		**No**
Bosses		**No**
Ribs		**Yes, longitudinal**
Molded-in labels		**Yes, but not recessed**
Raised numbers		**No**
Finished surfaces (reproduces mold surface)		**Two**
Hollow sections		**Yes, longitudinal**
Wire inserts		**Yes, longitudinal**
Embossed surface		**No**

There is theoretically no limit to the size of profile that can be pultruded; however, raw material (mat and fabric) width availability and maximum die sizes present practical limits as does the in-feed capacity of the process line. As mentioned, continuous-strand mat is available only to 3050 mm (120 in.) in width. Conversely, parts having total product perimeter dimensions less than 25 to 32 mm (1–1.25 in.) are difficult to manufacture with mat reinforcement. Cutting a continuous-strand mat less than 100 mm (4 in.) wide eliminates the continuous nature of the strands in the product and reduces the critical processing tensile strength. Woven tapes

and cloth can be employed at the lower limits of size as a replacement for mat. Axially reinforced products (all roving) can be produced as small as 0.76 mm (0.030 in.) in diameter.

Because thermoset resin composites are exothermic in nature and dependent on conductive heat transfer for reaction initiation, it is more difficult to produce thick-wall products economically. When mat and roving are used in shapes, wall thickness is limited to approximately 25 mm (1 in.). With radio frequency preheating, all-roving reinforced solid rods up to 75 mm (3 in.) diameter have been successfully pultruded. If not properly processed, however, these thicker profiles are prone to crack or delaminate because of lack of control of exothermic temperatures and shrinkage.

The pultrusion process does not impose any limits on the cross-sectional draft angles designed into a part. A common condition referred to as toe-in is often seen when die angles are not properly compensated for by considering material shrinkage, especially at corners and at thickness transitions. Undercuts can be incorporated into the design of a part by using multipiece steel dies as long as the die can readily be disassembled for service in case a part should freeze (lock up) in the die cavity.

Longitudinal ribs and corrugations are possible, but care should be taken in any composite part to provide sufficient radius where one wall or rib section makes a transition to another. This permits a transfer of load without a concentrated stress in a sharp corner. Another reason for using a radius is related to pultrusion process considerations. Generally, with pultrusion dies that are chrome plated for wear resistance, it is difficult to obtain chrome that will plate in sharp corners or shallow ribs. Additionally, any sharp corner or parting line will wear significantly when fiberglass materials pass over them. It is good practice to radius mat-reinforced profiles by a minimum of 1.5 mm (0.06 in.) and roving reinforced shapes by a minimum of 0.76 mm (0.03 in.).

Isolated bosses cannot be produced unless they are longitudinal in nature, in which case they would be more properly described as a rib. Localized features, such as through-holes, cannot be molded in. Longitudinal inserts (or encapsulants), such as antenna wire, plywood, or polyurethane foam, can be accommodated with appropriate in-feed equipment.

It is desirable to maintain a uniform wall thickness when designing a profile. However, variations in thickness within a part are possible and common as long as proper forming control is executed that avoids mat folding and structural defects at the thickness transition. The pultruder must produce the profile at the speed required to cure the thickest section. With good communication and planning, the end user and pultruder can arrive at a part design that will meet the functional and performance requirements of the end user and also give the pultruder the best opportunity to design an efficient and highly productive pultrusion process.

Once a pultruded profile is produced, it can be fabricated in the same manner as aluminum or steel. However, because of the abrasive nature of fiberglass, continuous-rim diamond tools are recommended. Wet cutting with diamond tools reduces heat buildup and degradation of the composite material. When composites incorporating aramid fibers are fabricated, water-jet cutting is highly recommended and is the preferred technique to provide clean edge cuts. Joining techniques include mechanical fastening and adhesive bonding. When using adhesive bonding, care must be taken to sand or otherwise prepare the surface before applying the adhesive. The guidelines provided by the adhesive manufacturer should be followed with regard to clamping time and the temperature of the adhesive under clamp pressure. Adhesive bonding, when properly done, is as reliable as mechanical fastening.

Painting of a finished profile is often necessary when outdoor use is considered. In such cases, both on-line and off-line methods are used. Both cases require environmental control from the standpoint of cleanliness to avoid paint defects and to handle fumes from paint systems. Technology has been developed for water-based paints as well as 100% solids powder coating systems for use with pultrusions that minimize these issues. Paint adhesion is enhanced through formulation of both the paint and the substrate pultrusion resin system.

Future Outlook

The 1990s saw remarkable growth in capability as the knowledge base of pultrusion has expanded. A flood of published investigations of process and materials topics in the 1990s has finally provided a sound literature base for most topics of interest to current and prospective pultruders. Continued commercial and academic contributions to the literature base is expected to bring pultrusion process science to a level on par with other well-established plastics processing methods.

Processors will continue to utilize engineered materials to achieve optimized properties with the intention of minimizing composite product weight and cost, which will be key to penetrating markets held by conventional materials. The palette of new resin and fiber forms has expanded dramatically and tailored properties can be achieved cost effectively by matching application needs to material capabilities.

Computer-aided design tools for both profile design and laminate property analysis have been a key development and are now commonly used by pultrusion process engineers. The integration of FEA methods with solid modeling software now enables design optimization of finished composite products and structures rather than simply the basic profiles.

Pultrusion machinery has evolved in terms of control capability and envelope such that the most complex of shapes of very large size can now be addressed. The capability to monitor the process and product quality at a new level has recently emerged, and further advances are expected until a truly closed-loop-process quality-control capability is achieved. A recognition of the value of vertical integration to provide end users with a finished or near-finished product as opposed to a raw pultruded profile will continue to present new opportunities for pultruders to capture margin and secure a proprietary position. Both on-line and off-line fabrication as well as painting and assembly will be employed to achieve these goals.

Hybrid processes will continue to evolve, blurring the lines between conventional pultrusion and compression molding, injection, filament winding, and other useful thermoset and thermoplastic production processes. Products with three-dimensional features are now enabled with process-parameter manipulation and clever die and machine design approaches. In short, the future of pultrusion is very promising as one of the most cost-effective continuous production methods available to produce composite solutions to design problems.

Tube Rolling

Robert J. Basso, Century Design, Inc.; Paul A. Roy, Vantage Associates, Inc.

Introduction

TUBE ROLLING is the most widely used method of producing composite tubular parts that require high strength-to-weight properties as well as high production capabilities. The tube rolling process utilizes prepreg materials having accurate resin content, which are produced on very precise prepreg and filming machines. The combination of accurate resin content and good fiber areal weight in prepreg materials offers designers a method to produce structurally sound tubular parts at a very rapid rate using relatively unskilled factory labor.

Tube rolling has many advantages over other methods of producing composite tubes. High production rates of 5 to 10 s per part are common—some manufacturers of golf shafts produce quantities up to 30,000 shafts per day using semiautomated rolling tables. Part-to-part consistency is high, and excellent surface finish is obtained, using a light sanding/polishing operation after curing. In addition, the process uses inexpensive durable mandrels. Part shapes can be cylindrical, conical, circular, oval, or any combination of these shapes. Fiber orientation can range from 0 to 90°. Disadvantages include size limitation and higher material costs. Part sizes range from 0.76 to 609 mm (0.030 to 24 in.) diameter and 7.3 m (24 ft) maximum length. Material costs for rolling prepreg tubes are greater than those for wet- wound and pultruded parts due the requirement for the prepreg stage. However, higher production rates and lower labor costs can offset the difference in material costs in many instances.

Typical products produced using tube rolling include the following:

- Golf shafts
- Arrows
- Ski poles
- Tennis racquets
- Antennas
- Aerospace components
- Fishing rods
- Bicycle components
- Telescopes
- Launcher tubes
- Masts

Tube Rolling

Robert J. Basso, Century Design, Inc.; Paul A. Roy, Vantage Associates, Inc.

Process Description

The first step in the tube-rolling process is to prepare a mandrel with a release agent and/ or a tacking agent. Cut-to-size prepreg patterns are attached to the mandrel by hand pressure or warm tacking iron. Mandrel and pattern are placed on a rolling table surface and subsequently rolled into a compacted and densified laminate. Compaction and densification of the material during the wrapping process is accomplished using contact pressure between the mandrel, the prepreg, and the rolling table surfaces as shown in Fig. 1. Rolled parts are spirally wrapped with shrink tape under controlled tension to further debulk the laminate, and parts are cured in

a curing oven. After curing, the mandrel is extracted and shrink tape removed. Parts are cut to length, and the exterior of the part is sanded, ground, and/or painted.

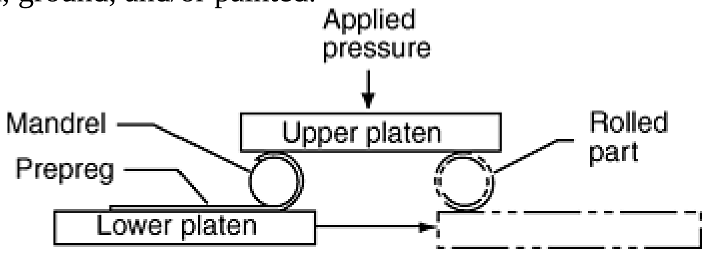

Fig. 1 Table rolling

Tube Rolling

Robert J. Basso, Century Design, Inc.; Paul A. Roy, Vantage Associates, Inc.

Process Equipment and Techniques

The same process and equipment are used to produce parts that are table rolled. Diameter and length of parts being produced dictate the size of the equipment required.

Mandrels. A variety of materials have been used for tube rolling mandrels. To produce small-to-intermediate-diameter tubing in volume, steel is commonly used because of its strength and stiffness. Steel mandrels are usually hardened and polished or chromed for ease of removal. Because the thermal expansion of steel is relatively low, heavy-duty mandrel pullers are required to remove the tube from the mandrel after cure.

Aluminum, which also has been used as a mandrel, is desirable for larger tubing because of its lower weight. Moreover, for a graphite tube that is greater than 50 mm (2 in.) in diameter, no puller is required because the differential expansion is sufficient to allow part removal after it has cooled. For fiberglass and aramid tubing, however, a mandrel puller is still required. In most instances, mandrel pulling is best attempted when the part is still hot, because cold parts are usually more difficult to pull.

Metal mandrels are used when external pressure is applied during cure. For thick-walled tubing where external pressure causes fiber wrinkling or where tube-geometry changes require internal pressure during cure, alternative mandrel materials are available. Female molds are usually used when internal pressure is required during cure.

Both Teflon and solid silicone rubber have been used as materials for mandrels undergoing internal pressure molding. The high thermal expansion coefficient of these materials can be used to exert exceptionally high pressures when the materials are properly confined. The amount of pressure applied is dependent on the cure temperature, mandrel volume, and restrictions imposed.

If more precise pressure control is required, a thin silicone rubber sleeve or a similar bladder material is placed over the mandrel, and the part is rolled over the sleeve. The sleeve can then be removed from the mandrel, with the uncured tube in place. The tube and rubber liner are then placed in a closed mold and the bladder is inflated during the cure. This method is particularly useful for fabricating irregularly shaped tubes. For round tubes, the mandrel can be left in place, and air can be applied through a port in the mandrel.

Sheeting. All rolling operations must start with sheet goods that are subsequently cut into patterns. Sheet cutting can be as simple as using a straight edge and a razor knife. For narrow sheets up to 460 mm (18 in.) wide, standard paper cutters fitted with hardened steel blades for longer life have been used. Outfitted with a creel for material feed, paper cutters can be a very efficient method of cutting large quantities rapidly. A method for cutting angle sheets (Fig. 2) has been used for many years to cut huge quantities of angle sheets.

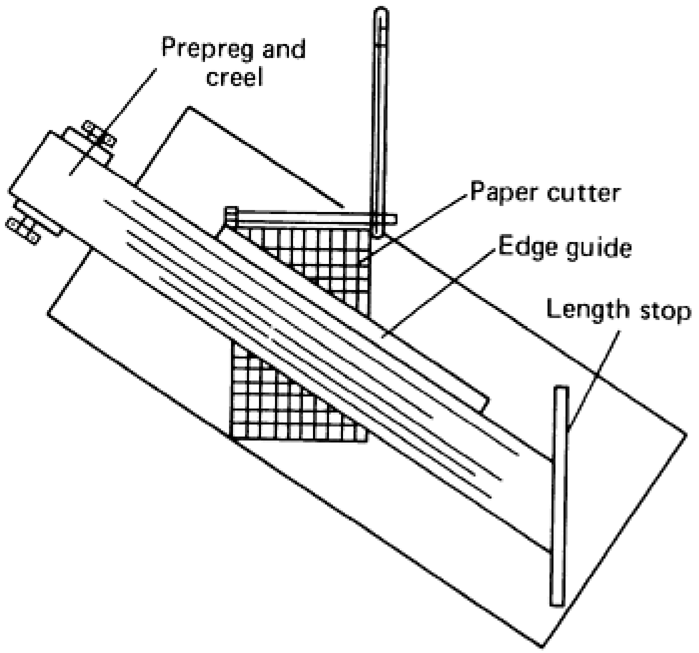

Fig. 2 Paper cutting for angle sheet cutting

In the area of automated equipment, high- speed sheet cutters are available. The typical fully automatic prepreg sheeter (Fig. 3), which digitally controls length of cut, can cut patterns at any angle automatically.

Fig. 3 Automatic angle-cutting prepreg sheeter. Courtesy of Century Design

Pattern cutting, like sheet cutting, can be done manually or with automated equipment. Razor knives and templates, though primitive, are still used to cut small quantities of material. The trick is to stack multiple sheets of material and cut several patterns at one time. Stacks of up to 20 sheets of graphite-epoxy tape can be cut this way. When complex or extremely long patterns are required or when higher-speed cutting is necessary, the options range from steel-rule dies and roller presses (Fig. 4) to computer-controlled knives and water-jet cutters.

Fig. 4 Roller press with steel-rule dies. Courtesy of Century Design

Tube Rolling. Tube rolling can be accomplished by hand or with rolling equipment. Rolling tables such as that shown in Fig. 5 are widely used to make tubular products such as golf shafts, fishing rods, and other tubes up to 9 m (30 ft) in length. The mandrel, with pattern tacked in place, is placed on the lower platen of the table. With the push of a button, the pneumatically controlled top platen drops to contact the mandrel, after which the movable lower platen slides back to totally envelop the pattern. The top platen is articulated to accommodate rolling either cylindrical or tapered tubes.

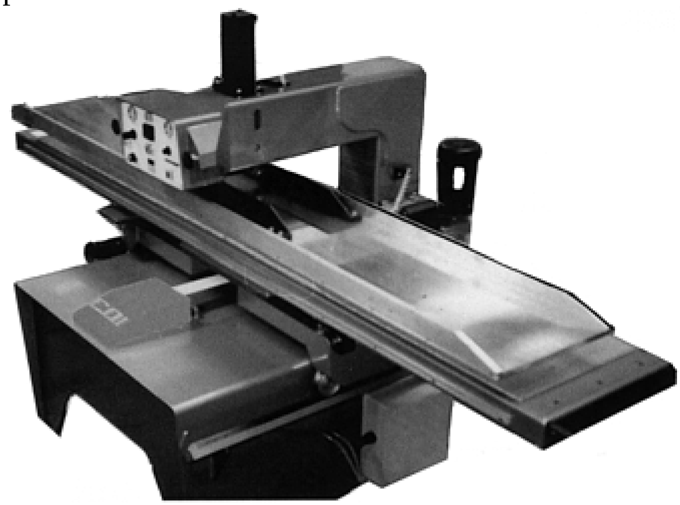

Fig. 5 Tube rolling table. Courtesy of Century Design

Shrink Tape Debulking and Cure. Heat shrinkable tapes such as cellophane, polypropylene, or nylon are used to incrementally debulk composite tubing after rolling. They are also used to apply the pressure during cure of noncritical parts such as golf shafts and fishing rods. The amount of actual pressure applied during cure depends on the type of tape used, its thickness, the number of layers applied, and the tension at which the tape is applied.

Typical shrink tapes of nylon, cellophane, polypropylene, and Tedlar (polyvinyl fluoride film, DuPont, Wilmington, DE) are readily available in appropriate widths and thickness. Polypropylene is limited to curing temperatures up to 145 °C (290 °F). Degradation of properties occurs above this temperature. Automatic shrink tape wrapping machines provide consistent tape- tension control as well as uniform spacing (pitch) of tape wraps.

One tape wrapping machine that is used extensively in the production of golf shafts, fishing rods, and other tubular parts is shown in Fig. 6. It can accommodate parts from 1 to 150 mm (0.04 to 6 in.) diameter and has adjustable pitch (overlap) from 0.75 to 25 mm (0.03 to 1.0 in.).

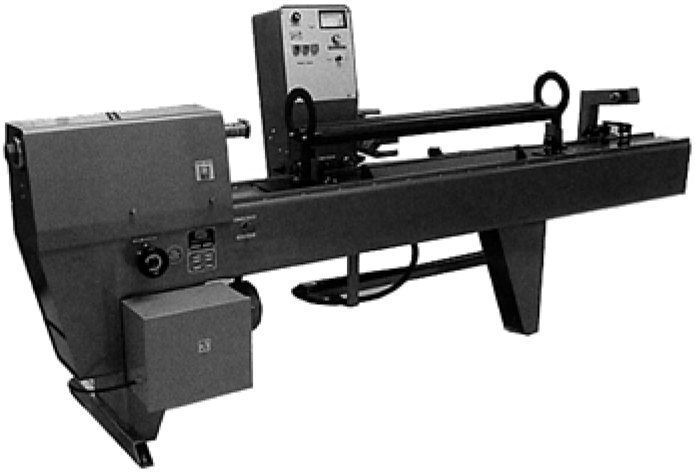

Fig. 6 Automatic shrink tape wrapping machine. Courtesy of Century Design

Finishing. Tubular products lend themselves to high-speed finishing methods. After cure, some amount of sanding or grinding is usually required. Sanding produces a good quality surface for cosmetic purposes, whereas centerless grinding is used when precise diameter control is required. Centerless sanders are widely used for high production rate items such as golf shafts and fishing rods. The machine shown in Fig. 7 is designed to provide uniform material removal for both straight and tapered parts at rates of up to 0.30 m/s (1 ft/s). Material removal is controlled by pressure application and feed rate. Sanding is performed with water as a coolant to improve the final finish quality and to eliminate fiber "dust."

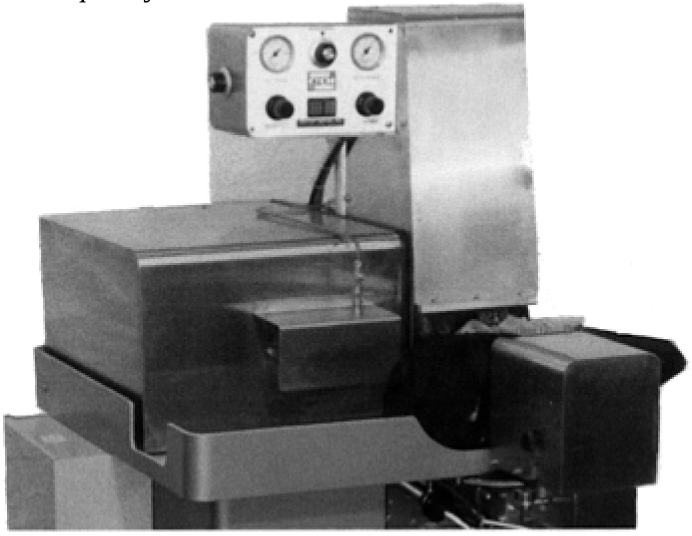

Fig. 7 Centerless sander. Courtesy of Century Design

Tube Rolling

Robert J. Basso, Century Design, Inc.; Paul A. Roy, Vantage Associates, Inc.

Material Forms

Preimpregnated (prepreg) materials are most suitable for tube rolling when their form is either a fabric or unidirectional tape. Typically, fabrics are used when a 0/90° fiber orientation is required. Tubes made with this fiber orientation have good longitudinal and circumferential properties but poor torsional properties. Variants in longitudinal and circumferential mechanical properties depend on the fabric style selected. For example, the standard 181 style glass fabric will produce a tube with nearly equal properties in the two directions, whereas a 1543 weave style will produce a tube with a property imbalance of 8 to 1. Therefore, caution should be

exercised when rolling fabrics to ensure that the warp and fill yarns are always wrapped in the proper orientation with respect to the tube axis.

Unidirectional tapes are used for tubes that require a higher degree of refinement in structural properties. It is possible to achieve any combination of axial, hoop, and torsional mechanical properties with unidirectional tapes by using a predetermined combination of wraps. Unidirectional tape also provides better fiber translation than do fabrics and yields a more weight-efficient tube.

Both material forms require cutting of patterns in preparation for rolling. Prepreg pattern design is determined by the product being fabricated, the material form employed, and the equipment being used for fabrication. Generally, tubes made from prepreg fabrics are convolute wrapped, whereas tubes based on unidirectional prepreg tapes can be either convolute or spiral wrapped.

Tube Rolling

Robert J. Basso, Century Design, Inc.; Paul A. Roy, Vantage Associates, Inc.

Wrapping Techniques

Convolute wrapping of cylindrical (constant-diameter) tubes is by far the fastest and simplest method of rolling. A rectangular sheet of material with a length equal to the desired number of circumferential wraps is continuously wrapped around the mandrel. For thin-walled shapes, a tube can be wrapped in one operation. When making thick-walled tubing or when using materials with a high bulk factor, it is desirable to wrap the tube in multiple wrap increments, debulking in between wraps by applying and removing shrink tape on automated tape wrapping machines with consistent tape-tension control.

Fabrics, as noted earlier, offer a simple and extremely rapid method of rolling tubes that have a 0/90° fiber orientation. Patterns are sized to the tube length, and an integral number of circumferential wraps are placed on the rolling surface. The prepreg pattern is heat-tacked to the mandrel on a work table commonly referred to as a “tacking table.” The pattern/mandrel combination is transferred to a rolling table, and the prepreg pattern is tightly rolled with controlled pressure.

Unidirectional prepreg tape is the preferred material when a combination of longitudinal and helical wraps is desired. Longitudinal wraps are easily accomplished by cutting sheets to the desired tube length and splicing them together to form a single, wide sheet for the desired number of wraps. Splicing can be done by butting the plies. Figure 8 illustrates the procedure for rolling longitudinal (0°) plies. The release paper is removed, the mandrel is tacked in place, and the pattern is simply rolled up. It is generally preferable to lay the pattern on the table with the release paper side up, because it usually has more tack, which makes it easier to start the mandrel.

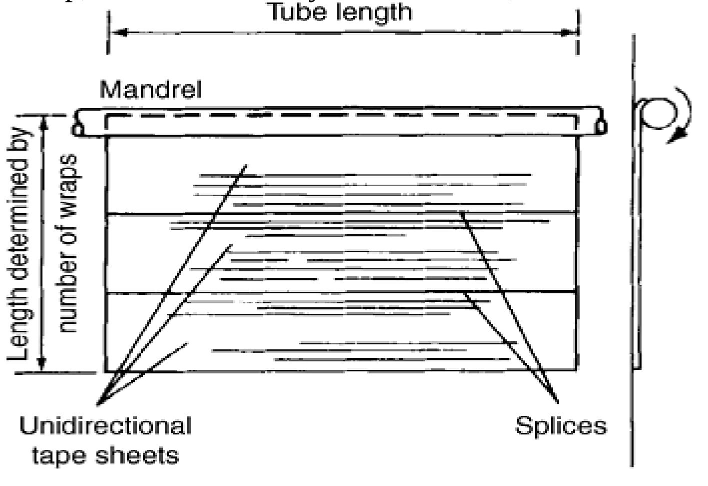

Fig. 8 Unidirectional tape, longitudinal ply rolling

Preparing the pattern is slightly more difficult if circumferential (90°) patterns are required. Typically, because tube length is greater than the width of standard materials, patterns must be spliced together. Although overlap

splices are normally out of the question, thin glass tape may be acceptable, or the patterns can be butted and "tacked" together with a warm iron.

A workable solution is to combine the hoop patterns with other patterns to form an integral unit that facilitates alignment and release paper removal. For example, if the tube design dictates a 0/90° construction, the two patterns can be combined as depicted in Fig. 9. The best way to accomplish this is to lay one pattern face down on top of the next pattern. The overlap zone should be firmly pressed together, using heat if necessary, to form a good bond. For volume production these patterns can be stacked for later use, at which time the release paper can be removed. Because the overlap is accomplished with the second pattern on top of the first, rolling is easier. If the overlap were on the underside, it could peel as it winds around the mandrel. The amount of overlap to use is at the designer's discretion. If the tube design indicates a precise ply- stacking sequence allowing no commingling of plies, the most exacting designer would not want to allow any overlaps in which case spiral wrapping should be considered. In convolute wrapping, at least one circumferential wrap overlap should be used.

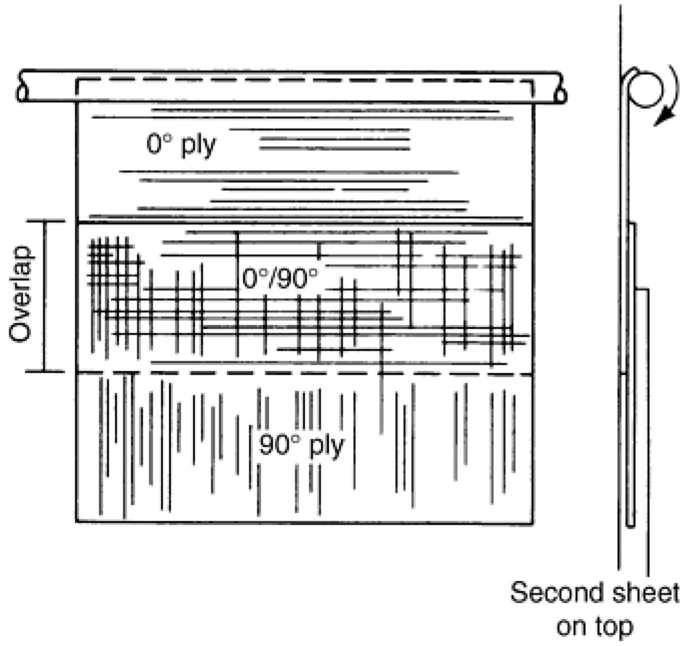

Fig. 9 Unidirectional tape, 0/90° rolling

With thin prepregs, a full overlap (double ply) could be used, although it is usually easier to start wrapping with a one-ply thickness before moving into the two-ply-thick material. Good design practice dictates that the overlap be made in equal circumferential wrap increments. If overlapping is used, the pattern size should be adjusted to accommodate the change in thickness.

For angle patterns, the unidirectional tape must be converted into a bias tape (Fig. 10). Unidirectional tape is cut at the desired bias angle, with the length of each sheet being determined by the number of wraps desired. The bias sheets are then rotated 90° and spliced together to create a continuous bias tape that can then be cut into the desired patterns. Taping together the sides with the release paper is preferable. By exercising care in the cutting operation, precise angle control can be maintained.

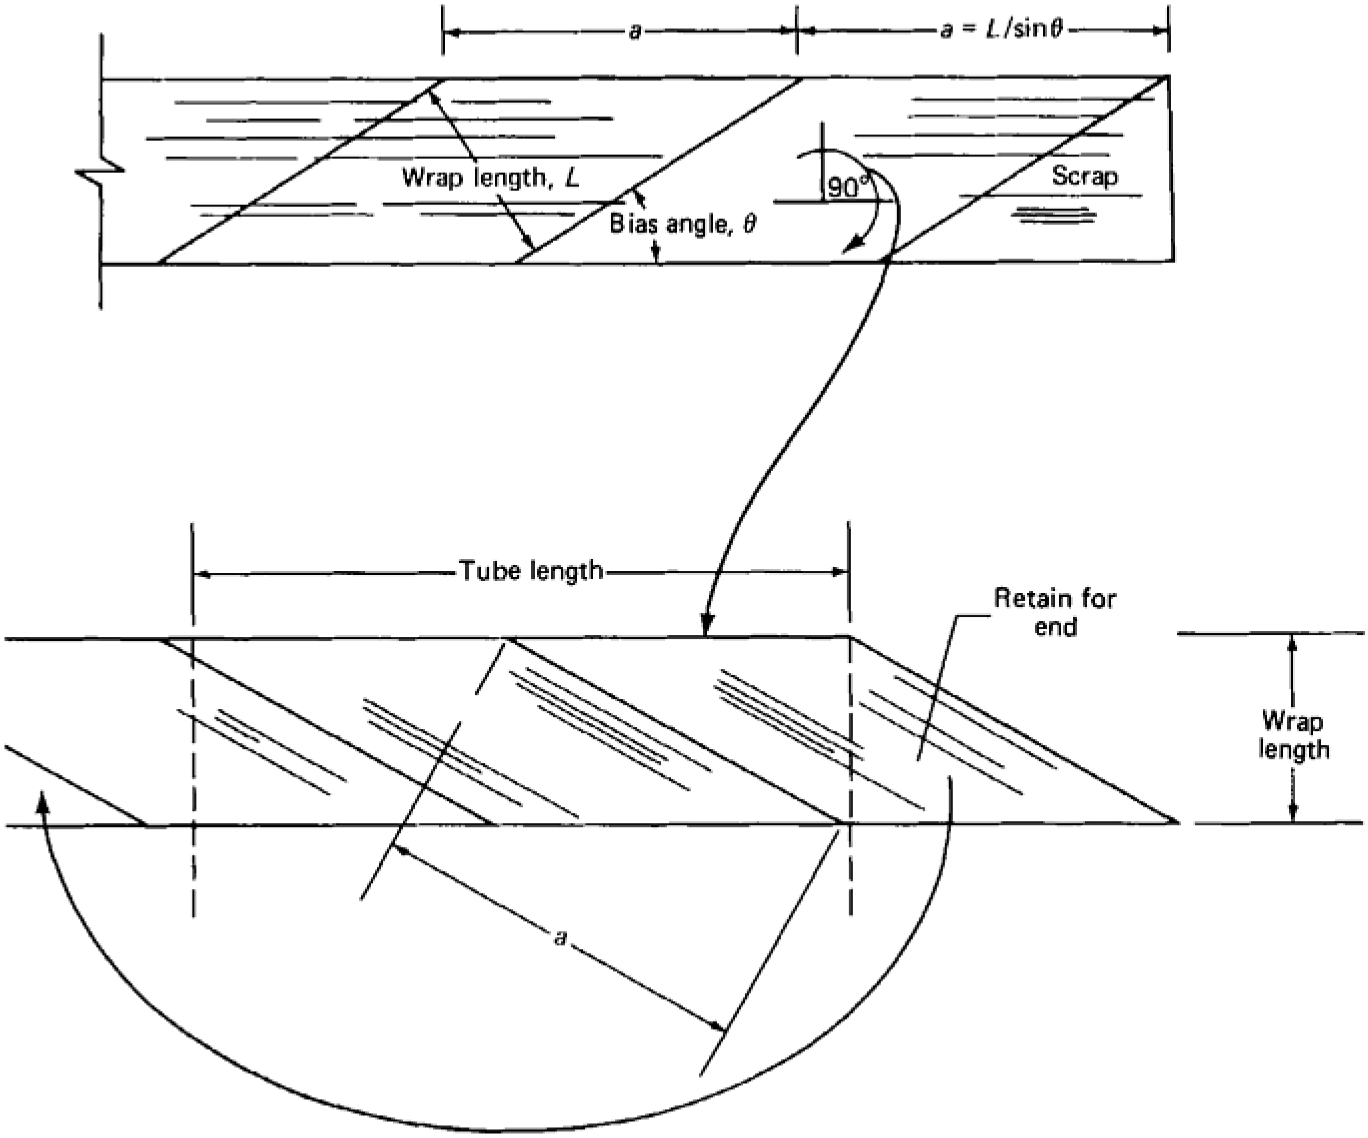

Fig. 10 Generating bias tape from unidirectional tape. (a) Unidirectional tape, bias cuts. (b) Bias tape lay-up

Once the patterns are cut, it is usually best to overlap the opposing angle patterns before rolling. This facilitates release paper removal and helps maintain pattern integrity. The amount of overlap is a matter of choice, but integral multiples of the circumference (clocking) are desirable. Although overlapping is considered undesirable by some because of the commingling of plies, it is usually superior to rolling individual plies. Overlapping helps to align the plies, remove release paper, and hold the pieces together during handling and rolling. These benefits should outweigh any detrimental effects of ply commingling.

Convolute wrapping of tapered tubes is similar to rolling constant-diameter tubes, except that tapered patterns are used and provisions must be made to allow the mandrel to roll along a curvilinear path during rolling, as shown in Fig. 11. Commercially available rolling tables compensate for this lateral shift.

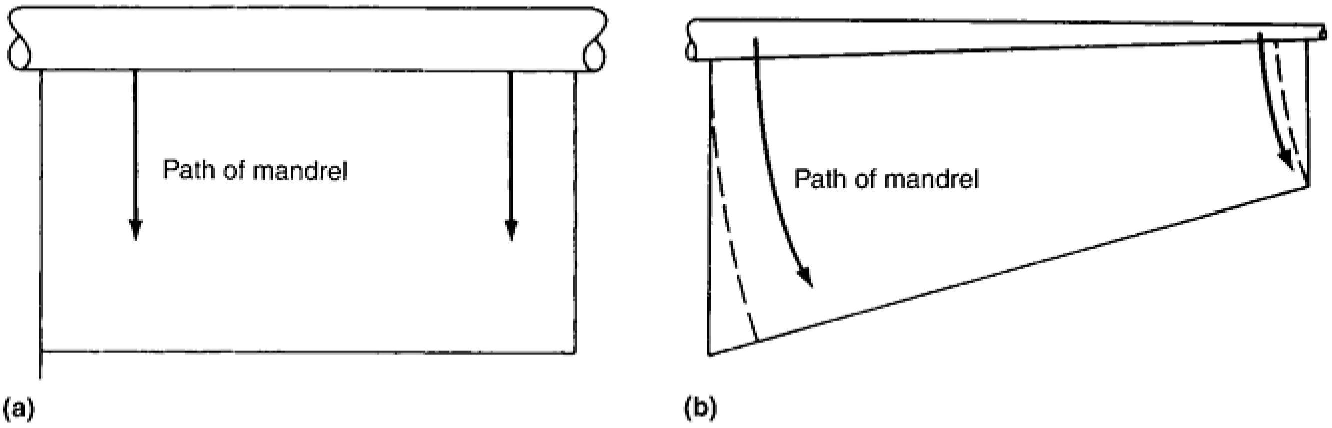

Fig. 11 Cylindrical versus tapered tube rolling. (a) Cylindrical mandrel. (b) Tapered mandrel

If precise fiber alignment is required, multiple convolute wrapping can present a problem. This is best illustrated by considering a multiple wrap using unidirectional tape. Figure 12(a) presents the usual approach of cutting a symmetrical pattern from the tape without regard to scrap. A close examination of the pattern shows that not all fibers are continuous, which could be a problem, although overlapping during wrapping can provide good fiber translation.

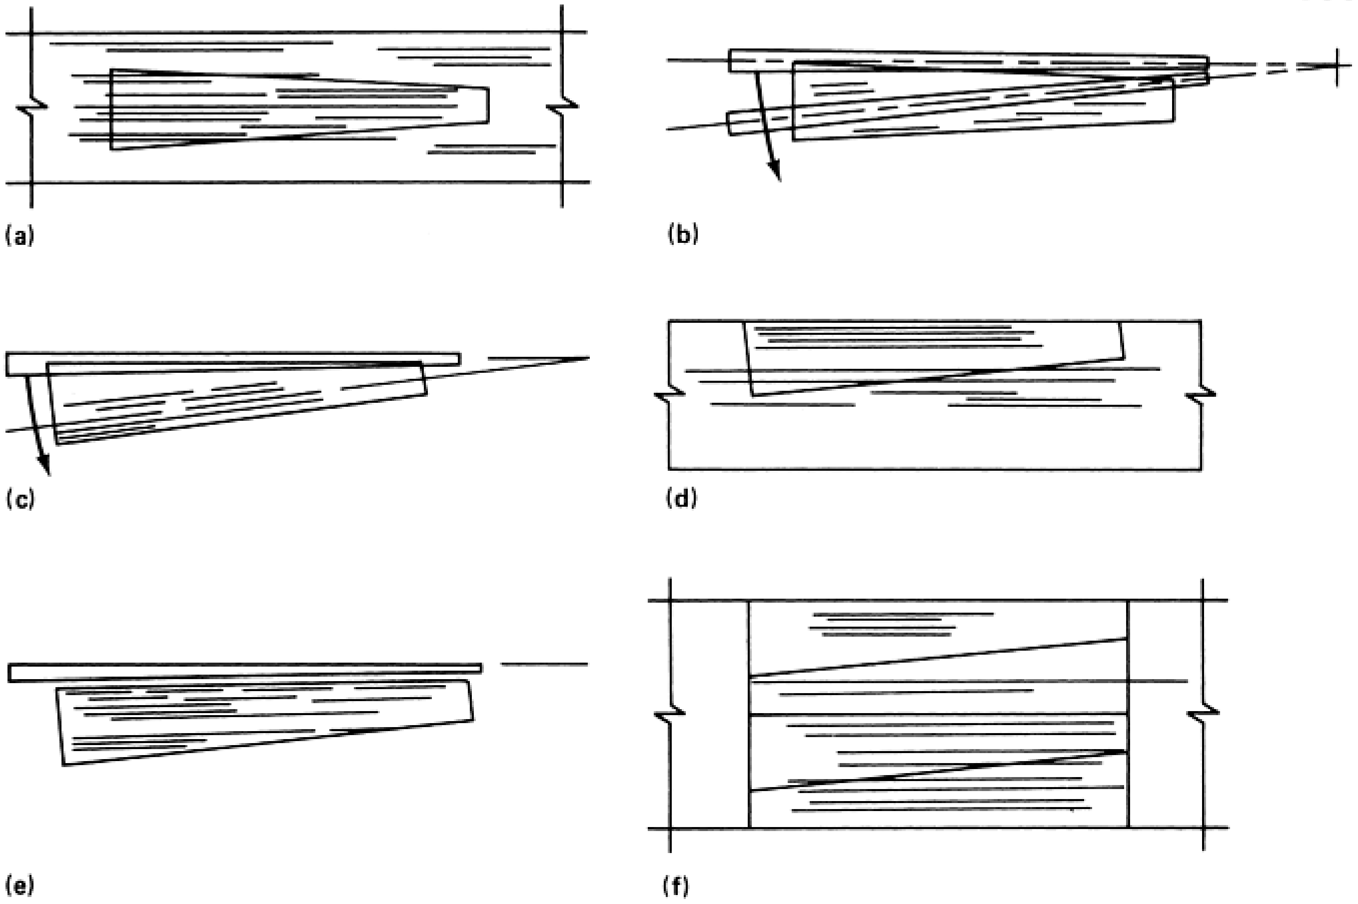

Fig. 12 Tapered tube pattern cutting and rolling. See text for discussion.

Starting the mandrel so that it is parallel to the fibers and then rolling it straight, on the mandrel, turns out to be difficult, as illustrated in Fig. 12(b). Because the mandrel is tapered, it must roll along an arc, which causes the fibers to be off-axis. Also, an uneven buildup on the mandrel would make it difficult to roll or to obtain good compaction. Starting the mandrel parallel to an edge, as shown in Fig. 12(c), improves the quality of rolling but does not alter the fiber misalignment problem. Moreover, starting the rolling with short discontinuous fibers is sometimes difficult. Figure 12(d) presents an alternative for one who accepts the fact that one must live with some fiber misalignment when convolute-wrapping taper tubes. In Fig. 12(d), the pattern is cut with one side parallel to the fiber direction. With the continuous fibers along the starting edge, the rolling process is easier to start, as shown in Fig. 12(e).

Figure 12(f) presents the preferred no-scrap method for cutting multiple tapered patterns. A sheet is sized for an even number of patterns, and a simple flip-flop cutting procedure will quickly and easily produce a large number of patterns.

Patterns that are cut as in Fig. 12(a) tend to compensate with a ± angle variation in increments of three layers, whereas wrapping with plies that are cut as in 12(d) and 12(f) tends to result in the accumulation of wrap in one angular orientation. This unbalanced angular wrap could cause problems with part stiffness and/or straightness if the angular deviation becomes too great. A greater than 5° angle change should be avoided. One solution is to wrap with single- layer patterns. This slow process is easily accomplished with longitudinal wraps but is much more difficult with high-angle wraps. A more desirable approach is to use spiral wrapping.

Spiral wrapping is an alternate method for making tubular shapes from composite materials. Hand or table rolling using spiral wrapping is slower than convolute wrapping because only one ply at a time is rolled. With automated wrapping equipment, however, spiral wrapping can be very competitive with convolute wrapping.
Spiral wrapping should be considered for thin- walled tubes to avoid overlaps or gaps in plies that could cause variations in circumferential stiffness (spine) or whenever precise dimensional control is required.
Single-ply angle-wrap applications also favor spiral wrapping because the fibers can be wrapped continuously from end to end with no overlaps or butts. Using ultrahigh-modulus fibers could also dictate the need for a spiral wrap design.
In the strictest sense, spiral wrapping can be used with fabrics, unidirectional materials, or even paper. In fact, most cardboard cores are spiral wrapped. The following discussion is restricted to structural tubing in which fiber continuity from end to end is required. Therefore, only unidirectional tape will be considered.
Spiral Wrapping of Cylindrical Tubes. The significance of spiral wrapping to structural tubing is in the application of angle plies. Longitudinal plies in spiral or convolute wrapping are equivalent with angle plies, however, spiral wrapping enables the designer to use the full capability of the composite by having continuous helical fibers with no overlaps or gaps. Spiral wrapping involves the use of long strips of material of a width determined by the tube diameter and the wrap angle. For short tubes or shallow angles, the wrap may not make one complete circumferential circuit around the mandrel, as shown in Fig. 13, whereas for long tubes or high angles, several spiral circuits around the mandrel will be needed, as illustrated in Fig. 14.

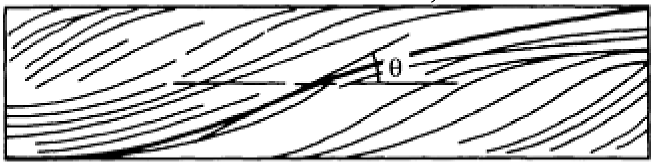

Fig. 13 Large-diameter shallow-angle wrap

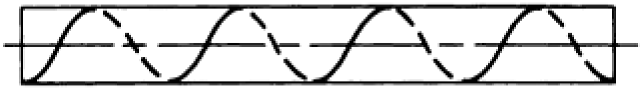

Fig. 14 Small-diameter high-angle wrap

Figure 15 shows the pattern configuration and rolling procedure for spiral wrapping an angle pattern on a cylindrical mandrel. The pattern shown is a parallelogram with continuous fibers, and its width is a function of the mandrel diameter and the wrap angle. The pattern length is determined by the tube length and the fiber wrap angle. A few simple calculations show that as the wrap angle increases, the pattern width decreases and the pattern length increases. For very steep angles, long, thin patterns are needed.

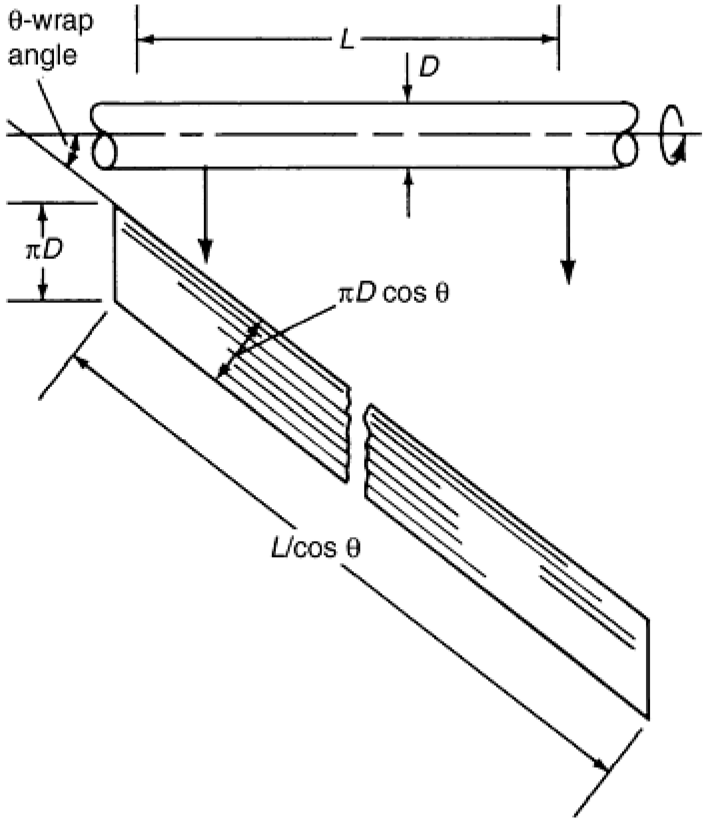

Fig. 15 Spiral wrap pattern, cylindrical tube

The difficulty encountered in spiral wrapping multiple angle-plied tubes is that the width of each successive ply must be slightly larger to account for the diameter change introduced by the preceding layer, if a gap-free lay-up is to be achieved. Additionally, the mandrel should always be rolled in one direction, as in convolute wrapping. Reversing the rolling direction may loosen the ply previously wrapped, resulting in a poorly wrapped tube. With respect to spiral wrapping, this means that each successive ply should be started from opposite ends of the mandrel, as shown in Fig. 16. The first layer starts at the left end of the mandrel, with the pattern trailing off to the right. The second, opposing angle layer is rolled from the opposite end of the mandrel, maintaining consistency in the number of mandrel rotations. Also shown are reference lines, which are usually inscribed on the rolling table to facilitate mandrel and pattern alignment. Correct sized patterns and proper alignment should produce gap-free wraps around the mandrel.

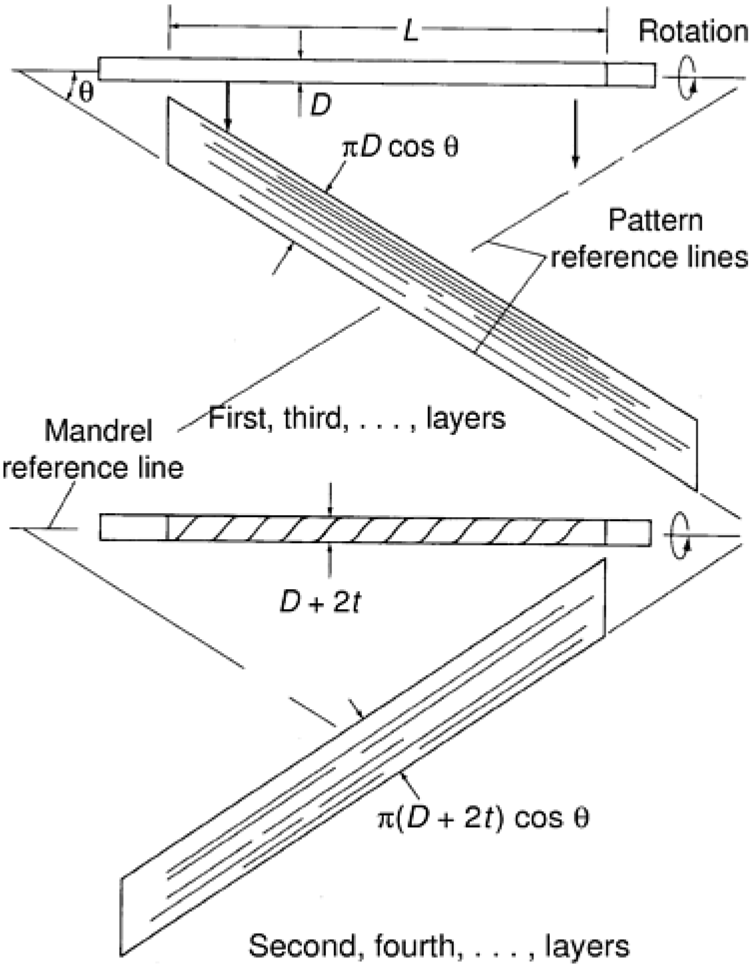

Fig. 16 Multiple spiral wraps

Spiral wrapping of tapered tubes is similar to wrapping cylindrical tubes, with the exception that the patterns must be tapered to conform to the change in diameters of the tapered mandrel. Tapered patterns are generally cut on commercial roller presses that utilize simple steel-rule dies. Pattern lengths up to 12 m (40 ft) can be cut by this method.

For tubes with large diameter or steep tapers, spiral wrapping becomes less desirable because of the pattern shapes required. Not only are the patterns tapered, but because of the taper, the edges are curved (Fig. 17) and the advantage of end-to-end fiber continuity is lost.

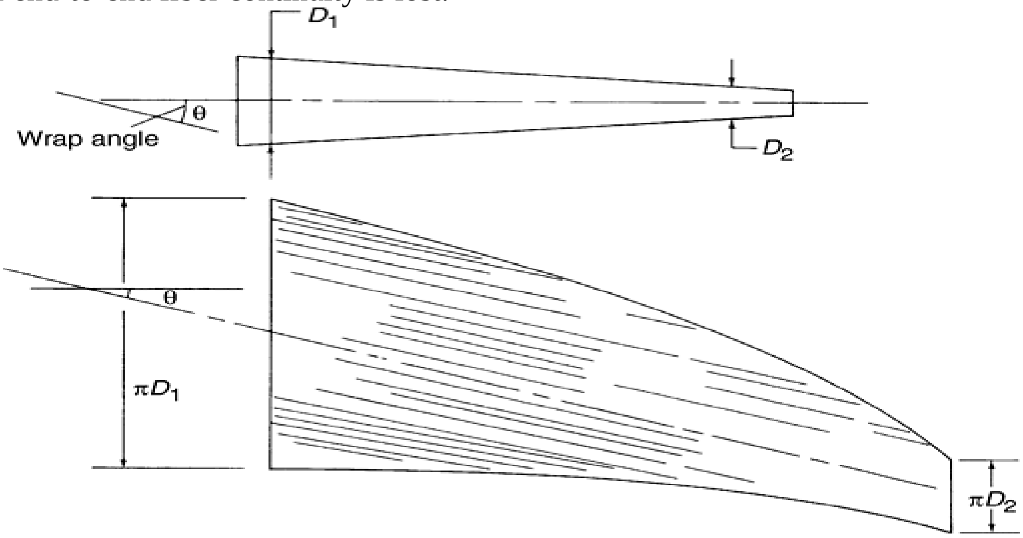

Fig. 17 Curved and tapered patterns for spiral wrapping large-diameter or steeply tapered tubes

To facilitate wrapping, it is usually desirable to start at the small end and work up the taper. This can be accomplished by starting the first ply on the under surface of the mandrel and the second layer on the top and by alternating for each successive layer (Fig. 18). In this way, the mandrel rotation direction is better maintained and compaction is achieved.

Outlook

Prepreg materials development is a continuous endeavor and the benefits of improved prepreg properties translate into newer and novel applications. Thermoplastic prepregs are working their way into advanced versions of parts that formerly comprised thermoset prepregs. The processing machinery is also changing to accommodate the higher temperatures required for thermoplastic prepregs. Production processes are being fully automated to reduce labor costs and to maintain part-to-part consistency.

Thermoplastic Composites Manufacturing

B. Tomas Åström, IFP SICOMP AB, Sweden

Introduction

THE GREATER PART of the "Manufacturing Processes" Section in this Volume is devoted to widely accepted and commercially important manufacturing techniques for polymer composites, and it so happens that with one notable exception (compression molding), these techniques almost entirely rely on the matrix being a thermoset polymer. The main reason for the lack of widespread acceptance of thermoplastic matrices is that

they tend to be more difficult to process into a composite than thermosets. However, this fact does not mean that there are no techniques to manufacture composites with thermoplastic matrices. In fact, a number of techniques have been developed and are in limited use, and intense research and development efforts are underway to develop both new techniques and more easily processable thermoplastics. This article provides an overview of the more common techniques to manufacture structural thermoplastic composites. The term “structural” is used to refer to the ability to support substantial mechanical loads, meaning that structural composites are reinforced with continuous or at least relatively long fibers, thus deliberately excluding, for example, injection molding.

Thermoplastic Composites Manufacturing

B. Tomas Åström, IFP SICOMP AB, Sweden

Characteristics of Thermoplastic Composites

What sets the materials discussed in this article apart from materials discussed in all but one of the other articles of the “Manufacturing Processes” Section in this Volume is that the matrix is a thermoplastic rather than a thermoset. It is relevant, thus, to first consider what influence the matrix type has on composite properties, processability, and cost.

There are small differences in the engineering properties of neat (unreinforced) thermosets and thermoplastics, although thermosets tend to be somewhat stiffer and more tolerant of elevated temperatures, courtesy of their (covalent) intermolecular crosslinks. Thermoplastics, on the other hand, have considerably higher strain-to-failure values, meaning that they are usually more damage tolerant. These differences between matrix types largely transfer into similar differences in the reinforced polymers. However, in-plane mechanical properties of composites are generally strongly fiber-dominated, meaning that any difference in the mechanical properties of the matrix tends to be obscured. In contrast, for out-of-plane properties and temperature-tolerance characteristics, which are usually matrix- dominated, such a difference may well be apparent.

Among the many issues that influence processability are matrix viscosity, processing requirements (e.g., in terms of temperature, pressure, and time), and worker health concerns. Low viscosity facilitates reinforcement impregnation, where each reinforcing fiber ideally should be surrounded by matrix without any voids. Fully polymerized thermoplastics have very high molecular weights, meaning that their melt viscosities are at least two orders of magnitude higher than melt viscosities for thermosets, which makes impregnation significantly more difficult. While some thermosets may be crosslinked at ambient temperature, other thermosets and all thermoplastics require a high processing temperature that must be precisely controlled to achieve consistent and expected properties. The higher viscosity of thermoplastics means that higher pressures tend to be required to achieve the same degree of material flow as with thermosets, but in many cases this difference is not dramatic. Whereas thermoplastics only need to be melted, shaped, and then cooled to achieve dimensional stability in a matter of seconds at the one extreme, thermosets may take several days to fully crosslink at the other extreme. In reality, the difference is considerably smaller, but it is generally true that thermoplastic composites may be manufactured more rapidly than thermoset ones. The very nature of thermosets makes them unpleasant to work with since chemical reactions involving volatile and potentially toxic substances are involved. In contrast, the molecular structure of fully polymerized thermoplastics makes them chemically inert if processed correctly, meaning that no hazardous substances need to be considered. Table 1 summarizes manufacturing-related properties and processing requirements for some representative matrices.

Table 1 Typical manufacturing-related properties and requirements for selected thermoplastic and thermoset matrices

Matrix type	Viscosity[(a)]		Temperature[(b)]		Pressure[(b)]		Time[(c)]	Health concerns[(a)]
	Pa · s	cP	°C	°F	MPa	psi		
Thermoplastics

(d) Refers to partly cross-linked matrix in semifinished raw material form.
Source: Ref 1

The costs of neat thermosets and thermoplastics are comparable, unless tolerance to high temperature is an issue. Then, thermosets are advantageous. Also when the starting point for a given manufacturing technique is some semifinished material form where part or all of the reinforcement impregnation has already been accomplished, thermoset-based materials are generally less costly (courtesy of their lower viscosity, which simplifies impregnation). However, under the right circumstances, the final component cost may end up lower for a thermoplastic composite due to faster, simpler, and, thus, cheaper manufacturing.

While thermosets clearly dominate in structural composite applications, the interest in thermoplastics is driven by several potential advantages, as summarized in Table 2. When considering this table it is important to keep in mind that no such sweeping comparison can ever be absolutely fair. For example, a high-performance thermoplastic matrix will contribute to better composite properties than a standard-performance thermoset (except in terms of cost).

Table 2 Qualitative comparison between thermoset and thermoplastic matrix composites

Property	Composite(a)	
	Thermoset	Thermoplastic

Material Forms

The two main constituents in a polymer composite are the matrix and the reinforcement. The general types, forms, and representative properties are treated in the Section "Constituent Materials" in this Volume. However, for the purpose of this article, a brief recapitulation of material forms and representative composite properties is appropriate. Broadly speaking, possible raw material forms for use in composites manufacturing are the following:

- Reinforcement and matrix separately (for in- process impregnation)
- Molding compound (randomly oriented, continuous or discontinuous reinforcement at a volume fraction typically in the range 0.1 to 0.3, reinforcement partly or completely impregnated)
- Prepreg (short for preimpregnated reinforcement; oriented and usually continuous reinforcement at a volume fraction up to 0.6, reinforcement partly or completely impregnated)

In manufacturing of thermoset composites, separate reinforcement and matrix forms and molding compounds are the most common, whereas prepregs are the norm in high-performance applications. In contrast, in manufacturing of thermoplastic composites, use of reinforcement and matrix separately was more or less unheard of, due to impregnation difficulties, and molding compounds or prepregs were essentially always required. However, it is possible to impregnate the reinforcement as part of manufacturing starting out with a liquid monomer, which has low molecular weight and, thus, also viscosity. Following impregnation, the monomer is polymerized (but *not* crosslinked) to achieve high molecular weight (and thus structurally useful properties). This concept is not new, but it has essentially never made it out of the laboratory to see any significant commercial success until recently, due to unforgiving processing requirements that now appear to have been relaxed. Such in situ polymerizable thermoplastics may be used in many conventional thermoset manufacturing techniques, thus opening up a whole range of new opportunities for thermoplastic composites. However, with in situ polymerizable thermoplastics, the previously discussed good work environment facilitated by an inert matrix can no longer be taken for granted.

Fully polymerized thermoplastics are solids at ambient temperature and may be obtained in the form of pellet, powder, film, or fiber. Monomers intended for in situ polymerization are typically also solids at room temperature and, thus, need to be melted prior to mixing with the catalyst and initiator required to achieve polymerization. Courtesy of its low molecular weight, the melt temperature of a monomer is notably lower than that of the fully polymerized (high-molecular–weight) thermoplastic.

In both thermoplastic molding compounds and prepregs, the reinforcement may either be completely impregnated with the fully polymerized matrix (through melt or solvent impregnation) or just intimately physically mixed (through powder impregnation or commingling of reinforcing fibers with matrix fibers). In the latter case, melt impregnation must be accomplished at a later stage, either in an intermediate consolidation step or as part of final component molding. Fully impregnated thermoplastic prepregs are generally supplied as wide sheet or narrow tape on rolls. In most cases, the reinforcement is unidirectional (in the longitudinal direction), but woven and braided material forms are also available. Powder-impregnated and commingled prepregs are supplied as yarns, often woven or braided into a fabric, although fabrics may also be powder

impregnated. Melt-impregnated molding compounds are supplied as rigid sheet, often cut to specification. In contrast, powder-impregnated molding compounds are flexible and usually delivered on rolls. Material forms that are already fully impregnated are bound to yield more complete consolidation and lower void content in the composite, but powder- impregnated and commingled prepregs have advantages in lower cost and better drapeability and in that they are easily woven and braided into fabrics.

Tables 3 and 4 provide indicative tensile properties of thermoplastic composites manufactured from different raw material types and forms with some thermoset composites included for references. Note that the tensile properties given are strongly fiber dominated.

Thermoplastic Composites Manufacturing

B. Tomas Åström, IFP SICOMP AB, Sweden

Technique Descriptions

Composite manufacturing requires precise control of temperature and pressure throughout the manufacturing cycle and throughout the material. The basic requirement on any manufacturing technique is to apply sufficient pressure to maintain the liquid reinforcement-matrix mass in the desired shape at a specified temperature for the time required for it to achieve dimensional stability. If the reinforcement is also to be impregnated as part of the process, a pressure gradient is first required to drive the matrix through the reinforcement. Manufacturing of thermoplastic composites involves the following steps:

1. Heat the matrix until it is liquid (or, alternatively, heat the monomer until it is liquid and mix it with catalyst and initiator)
2. Apply pressure gradient to impregnate the reinforcement (unless molding compounds or prepregs are used)
3. Apply pressure to make the impregnated reinforcement conform to the mold
4. Allow time for polymerization (if applicable)
5. Cool the material until the matrix solidifies and the component is dimensionally stable
6. Remove the component from the mold

With the exception of compression molding, which essentially always employs molding compounds, the following treatment concentrates on use of prepregs (containing fully polymerized thermoplastics) as raw material since prepregs have been and still are the starting point in most cases. With prepregs, composite manufacturing may be batchwise or more or less continuous. In batch techniques, the route from prepreg to final component may be divided into three basic steps: layup, consolidation, and molding. In the first step the number of prepreg plies required to form the desired postconsolidation thickness are laid up. The second step is to consolidate the plies into a monolithic laminate, and the third step is to form the sheet into the final geometry. In some cases two or even all three of these steps may be combined into one operation, but more commonly the steps are distinct and separate. In the continuous techniques, prepreg layup usually becomes an integral part of the consolidation step and sometimes also the molding step, which are accomplished on line through localized application of heat and pressure. This has given rise to the term on-line consolidation.

The mechanism responsible for bonding between thermoplastics is called autohesion and may yield virgin strength across a material interface in a fraction of a second, provided the surfaces are at sufficiently high temperature to allow significant molecular mobility and instantaneously are brought into intimate contact. While virgin strength may be achieved very rapidly in laboratory composite consolidation experiments, it is rarely possible to realize equally short consolidation times in real manufacturing situations. In most cases it is not autohesion that limits processing rate; it is the time required to heat and cool the material, since it has very low thermal conductivity.

While this article concentrates on relatively well-known manufacturing techniques, there are few limitations to what means may be employed to manufacture a composite. Thus, any process in which the liquid reinforcement-matrix mass is subjected to sufficient temperature and pressure is likely to result in a composite; whether the resulting composite properties fulfill requirements and the technique is economically feasible are entirely different issues. In attempting to understand the essential technical aspects of a composite manufacturing technique, considering answers to the following questions should prove helpful:

- What is used as a mold to give the composite its shape?
- How is the raw material made to conform to the mold?
- How is the impregnation pressure gradient created (if applicable)?
- How is the consolidation pressure applied?
- How is temperature controlled?

It deserves notice that most of the techniques discussed later in this article are known by more than one name, and the designations used herein are not necessarily the most common ones.

Prepreg Lay-Up. The most straightforward way of laying up prepreg plies to gradually build up a composite is to cut the prepreg by hand and, likewise, to lay up the plies by hand. However, in many cases automated equipment is used to cut the prepreg to size (see the article “Prepreg and Ply Cutting” in this Section). Layup of thermoplastic prepreg is similar to the thermoset counterpart (see the article “Thermoplastic Composites Manufacturing”in this Section), but a major difference is the complete lack of tack (stickiness) in thermoplastic prepregs, which may be artificially achieved through localized melting of adjacent plies using, for example, a soldering iron or a hot air gun. For melt-impregnated and solvent-impregnated prepregs the drape (formability) is also poor, and to permit conformation to the mold during layup, drape may also be artificially achieved through localized heating. Fabrics made from powder-impregnated and commingled material forms, in contrast, possess drape, but tack must still be artificially created. Following layup, the prepreg stack is consolidated and molded employing techniques described below.

Hand layup is naturally very time-consuming, but is nevertheless quite common due to the research and development status of many manufacturing operations. However, there are also automated means to layup thermoplastic prepreg tapes. Equipment conceptually similar to that used for automated layup of thermoset prepreg tapes (see the article “Automated Tape Laying” in this Section) may also be used to layup thermoplastic prepregs directly onto the mold. In this case the mating surfaces are first heated and then joined under pressure; see Fig. 1. If both the previously laid ply and the incoming tape have completely melted surfaces when they are joined, a separate consolidation step may not be needed, and the component thus is ready for removal from the mold as soon as layup is completed (meaning that layup, consolidation, and molding are simultaneously accomplished). However, due to the localized and highly nonuniform heating, it is most difficult to avoid residual stresses and component warpage, and it may therefore be more appropriate to

only aim for partial (and thus more rapid) consolidation to ensure that the prepregs stay in place and then complete consolidation and molding in separate steps (as outlined in the following).

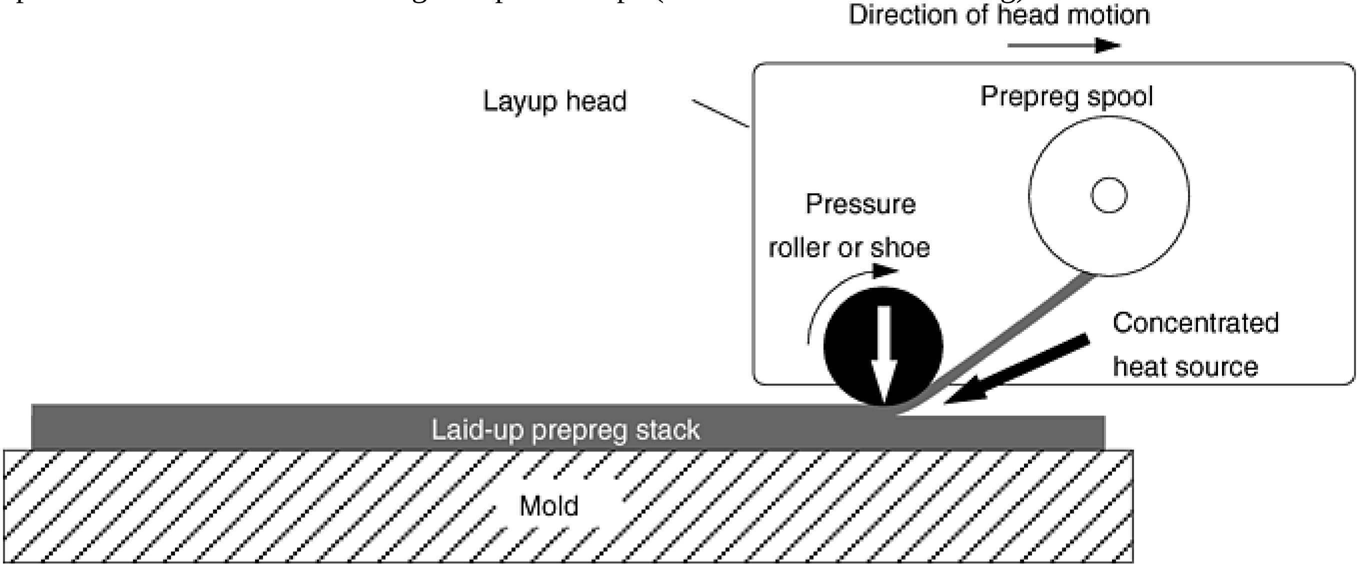

Fig. 1 Schematic of automated thermoplastic prepreg layup (resulting in partial or complete consolidation)

Prepreg Consolidation. While a range of techniques is technically feasible to consolidate a stack of laid-up thermoplastic prepregs into a flat laminate (Ref 13), only a few are likely to be economically feasible for longer series: matched-die consolidation, double-belt-press consolidation, and calendering.

In matched-die consolidation, one or more hydraulic presses are used to consolidate the prepreg stack in a flat mold. One version of this technique employs an oven to heat the prepregs to melt the matrix, whereupon the prepreg stack is quickly transferred to a press with a cooled mold (Fig. 2). The press then very rapidly closes to apply sufficient consolidation pressure during cooling. This consolidation technique is best suited for fully melt-impregnated prepregs, and cycle times of less than a minute may be achieved assuming the matrix is completely melted when exiting the oven. In intermittent matched-die consolidation the incoming prepregs are heated in an oven to melt the matrix, whereupon the molten material is indexed into a press with a cooled mold, which closes to consolidate the prepreg stack (Fig. 3). The press then opens, the material is indexed again, and the process is repeated to gradually produce a continuous component.

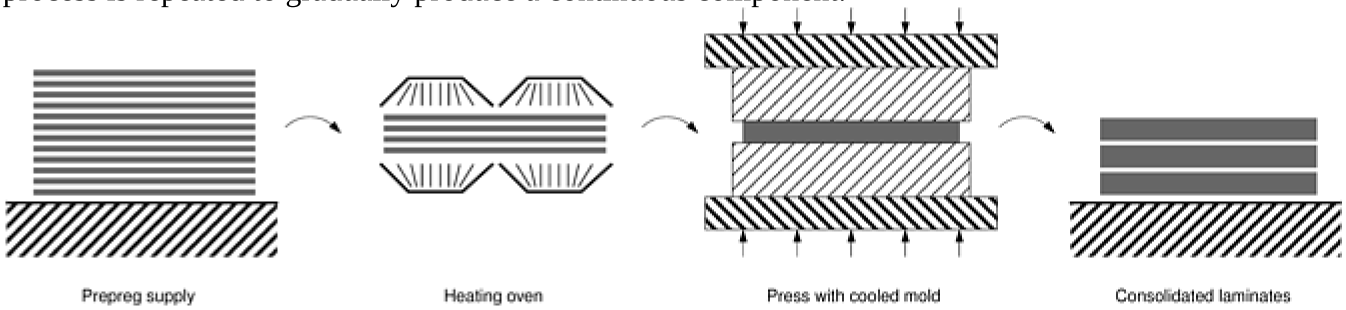

Fig. 2 Schematic of thermoplastic matched-die consolidation in press

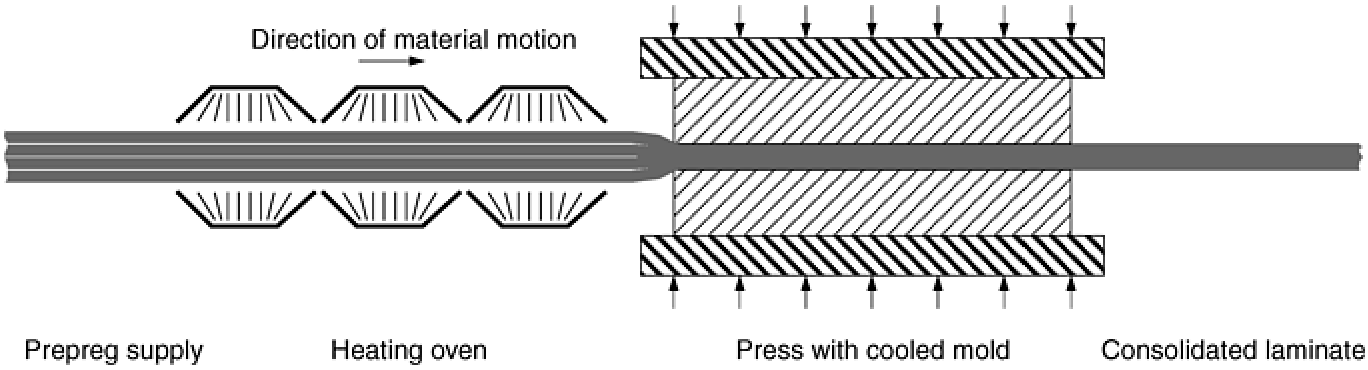

Fig. 3 Schematic of thermoplastic intermittent matched-die consolidation

A double-belt press offers one of the most efficient means of continuously consolidating prepregs into flat laminates (Fig. 4). The prepregs enter the press and are heated under pressure until the matrix melts, whereupon the laminate is cooled under pressure so as to exit the press fully consolidated. In this case, prepreg layup and consolidation are essentially performed simultaneously since the incoming prepregs are uncoiled from rolls of material through the forward motion of the belts of the press. In the related technique of calendering, the prepregs are heated in an oven to melt the matrix before they are consolidated in the nips between pairs of cooled calendering rolls (similar to rollforming as described subsequently, but with constant-diameter rolls).

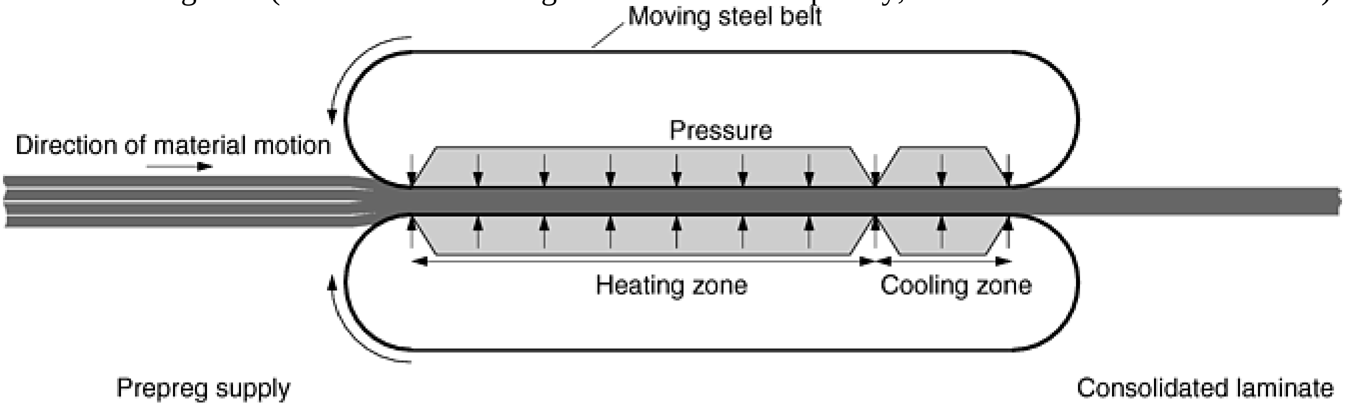

Fig. 4 Schematic of double-belt–press consolidation

These techniques to consolidate prepregs into flat laminates should be seen as a way to produce semifinished raw material for other techniques, including autoclave molding, diaphragm forming, compression molding, and rollforming, which are addressed separately subsequently. At least the latter three of these tend to yield better composite properties if the raw material is already fully consolidated rather than consisting of a stack of unconsolidated prepregs.

Autoclave Molding. In autoclave molding, prepregs are laid up onto a contoured mold, meaning that already during lay-up, the component more or less receives its final shape. This layup may either be performed manually or with some form of automated tape-laying equipment. The laid-up prepreg stack is then vacuum bagged in essentially the same way as thermoset prepregs, except that processing temperatures are so high that conventional bagging materials cannot be used. The prepreg stack is compacted and consolidated in an autoclave in a time frame of a few hours; consolidation and molding consequently occur simultaneously.

Since much of the early interest in thermoplastic composites had its origin in the military aerospace industry, autoclave consolidation has been used extensively. Although a technically feasible way to manufacture a range of aircraft components, the technique is not in widespread commercial use since it appears to offer no processing advantage over the thermoset relation. The only reason to select this route would be to exploit the inherent properties of the thermoplastic matrix, such as excellent damage tolerance.

Diaphragm forming may be seen as a derivative of autoclave molding. The main characteristic of the technique is that deeply drawn and geometrically complex components may be molded; examples include various aircraft components. The raw material is first placed between two flexible diaphragms. The diaphragms, but not the raw material, are then clamped around the entire perimeter, using a clamping frame, and the air is evacuated between the diaphragms.

In one version of the technique, the diaphragm-material stack is placed in an oven and heated to melt the matrix. The stack is then rapidly placed onto a one-sided female mold, and vacuum is drawn in the enclosed space between the lower diaphragm and the mold and/or pressure applied above the upper diaphragm to force the material to conform to the mold (Fig. 5). Since the mold is likely unheated, the component solidifies quickly after coming into contact with the mold. With this technique, forming times are measured in seconds and cycle times in minutes (excluding preheating).

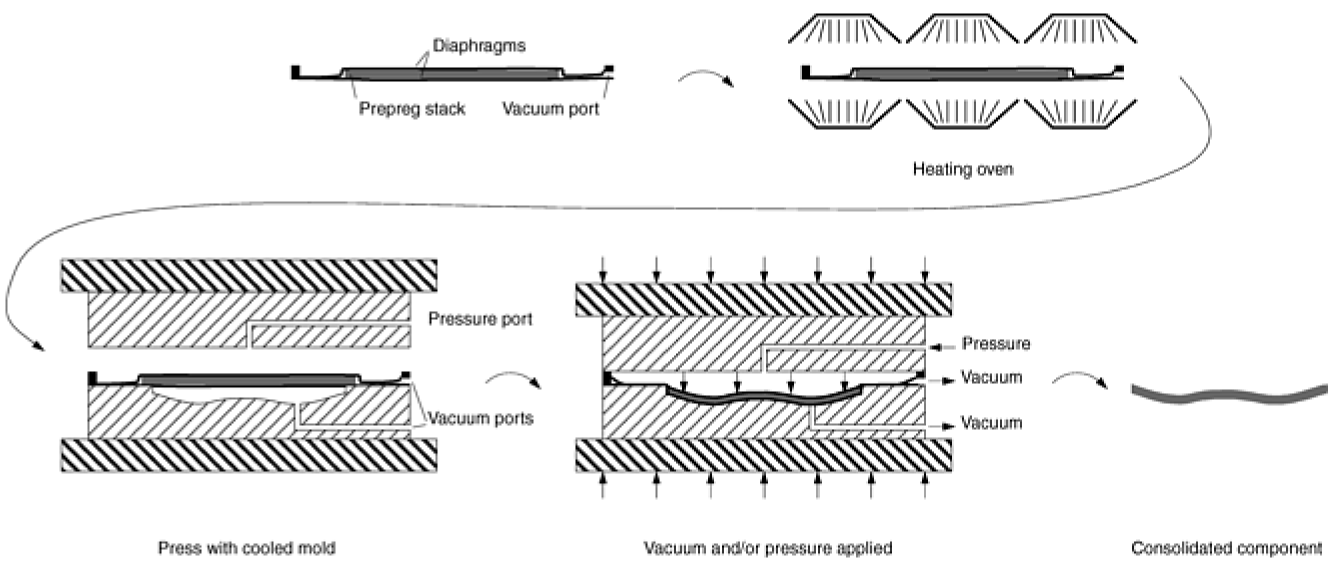

Fig. 5 Schematic of thermoplastic diaphragm forming in press

In another version, the diaphragm-material stack is fixed to the top of the thin-walled female mold and the entire assembly is then placed in an autoclave. Following evacuation of the air between the diaphragms, the internal autoclave atmosphere is heated to melt the matrix, whereupon vacuum below the lower diaphragm and pressure above the upper diaphragm make the material conform to the mold (Fig. 6). When forming is completed, the autoclave temperature is reduced to solidify the component. With this technique, forming takes only a few minutes, but the full cycle time is an hour or more. This version of diaphragm forming permits molding of more complex geometries than the previously described one since forming times are much longer.

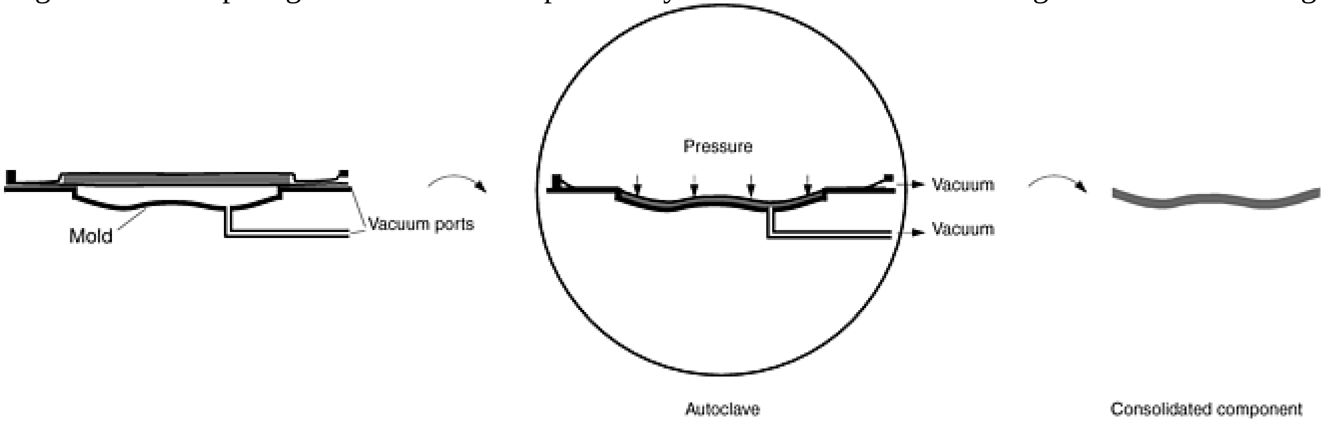

Fig. 6 Schematic of thermoplastic diaphragm forming in autoclave

Most types of prepregs have been used in diaphragm forming, but it appears as if investigations using melt-impregnated prepregs and fabrics woven from commingled and powder- impregnated yarns have been particularly successful. Diaphragms may be superplastic aluminum, sheet rubber, or polymer films. Rubber diaphragms have an advantage in that they may be reused, whereas aluminum and polymer films are permanently deformed.

Compression molding of thermoplastic composites is covered in more detail in the article “Compression Molding” in this Section, but for completeness, a discussion is also included in this article. Techniques to compression mold thermoplastic composites may be differentiated by whether they involve a significant amount of material flow to fill the mold or whether the material predominantly is deformed to conform to the mold. Randomly reinforced molding compounds, often called glass-mat–reinforced thermoplastics (GMT), permit flow since no straight, continuous fibers prevent it. In contrast, prepregs reinforced with continuous and aligned fibers cannot flow in the fiber direction without fracturing fibers, which is usually unacceptable.

The raw material is heated in an oven to melt the matrix and then stacked to form a charge that is rapidly placed in the cooled mold. Alternatively, long-fiber–reinforced thermoplastic (LFT) pellets may be fed into an extruder, which produces a charge that is quickly transferred to the mold. The press then quickly closes to mold the component before it solidifies and is ejected (Fig. 7). With GMT, the charge only covers about half the mold surface, meaning that material flow is notable. Since flow is significant, so is reinforcement orientation,

and properties therefore may vary significantly within a component. In contrast, with continuously fiber-reinforced raw material, the charge must have at least the same in-plane dimensions as the component, and it is difficult to manufacture components with complex or deeply drawn geometries, which is relatively straightforward with GMT. Much work is ongoing to combine the good structural properties of prepregs with the straightforward manufacturing of GMT through a combination of the two material forms (but generally with the same matrix and fiber types in both materials). This may, for example, be realized by placing prepreg plies between sheets of GMT, where the latter flow to generate a complex component geometry. Work is also underway to develop compression molding techniques to manufacture all-thermoplastic sandwich components in which the foam, tube, or honeycomb core is based on the same polymer as that in the faces.

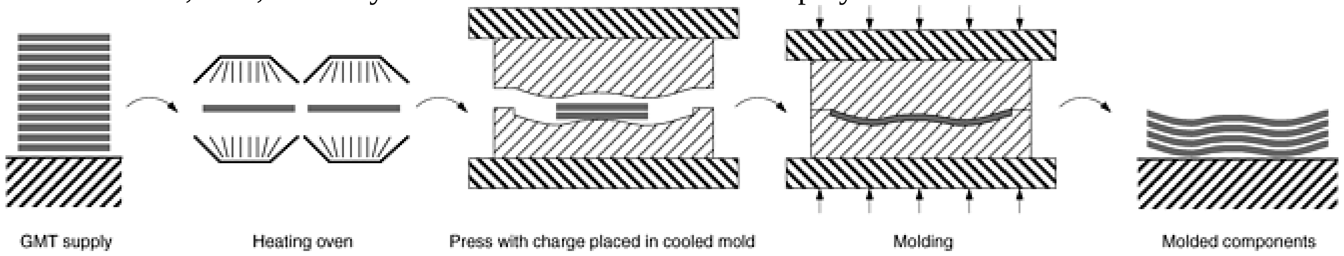

Fig. 7 Schematic of thermoplastic compression molding with molding compound. GMT, glass-mat reinforced thermoplastics

Compression molding of GMT is currently the only commercially widespread technique to manufacture thermoplastic composites with any appreciable fiber length. The technique is mainly used in the automobile industry, where the similarities with sheet metal stamping and thermoset compression molding have facilitated widespread acceptance.

Several modifications to conventional compression molding have been developed to permit molding of prepregs. Figure 8 illustrates rubber- block molding and Fig. 9 hydroforming, both of which reduce the risk of wrinkles in the component and employ cheaper molds. In hydroforming, a pressurized liquid is contained behind a flexible membrane that is capable of conforming to the shape of the lower mold half. Pressures may be significantly higher in hydroforming than in rubber-block molding.

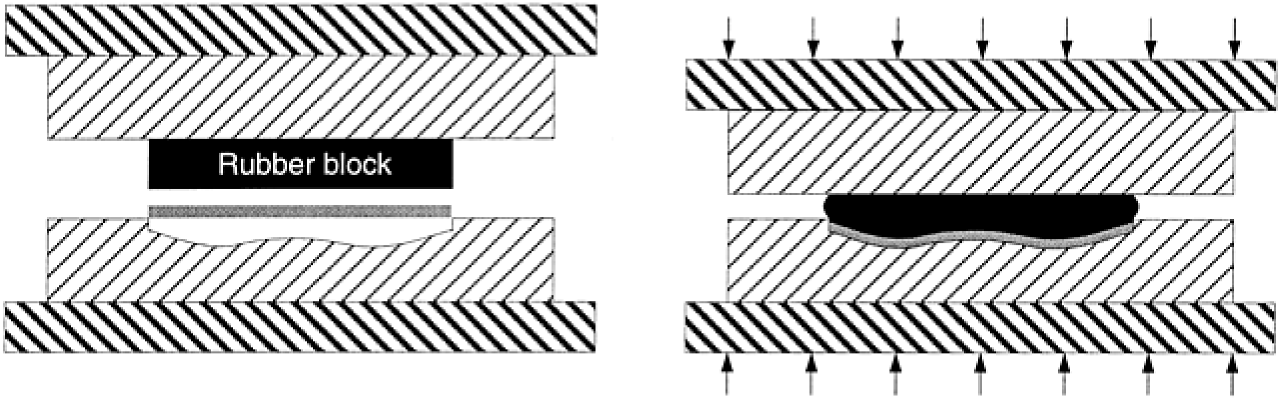

Fig. 8 Schematic of rubber-block molding

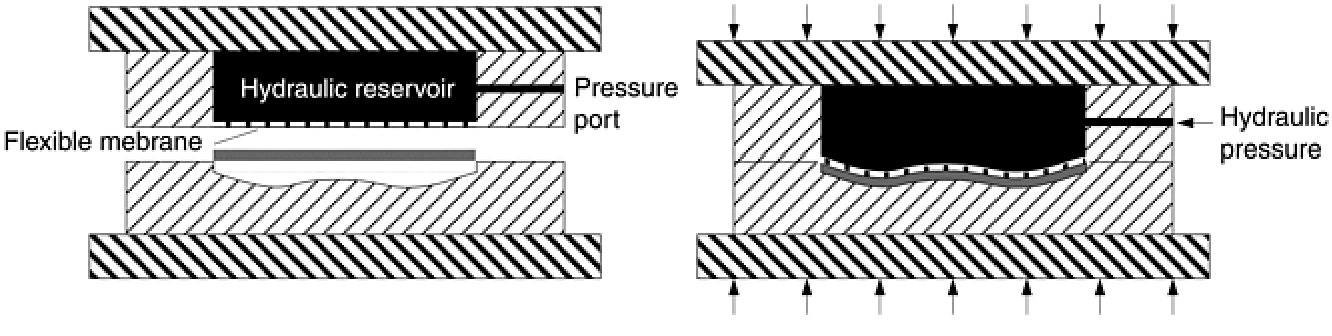

Fig. 9 Schematic of hydroforming

In deep drawing the material to be formed is mounted in a frame that keeps it under tension until forming is completed. As the molten material leaves the preheater it is placed over a female “mold” essentially consisting

of a frame the shape of the projected final product (Fig. 10). A male mold then rapidly punches the molten material through the frame and, since the male mold is cooled, the material quickly solidifies.

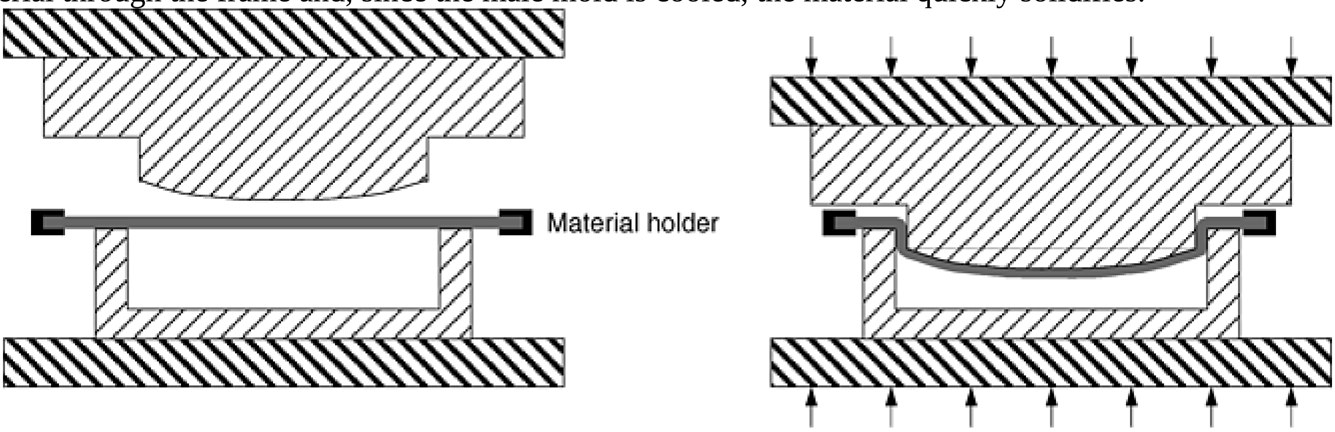

Fig. 10 Schematic of deep drawing

Melt-impregnated GMT is the most commonly used material form, but powder-impregnated GMT is also available. While it is the norm that GMT sheets are bought from a dedicated raw material supplier, in-house manufacture of thermoplastic molding compounds is becoming increasingly common. In molding of continuously reinforced composites, results are likely improved if preconsolidated composite panels are used rather than stacks of individual prepregs, since the time allowed for consolidation in most compression molding cases is very brief.

Roll Forming. In roll forming, several consecutive pairs of contoured, matching rolls, normally four or more, gradually deform the melted raw material to the desired shape (Fig. 11). The rolls, which are driven, are normally unheated, and they consequently cool the component. Roll forming is potentially capable of manufacturing any constant cross-section geometry, and components may be curved if desired. Nevertheless, so far thermoplastic composite roll forming has only been used to manufacture simple cross-sections, such as hat and Z-shapes. Most work to date has utilized preconsolidated panels as raw material, despite there being little reason why consolidation of prepregs should not be continuously carried out (e.g., with calendering rolls) in line with the actual roll-forming operation. Compared to most of the other manufacturing techniques described herein, little work on roll forming appears to be ongoing despite the technical feasibility of the technique having been proven.

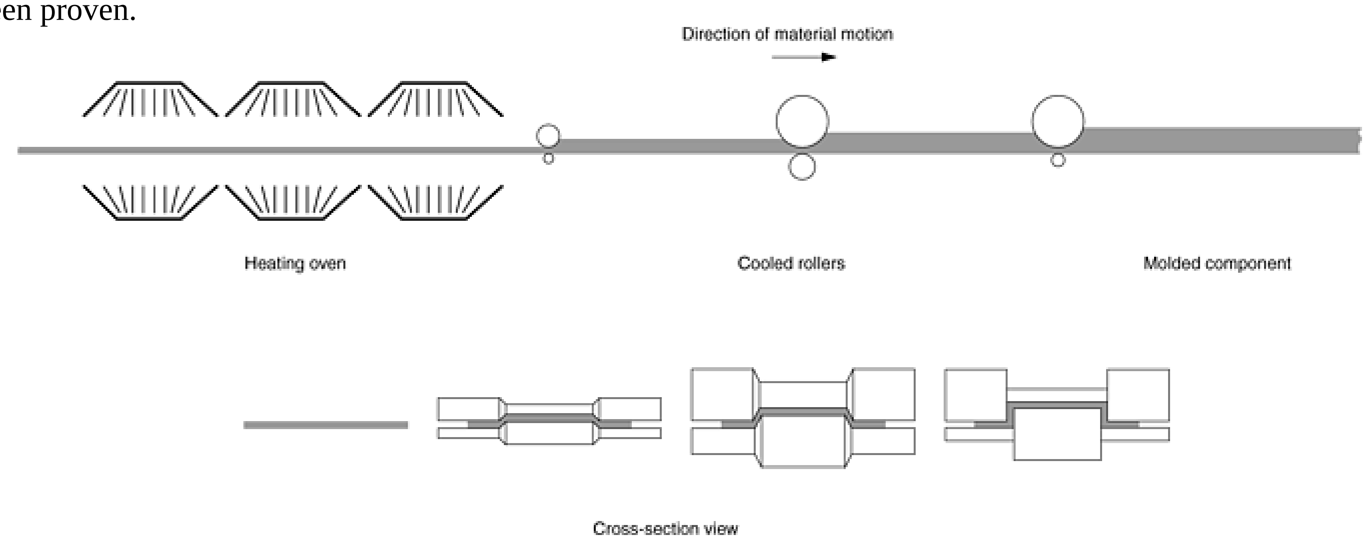

Fig. 11 Schematic of roll forming

Bladder molding is used to manufacture hollow products by means of an internal, pressurized bladder compacting the raw material against an external mold (Fig. 12). The raw material, usually in the form of a hollow braid made from commingled yarns, is draped over the bladder and is placed in the mold, which is closed. The bladder is then pressurized and the mold heated to melt the matrix fibers. When the matrix is melted and the reinforcement fully impregnated, the mold is cooled while maintaining bladder pressure. The mold temperature only needs to be reduced to where the composite is dimensionally stable, meaning that

subsequent heating cycles need not commence from ambient conditions, thus reducing cycle time and energy requirements.

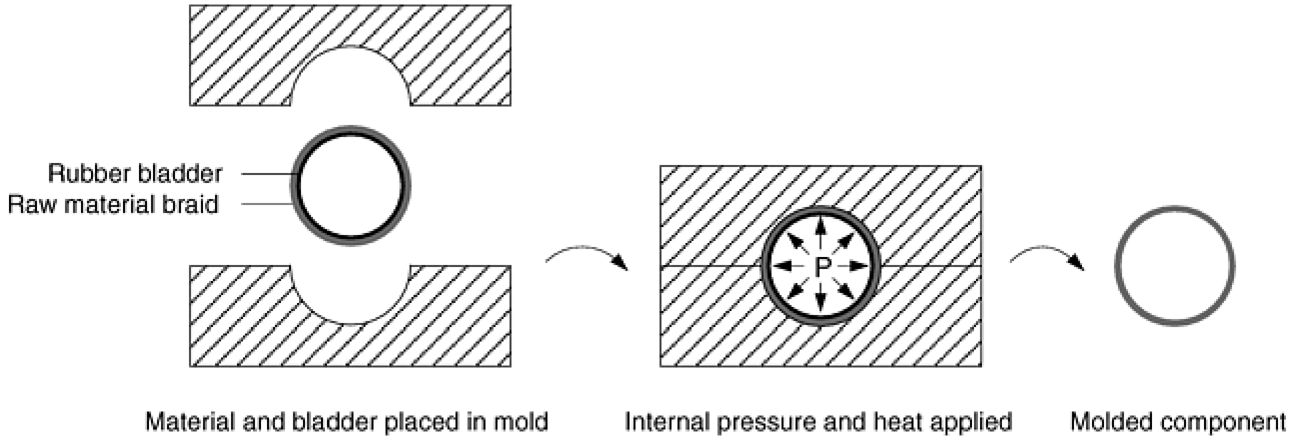

Fig. 12 Schematic of bladder molding

The liquid molding processes that may yield structurally capable thermoset composites, that is, resin transfer molding (RTM), vacuum infusion, and structural reaction injection molding (SRIM), all require that the matrix has very low viscosity to permit impregnation of the reinforcement present in the mold. Since fully polymerized thermoplastics have very high melt viscosities, direct adaptation of the conventional thermoset liquid molding techniques is not possible. (In injection molding, the short fibers are already intimately mixed with the fully polymerized thermoplastic, and this mixture is injected into the empty mold.) However, with in situ polymerizable thermoplastics, liquid molding may be realized since polymerization can be put off until the reinforcement is completely impregnated; Fig. 13 schematically illustrates such a process.

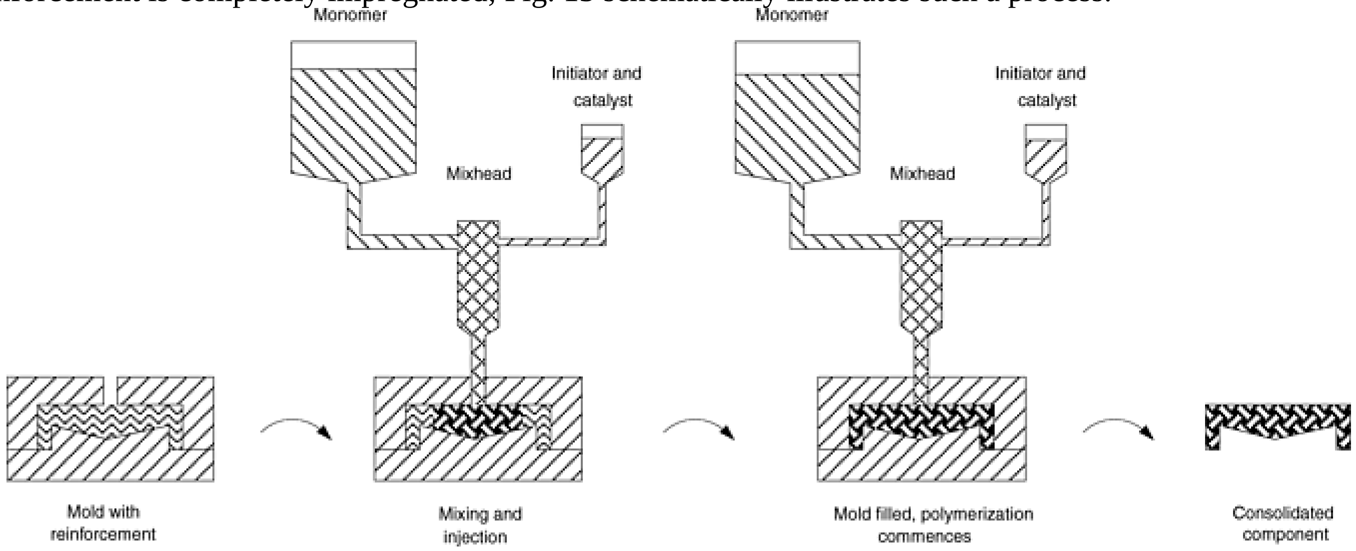

Fig. 13 Schematic of thermoplastic liquid molding. Source: Ref 10

Filament Winding. Most thermoplastic filament-winding facilities have the elements of Fig. 14 in common. The prepreg tape is preheated on its way to the rotating mandrel. At the contact point the previously wound layer is heated and the incoming prepreg often given a further thermal boost. To ensure good consolidation, both surfaces must have melted surfaces when brought in contact. Heating sources that have been successfully used include hot-gas guns, infrared heaters, lasers, and open flames. To compensate for the low thermal conductivity of thermoplastics, the preheating oven may need to be quite long, and the mandrel may also be heated.

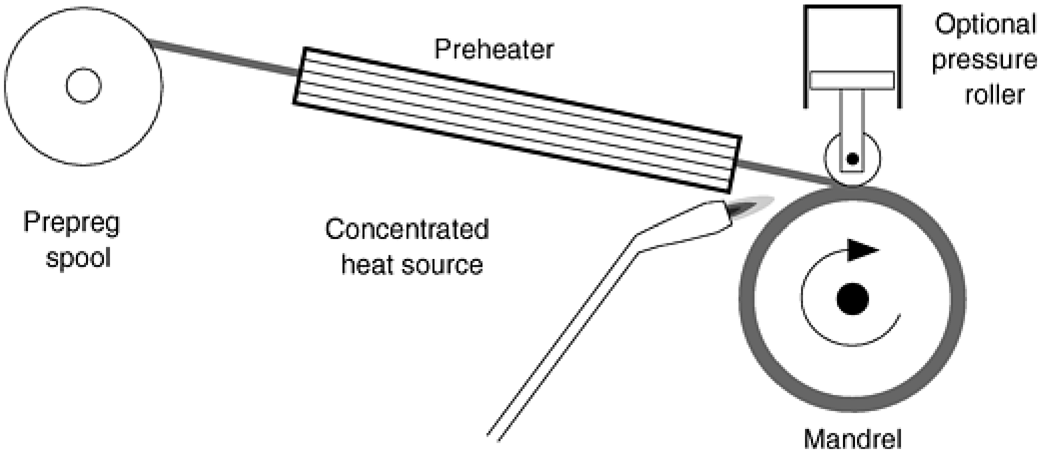

Fig. 14 Schematic of thermoplastic filament winding

As long as only convex surfaces are wound, it may be sufficient to use back tension on the prepreg as the sole means of compaction. However, since the prepreg tape may be on-line consolidated in a fraction of a second, flat and concave surfaces may be wound without sacrificing consolidation quality or experiencing tape bridging, provided that an external pressure source, such as a pressure roller or sliding shoe, is used. Apart from permitting concave winding, on-line consolidation also virtually eliminates the need to follow the geodesic path to avoid slippage, thus allowing much greater freedom in geometries and reinforcement orientations than thermoset filament winding. Moreover, on-line consolidation may result in considerably lower thermally induced residual stresses than if the entire component concurrently went through the thermal cycle from processing temperature to ambient conditions. It is thus at least theoretically possible to build up any wall thickness without much worry of thermally induced residual stresses.

Since the matrix is melted for such a short time, it is natural that fully melt-impregnated prepregs result in better component properties than when commingled or powder-impregnated yarns are used, although all material forms have been used with success. Hoop winding speeds in excess of 1 m/s (3 ft/s) have been realized with laser and open flame heating using melt-impregnated prepregs, but lower speeds are the norm. Attempts at on-line impregnation with polymer powder and liquid impregnation with in situ polymerizable thermoplastics have also been carried out but have not been widely accepted.

Pultrusion. A basic thermoplastic pultrusion facility is schematically illustrated in Fig. 15. The raw material in prepreg form is pulled into a preheater and then enters a heated die, which has a taper where the material is gradually shaped to the final cross-section geometry before it is consolidated in a cooled die. Although one-piece dies have been tried, it is more common that at least two separate dies are used to allow higher temperature gradients. Consolidation is a gradual process that starts in the taper of the heated die and continues until the cooled die solidifies the matrix. The consolidation time is therefore a function of die lengths, die temperatures, and pulling speed. While speeds near 100 mm/s (4 in./s) have been reported for pultrusion of simple components using melt-impregnated prepregs, speeds an order of magnitude lower are more common. Ultrasonically vibrating dies are said to allow higher pulling speeds when melt- impregnated prepregs are used.

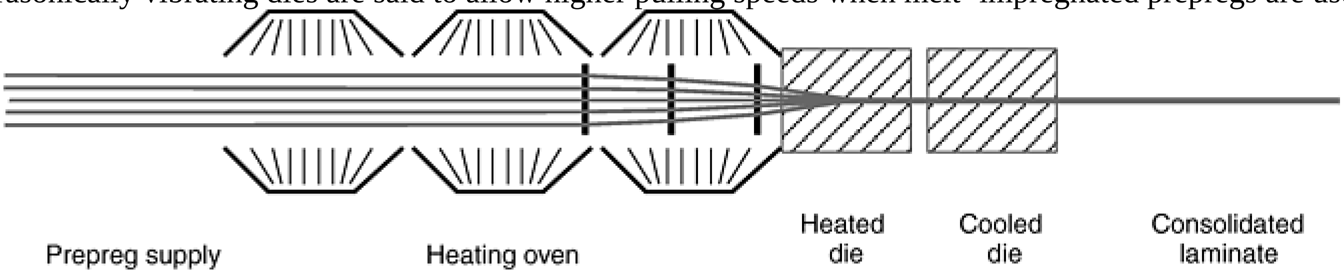

Fig. 15 Schematic of thermoplastic pultrusion

All prepreg forms have been tried, but there is little doubt that melt-impregnated prepregs result in the best component properties and the highest pulling speeds as long as the reinforcement is essentially longitudinal. To include nonlongitudinal reinforcement, it may be necessary to employ woven and braided material forms, and these are more readily available based on powder-impregnated and commingled yarns.

In order to improve process economy, the reinforcement should of course ideally be impregnated as part of the process in analogy with the thermoset technique. While various methods have been tried, use of in situ

polymerizable thermoplastics in injection pultrusion is a technically proven solution that is being commercialized (Fig. 16).

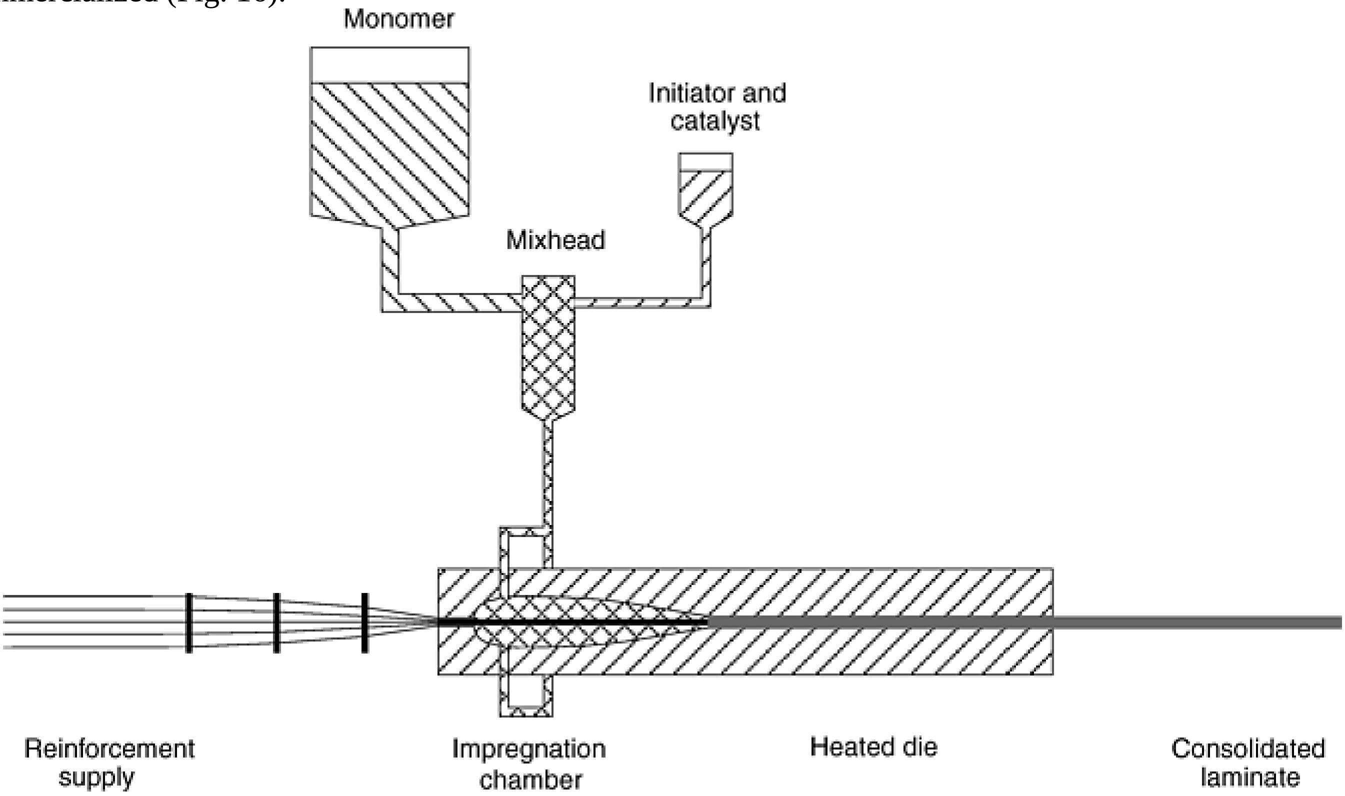

Fig. 16 Schematic of thermoplastic injection pultrusion. Source: Ref 10

Postforming. Localized postforming offers a simple yet effective means of making limited changes to already consolidated thermoplastic composites. For example, sheet and bar stock may be folded, flattened, and so forth through localized heating and subsequent forming. Despite the fact that if continuous reinforcement fibers are involved they are likely to buckle or fracture, line heating and subsequent folding of sheets and even sandwich panels has proven commercially viable in certain applications.

Outlook

While techniques to manufacture thermoset composites to a significant degree must be considered mature, most techniques to manufacture thermoplastic composites are significantly less developed, and the scope for technique improvements and innovation of completely new techniques is vast. The techniques described above have all been technically proven, but in most cases (with the exception of compression molding of GMT and the odd prepreg-based technique), they have failed to be economically competitive, which is generally due to the prohibitively high cost of thermoplastic prepregs. From this perspective, the introduction of relatively easily

processable in situ polymerizable thermoplastics offers a very attractive opportunity, which is likely to bring on a transformation of the industry. While there will continue to be niche markets for composites manufactured from materials containing fully polymerized thermoplastics, in situ polymerized thermoplastics have a chance to capture volume markets since price and cycle times are competitive with the thermoset alternatives.

Processing of Metal-Matrix Composites*

Introduction

METAL-MATRIX COMPOSITES (MMCs) are a class of materials with a wide variety of structural, wear, and thermal management applications. Metal-matrix composites are capable of providing higher-temperature operating limits than their base metal counterparts, and they can be tailored to give improved strength, stiffness, thermal conductivity, abrasion resistance, creep resistance, or dimensional stability. Unlike polymer-matrix composites, they are nonflammable, do not outgas in a vacuum, and suffer minimal attack by organic fluids such as fuels and solvents.

In an MMC, the matrix phase is a monolithic alloy (usually a low-density nonferrous alloy), and the reinforcement consists of high-performance carbon, metallic, or ceramic additions. Reinforced intermetallic compounds, such as the aluminides of titanium, nickel, and iron, are also under development. Reinforcements, characterized as either continuous or discontinuous, may constitute from 10 to 70 vol% of the composite. Continuous fiber or filament (f) reinforcements include graphite, silicon carbide (SiC), boron, aluminum oxide (Al_2O_3), and refractory metals. Discontinuous reinforcements consist mainly of SiC in whisker (w) form, particulate (p) types of SiC, Al_2O_3, and titanium diboride (TiB_2), and short or chopped fibers (c) of Al_2O_3 or graphite.

This article discusses primary processing methods used to manufacture MMCs. A general introduction to MMCs is provided in the article "Introduction to Composites" in this Volume. Additional information on reinforcements and matrix alloys is provided in the articles "Discontinuous Reinforcements for Metal-Matrix Composites," "Continuous Reinforcements for Metal-Matrix Composites," and "Metallic Matrices." Extrusion, considerations are discussed in the article "Extrusion of Particle- Reinforced Aluminum Composites." Extensive property data are provided in the article "Properties of Metal-Matrix Composites." Other coverage of MMCs in this Volume can be found by referring to the table of contents and index.

Processing of Discontinuously Reinforced Aluminum

Most of the commercial work on MMCs has focused on aluminum as the matrix metal. The combination of light weight, environmental resistance, and useful mechanical properties has made aluminum alloys very popular; these properties also make aluminum well suited for use as a matrix metal. The melting point of aluminum is high enough to satisfy many application requirements, yet low enough to render composite processing reasonably convenient. Also, aluminum can accommodate a variety of reinforcing agents. Although much of the early work on aluminum MMCs concentrated on continuous fiber types, most of the present work is focused on discontinuously reinforced (particle or whisker) aluminum MMCs because of their greater ease of manufacture, lower production costs, and relatively isotropic properties. As shown in Fig. 1, however, higher performance composites are produced by more expensive, continuous fiber reinforcements. At the opposite end of the cost/ performance spectrum are the particle-reinforced molten (or cast) metal composites. In between lie medium-priced composites, including those produced by preform infiltration and powder metallurgy (P/M) techniques.

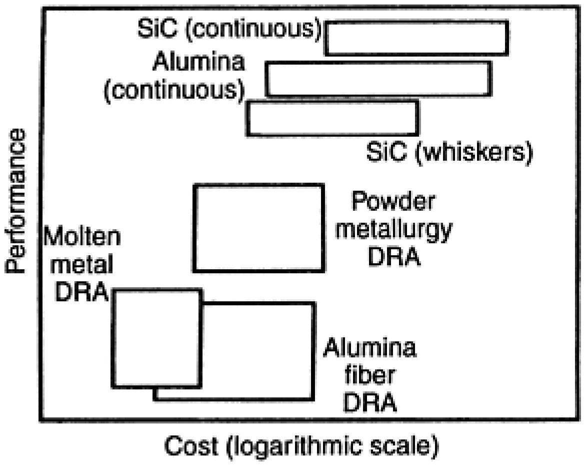

Fig. 1 The material cost versus performance of various aluminum-matrix composites. DRA, discontinuously reinforced aluminum

The most commonly used reinforcement materials in discontinuously reinforced aluminum composites are SiC and Al_2O_3, although silicon nitride (Si_3N_4), TiB_2, and graphite have also been used in some specialized applications. For example, aluminum-graphite alloys have been developed for tribological applications because of their excellent antifriction properties, wear resistance, and antiseizure characteristics. Table 1 lists properties of materials used to reinforce aluminum alloys.

Processing methods for discontinuous aluminum MMCs include various casting processes, liquid metal infiltration, spray deposition, and P/M. Each of these processes is briefly reviewed in the following sections.

Casting

Virtually every casting method that can be used with unreinforced aluminum has been used with aluminum MMCs. These include the sand, gravity die (permanent mold), investment, squeeze, and lost foam casting processes as well as high-pressure die casting, which is emphasized subsequently. However, experience has shown that several modifications must be made to the normal melting and casting practice in order to produce high-quality castings from a composite. Some of the differences in composite foundry practice are (Ref 1):

- Melting under an inert cover gas is at the discretion of the caster. Conventional degassing techniques, such as plunging tablets or gas injection, can cause nucleation of gas bubbles on the SiC particles and subsequent dewetting of the ceramic. Salt fluxing removes the SiC. On the other hand, a rotary injection system is available that can successfully flux and degas the melt. It uses an argon-SF_6 gas mixture. Additionally, simply bubbling argon through the melt using a diffuser tube can be used to remove hydrogen that has been absorbed by the melt.
- Close control of melt temperature is needed to avoid overheating and subsequent formation of aluminum carbide.
- The melt must be gently stirred during casting to maintain a uniform dispersion of SiC particles. The ceramic particles do not melt and dissolve in the matrix alloy, and because they are denser than the host alloy, there is a tendency for the particulate to sink to the bottom of the furnace or crucible.
- Turbulence during casting must be minimized to avoid entrapping gas.

By heeding these general guidelines, MMC ingots can be successfully remelted and cast using the current casting methods mentioned previously. Additional information on casting of aluminum MMCs can be found in Ref 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11.

Melting. Aluminum MMCs are melted in a manner very similar to that used for unreinforced aluminum alloys. Conventional induction, electric-resistance, and gas- and oil-fired crucible furnaces are suitable. If a protective gas is used, the crucible should be charged with the gas prior to adding dry, preheated ingots. The ingots are dried at a temperature above 200 °C (390 °F) to drive off unwanted moisture, which could contaminate the melt. All furnace tools, such as skimmers, ladles, and thermocouples, also must be coated and thoroughly dried and preheated before use.

Melt-temperature control is standard, and, in general, pouring temperatures are similar to those used for unreinforced alloys. However, care must be taken to avoid overheating, which can cause the formation of aluminum carbide via the reaction $4Al + 3SiC \rightarrow Al_4C_3 + 3Si$. This reaction occurs very slowly at temperatures to about 750 °C (1380 °F), but accelerates with increasing temperatures from 780 to 800 °C (1435 to 1470 °F) for matrices containing a nominal 9% Si. The Al_4C_3 precipitates as crystals that adversely affect melt fluidity, weaken the cast material, and decrease the corrosion resistance of the casting.

Stirring. Because the SiC particles are completely wetted by liquid aluminum, they will not coalesce into a hard mass but will instead concentrate on the bottom of the furnace if the melt is not stirred. The density of most aluminum alloys is approximately 2.7 g/cm^3, while the density of SiC is ~3.2 g/cm^3. Therefore, the use of a stirrer that disperses the particles throughout the melt is recommended. (Any steel utensils immersed in the melt must be coated to prevent iron contamination and dried and preheated to avoid hydrogen generation.)

The stirring action must be slow to prevent the formation of a vortex at the surface of the melt, and care must be taken not to break the surface, which could contaminate the bath with dross. A scooping action, whereby the lower portion of the melt is gently but firmly made to rise, is the best method of hand stirring. Use of a slowly rotating, propeller-like mechanical stirrer is preferred by some foundries. In fact, results of laboratory studies indicate that the mechanical properties of the casting are maximized by continuous stirring versus intermittent (hand) stirring. When induction melting, the natural eddy- current stirring action of the furnace usually is sufficient to disperse the particles, although supplementary hand stirring (with the power off) is recommended to ensure that no particles have congregated in potential “dead” zones.

After stirring, the settling rate of the SiC particles is quite slow, due partially to thermal currents in the melt and to the “hindered settling” phenomenon. After 10 to 15 min, however, approximately the top 30 mm (1.2 in.) of

the unstirred bath becomes devoid of SiC particles, although the distribution remains uniform throughout the balance of the melt. Consequently, it is important to stir the metal immediately before pouring, regardless of whether it was stirred during the melting and holding stages.

Fluxing and Degassing. A patented method of fluxing and degassing composite melts has been developed that uses a rotating impeller-like device to both stir the bath and inject a blend of argon and SF_6 gases. It also can be used to keep the SiC particles in suspension. The system employs a six-blade graphite impeller, which is connected to a threaded graphite drive shaft. A 610 mm (24 in.) diameter crucible requires the use of a 205 mm (8 in.) diameter impeller. Ten minutes of operation at a speed of 200 rpm usually is sufficient to shear the argon-SF_6 bubbles into an effective size. The thick, foamy dross that results is removed after the cycle is completed. Additional information on rotary fluxing and degassing can be found in the article "Nonferrous Molten Metal Processes" in *Casting*, Volume 15 of *ASM Handbook*. The melt can also be degassed by simply bubbling argon through the melt via a diffuser tube designed to provide a distribution of small bubbles. The melt should be stirred while bubbling the argon through the melt. A degassing time of 20 min at an argon flow rate of approximately 0.30 m^3/h (10 ft^3/h) can effectively reduce the hydrogen content of the melt to less than 0.10 mL/100 g for a 225 kg (500 lb) batch of molten composite. Some degree of melt cleansing or oxide removal is observed due to the attachment of oxides to the rising argon bubbles. The thick, frothy dross generated by bubbling argon through the melt should be continuously skimmed from the melt surface during the degassing period. Subsequent to degassing, the melt should be allowed to "rest" for 30 to 45 min without stirring to allow any remaining bubbles to float to the melt surface.

Pouring. It is neither practical nor necessary to maintain either an inert gas cover or stirring action while the liquid metal is transferred from furnace to pouring station. The recommended sequence of operations is to stir the bath thoroughly, skim off dross in the furnace, and then transfer the liquid to the pouring ladle (or remove the crucible). If the metal transfer involves pouring from, for example, a tilting furnace into a ladle, it is important to minimize turbulence in the metal stream to avoid entrapping gas. Tilting furnaces, however, generally are not recommended for use with composite melts. Pouring practice is the same as for unreinforced aluminum.

Gating Systems. The basic rules of running and feeding also apply to castable MMCs, including the use of filters that pass the SiC particles but trap oxides. However, the viscous melt behaves as though partially solidified, and the ceramic particles impede the free flow of gases. The composite is far less forgiving of turbulence than conventional aluminum. Thus, a poorly designed gating system can cause the formation and entrapment of gas bubbles in the liquid that remain in the solidified casting. Optimal running and feeding systems for castable MMCs are being developed, although many sound castings have been produced using existing schemes. More detailed information on gating systems for cast aluminum MMCs can be found in Ref 2, 5, and 12.

High-Pressure Die Casting

One casting process that aluminum MMCs have proved to be especially adaptable to is high- pressure die casting (Ref 8). The extremely rapid solidification rates achieved in die casting produce a very fine dendritic structure that is nearly pore-free and yields excellent mechanical properties.

Die Design. Aluminum MMCs have been high-pressure die cast without any changes to the die cast machines or dies (Ref 13). The dimensional shrinkage factor for these composite materials is in the range of 0.6%, which is similar to that of unreinforced aluminum alloys. In some cases, there is no need for alterations to the gating and venting of the dies that are currently used for conventional aluminum alloys. These composite materials can also be run with or without vacuum.

Flow Characteristics. Aluminum MMCs may be up to 50 times more viscous than their matrix alloy due to the fact that they are semisolid materials (molten metal/solid particle mixtures). The thixotropic behavior of these aluminum semisolid composites can best be used in high-pressure die casting. This is due to the fact that shear rates that are applied to the semisolid melt in order to inject it into the die cavity improve its fluidity. This combined with the fact that semi-solid materials are more viscous than their aluminum-matrix alloy means that they enter the die cavity with much less turbulence and less entrapped air.

To best use the thixotropic behavior of aluminum MMCs, a minimum gate velocity of 30 m/s (100 ft/s) is recommended. With this velocity, the composite material enters the die in an almost laminar flow, which has

produced castings that are of a higher quality (less porous) than castings from unreinforced aluminum alloys poured under the same conditions.

Die Wear. A concern of the high-pressure die casters of aluminum composites is the effect of SiC particles on die life. The presence of hard (2400 HK) SiC particles in the melt raises questions about die wear and the effect on die casting equipment. However, analysis of studies done on aluminum composites show that each of the SiC particles are completely wetted by the molten aluminum. As the molten metal is shot into the die, only the aluminum, not the SiC, comes into contact with the die and/or die cast equipment. Therefore, aluminum MMCs should not lead to premature wear of the die or die casting equipment, because only molten aluminum is coming into contact with the die. As a result, conventional die steels, such as H13 hot work tool steel, are recommended for aluminum MMC die-casting dies.

Die Hold Time. High-pressure die casters have observed that productivity can be increased due to shorter cycle times. The shorter cycle times may be attributable to the unique properties of these materials. There are several factors that contribute to these shorter cycle times.

Because up to 20% of the melt is solid ceramic, less heat of fusion must be removed during solidification, and the thermal conductivity is greater due to the addition of the SiC particles. Therefore, with less heat being removed more quickly, the casting will solidify faster, resulting in shorter cycle times.

Aluminum composites can be poured at low temperatures (as low as 650 to 675 °C, or 1200 to 1250 °F), which is much lower than the normal pouring temperature of 705 to 730 °C (1300 to 1350 °F) for high-silicon (16 to 18 wt% Si) A390 alloy. These lower temperatures result in less thermal shock to the die and decreased die casting cycle times. A cycle time reduction of up to 20% has been observed. These factors can also result in increased die life due to less thermal stress on the die.

Compocasting

When a liquid metal is vigorously stirred during solidification, it forms a slurry of fine, spheroidal solids floating in the liquid. Stirring at high speeds creates a high shear rate, which tends to reduce the viscosity of the slurry even at solid fractions as high as 50 to 60% volume. The process of casting such a slurry is called *rheocasting*. The slurry can also be mixed with particulates, whiskers, or short fibers before casting. This modified form of rheocasting to produce near-net shape MMC parts is called *compocasting* (Ref 14, 15, 16, 17, 18, 19, 20, and 21).

The melt reinforcement slurry can be cast by gravity casting, die casting, centrifugal casting, or squeeze casting. The reinforcements have a tendency to either float to the top or segregate near the bottom of the melt, because their densities differ from that of the melt. Therefore, a careful choice of casting technique as well as of mold configuration is of great importance in obtaining uniform distribution of reinforcements in a compocast MMC (Ref 22, 23).

Compocasting allows a uniform distribution of reinforcement in the matrix as well as a good wet-out between the reinforcement and the matrix. Continuous stirring of the slurry creates intimate contact between them. Good bonding is achieved by reducing the slurry viscosity as well as by increasing the mixing time. The slurry viscosity is reduced by increasing the shear rate as well as by increasing the slurry temperature. Increasing the mixing time provides a longer interaction between the reinforcement and the matrix.

Compocasting is one of the most economical methods of fabricating a composite with discontinuous fibers. It can be performed at temperatures lower than those conventionally employed in foundry practice during pouring, resulting in reduced thermochemical degradation of the reinforced surface.

Pressure Infiltration Casting*

Pressure infiltration casting (PIC) is an MMC fabrication technique that involves infiltrating an evacuated particulate or fiber preform with molten metal subjected to an isostatically applied gas pressure (Ref 24, 25, 26, and 27 28). As in more traditional casting processes, PIC produces components to near-net shape. This is an important attribute for producing MMC components, because it reduces the amount of machining needed for these often difficult-to-machine materials. One of the most common composite materials fabricated using the PIC process is discontinuously reinforced aluminum (DRA) (Ref 24, 25, and 26).

The greatest number of components fabricated via PIC are DRA electronic packages used to house and mount integrated circuits and multichip modules (Ref 29, 30, and 31). The benefits of DRA to this application include

a controlled coefficient of thermal expansion (CTE), which closely matches that of directly mounted integrated circuits, and a high thermal conductivity, which aids removal of the heat generated by these components. Components have also been prototyped for a number of applications in the automotive (e.g., brake rotors, connecting rods), aerospace (e.g., hydraulic manifolds, control links), gas turbine engines (e.g., stator vanes), and space propulsion (e.g., pump housings, flanges) industries.

Process Description. Although there are several variations to the PIC process (Ref 26) for fabrication of near-net shape DRA components, all involve the infiltration of molten aluminum into a free-standing, evacuated preform by an external isostatically applied inert gas. The PIC process begins by inserting a reinforcement preform into a mold, which is placed inside a metal canister (Fig. 2). The metal canister is used to maintain vacuum inside of the mold and preform during the pressurization stage of the process. For the top-fill version of the process (Ref 24, 26), the canister typically extends above the mold to contain the molten aluminum charge. The entry port to the mold is sealed with molten aluminum through the use of a filter with sufficient surface tension to maintain the molten aluminum head.

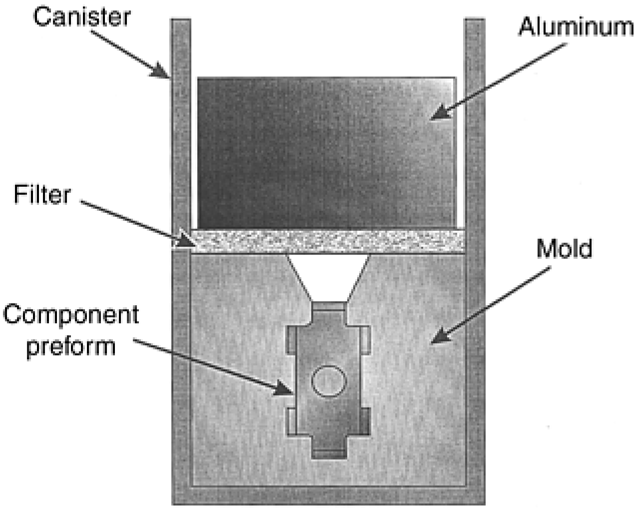

Fig. 2 Schematic of assembly for top-fill pressure infiltration casting

An early experimental variation of the process is known as bottom fill (Ref 26, 27). In this variation, the mold assembly is sealed within the metal canister, and a tube extends down to a separate crucible containing the aluminum charge. The entry to the mold is sealed when the aluminum melts, and the end of the tube is submerged in the aluminum.

In both variations, the mold and the preform within it are evacuated. The most common method of evacuating the mold and preform is to place the entire mold assembly in a vacuum/ pressure vessel and evacuate both the mold and vacuum/pressure chamber. The aluminum charge is then melted under vacuum, thus sealing the entry port to the evacuated mold.

In a variation of the top-fill approach, the aluminum is melted in a separate crucible and poured into the metal canister and onto the filter outside of the vacuum/pressure vessel (Ref 32). A tube leading through the filter and into the mold is then used to evacuate the mold and preform. After sufficient vacuum is attained, the tube is crimped and sealed. The entire assembly of both the mold and molten aluminum is placed inside a pressure vessel.

Regardless of the setup used, the mold and preform are heated to a predetermined temperature, so that the molten aluminum does not solidify upon contact and choke off infiltration (Ref 25). After the mold is preheated and the aluminum melt has reached the desired superheat temperature, inert gas pressure in the range of 2 to 10 MPa (300 to 1500 psig) is applied. The pressure difference between the gas outside of the mold and vacuum within the mold overcomes the surface tension forces of the reinforcement and drives the aluminum into the preform (Ref 33, 34, and 35). As liquid aluminum infiltrates into the preform, the pressure acting on the mold quickly approaches the isostatic state. Hence, the mold only supports the pressure difference for a very short period of time so that large, expensive, and cumbersome molds are not needed (Ref 24, 26). To aid filling-shrinkage porosity, the mold is cooled directionally, and pressure is maintained until the entire casting is solidified.

DRA Materials Produced by PIC. The PIC process can produce DRA parts with a wide range of reinforcement types and volume fractions using both conventional casting and wrought aluminum alloys as the matrix (Ref 24, 26).

Matrix Alloys. Most traditional casting alloys increase their fluidity through the addition of elements such as silicon. Because PIC is a pressure casting process, it does not need to rely on the inherent fluidity of the molten aluminum in order to fully fill the mold and preform. This allows the use of off-the-shelf commercial alloys, which helps lower the cost of DRA parts due to the widespread availability of the alloys. Additionally, using commercial alloys enables the performance gain of the DRA to be easily ascertained. Discontinuously reinforced aluminum components have been successfully fabricated using familiar aluminum alloys, such as 2024, 6061, and A356, as the matrix (Ref 26, 33).

Reinforcements. Discontinuously reinforced aluminum fabricated using a preform provides a uniform reinforcement distribution with no segregation of the reinforcement during solidification. In PIC, the preform acts as a nucleation site for solidification and inhibits large grain growth during solidification and cool down, resulting in a very fine cast microstructure between the reinforcement particles (Ref 25, 36, and 37). Additionally, because the preform is evacuated and the mold is directionally cooled, properly designed and processed components can be produced without porosity.

Preforms have been fabricated and pressure infiltration cast in a range of reinforcement levels varying from 30% to greater than 70%. Current technology does not provide for lower reinforcement volume fractions, because the preform must have sufficient reinforcement content to produce a stable geometry. A number of particulate reinforcements have been used to make preforms for the PIC process (Ref 24, 26, 33, 35). The most common reinforcements used are SiC and Al_2O_3 particulates. With a density only slightly lower than that of aluminum, boron carbide (B_4C) has also been investigated as a reinforcement—the close match in density means that settling of the reinforcement is avoided. However, at this time, boron carbide is not widely used in PIC, primarily due to its cost.

The Future of Pressure Infiltration Cast DRA. The ability to produce quality DRA components with the desired properties using PIC has been well documented (Ref 26, 29, 30, 31, 32, and 33). The performance gains enabled by this class of material have been demonstrated by the number of prototypes that have been manufactured and successfully tested. As with most new materials and processes, the primary barrier to increasing the number of pressure infiltration cast DRA components in use tends to be the initial high insertion cost. Currently, cost issues are being addressed through the application of new technologies, such as rapid prototyping/manufacturing methods and computer modeling and simulation software. These technologies have the potential to reduce the cost and time associated with the manufacture of pressure infiltration cast DRA components. For example, new rapid prototyping and manufacturing processes are being applied to the manufacture of particulate preforms directly from a three-dimensional computer-aided design solid model and do not require any tooling. Computer modeling and simulation software enables the design and selection of initial processing parameters and thereby reduces the expensive trial-and-error approach to determining the optimal manufacturing process. In conclusion, as costs are reduced and the economics of various systems demand higher performance (e.g., greater service life, lighter weight, etc.), the number of pressure infiltration cast DRA components will increase accordingly.

Liquid Metal Infiltration

The pressureless metal infiltration (Primex, Advanced Materials Lanxide) process is based on materials and process controls that allow a metal to infiltrate substantially nonreactive reinforcements without the application of pressure or vacuum. Reinforcement level can be controlled by the starting density of the material being infiltrated. As long as interconnected porosity and appropriate infiltration conditions exist, the liquid metal will spontaneously infiltrate into the preform.

Key process ingredients for the manufacture of reinforced aluminum composites include the aluminum alloy, a nitrogen atmosphere, and magnesium present in the system. During heating to infiltration temperature (~750 °C, or 1380 °F), the magnesium reacts with the nitrogen atmosphere to form magnesium nitride (Mg_3N_2). The Mg_3N_2 is the infiltration enhancer that allows the aluminum alloy to infiltrate the reinforcing phase without the necessity of applied pressure or vacuum. During infiltration, the Mg_3N_2 is reduced by the aluminum to form a small amount of aluminum nitride (AlN). The AlN is found as small precipitates and as a thin film on the surface of the reinforcing phase. Magnesium is released into the alloy by this reaction.

The pressureless infiltration process can produce a wide array of engineered composites by tailoring of alloy chemistry and particle type, shape, size, and loading. Particulate loading in cast composites can be as high as 75 vol%, given the right combination of particle shape and size. Figure 3 shows a typical microstructure.

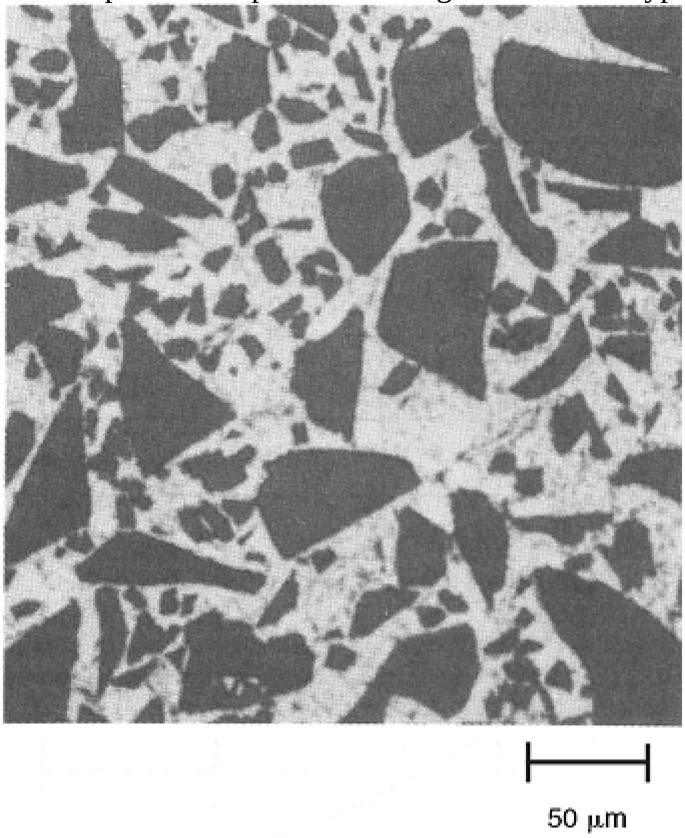

Fig. 3 Discontinuous Al-SiC MMC (60 vol% SiC) produced by the liquid metal infiltration process

The most widely used cast composite produced by liquid metal infiltration is an Al-10Si- 1Mg alloy reinforced with 30 vol% SiC. The 1% Mg present in this alloy is obtained during infiltration by the reduction of the Mg_3N_2. This composite system is being used for all casting processes except die casting. The composite most used for die casting is based on this system, with the addition of 1% Fe. Alloy modifications can be made to the alloy prior to infiltration or in the crucible prior to casting. The only universal alloy restriction for this composite system is the presence of magnesium to allow the formation of the Mg_3N_2. For the SiC-containing systems, silicon must also be present in sufficient quantity to suppress the formation of Al_4C_3. Composites consisting of Al_2O_3-reinforced aluminum that exhibit low excessive wear rates are also produced.

An important application area for pressureless molten metal infiltration is Al-SiC_p packages, substrates, and support structures for electronic components. Typical requirements include a controlled CTE to reduce mechanical stresses imposed on the electronic device during attachment and operation, high thermal conductivity for heat dissipation, high stiffness to minimize distortion, and low density for minimum weight. Compared with conventional aluminum alloys, composites having high loadings of SiC particles feature greatly reduced CTEs and significantly higher elastic moduli, with little or no penalty in thermal conductivity or density.

Spray Deposition

Spray deposition involves atomizing a melt and, rather than allowing the droplets to solidify totally as for metal powder manufacture, collecting the semisolid droplets on a substrate. The process is a hybrid rapid solidification process, because the metal experiences a rapid transition through the liquidus to the solidus, followed by slow cooling from the solidus to room temperature. This results in a refined grain and precipitation structure with no significant increase in solute solubility.

The production of MMC ingot by spray deposition can be accomplished by introducing particulate into the standard spray deposition metal spray, leading to codeposition with the atomized metal onto the substrate.

Careful control of the atomizing and particulate feeding conditions is required to ensure that a uniform distribution of particulate is produced within a typically 95 to 98% dense aluminum matrix.

A number of aluminum alloys containing SiC particulate have been produced by spray deposition. These include aluminum-silicon casting alloys and the 2xxx, 6xxx, 7xxx, and 8xxx (aluminum-lithium) series wrought alloys. Significant increases in specific modulus have been realized with SiC-reinforced 8090 alloy. Products that have been produced by spray deposition include solid and hollow extrusions, forgings, sheet, and remelted pressure die castings.

Spray deposition was developed commercially in the late 1970s and throughout the 1980s by Osprey, Ltd. (Neath, United Kingdom) as a method of building up bulk material by atomizing a molten stream of metal with jets of cold gas. Most such processes are covered by their patents or licenses and are now generally referred to as Osprey processes (Ref 38, 39, and 40). The potential for adapting the procedure to particulate MMC production by injection of ceramic powder into the spray was recognized at an early stage and has been developed by a number of primary metal producers (Ref 41, 42).

A feature of much MMC material produced by the Osprey route is a tendency toward inhomogeneous distribution of the ceramic particles. It is common to observe ceramic-rich layers approximately normal to the overall growth direction. Among the other notable microstructural features of Osprey MMC material are a strong interfacial bond, little or no interfacial reaction layer, and a very low oxide content. Porosity in the as-sprayed state is typically about 5%, but this is normally eliminated by secondary processing. A number of commercial alloys have been explored for use in Osprey route MMCs (Ref 43, 44, and 45).

Spray forming in the Osprey mode involves the sequential stages of atomization and droplet consolidation to produce near-net shape preforms in a single processing step. The as-sprayed material has a density greater than 98% of the theoretical density and exhibits a uniform distribution of fine equiaxed grains and no prior particle boundaries or discernible macroscopic segregation. Mechanical properties are normally isotropic and meet or exceed those of counterpart ingot-processed alloys. A major attraction of the process is its high rate of metal deposition, typically in the range 0.2 to 2.0 kg/s (0.4 to 4.4 lb/s).

Commercial viability mandates close tolerances in shape and dimensions, as well as consistency in microstructure and product yield. This requires an understanding of and control over the effects of several independent process parameters, namely: melt superheat, metal flow rate, gas pressure, spray motion (spray scanning frequency and angle), spray height (distance between the gas nozzles and the substrate), and substrate motion (substrate rotation speed, withdrawal rate, and tilt angle).

Powder Metallurgy Methods

Powder metallurgy processing of aluminum MMCs (Ref 46, 47) involves both SiC particulates and whiskers, although Al_2O_3 particles and Si_3N_4 whiskers have also been employed. Processing involves (1) blending of the gas-atomized matrix alloy and reinforcement in powder form; (2) compacting (cold pressing) the homogeneous blend to roughly 80% density; (3) degassing the preform (which has an open interconnected pore structure) to remove volatile contaminants (lubricants and mixing and blending additives), water vapor, and gases; and (4) consolidation by vacuum hot pressing or hot isostatic pressing. The hot pressed cylindrical billets can be subsequently extruded, rolled, or forged.

Whisker-reinforced aluminum MMCs may experience some whisker alignment during extrusion or rolling (Fig. 4). Control of whisker alignment enables production of aluminum MMC product forms with directional properties needed for some high-performance applications. Cross rolling of sheet establishes a more planar whisker alignment, producing a two-dimensional isotropy. The mechanical properties of whisker-reinforced aluminum MMCs are superior to particle-reinforced composites at any common volume fraction (Fig. 5).

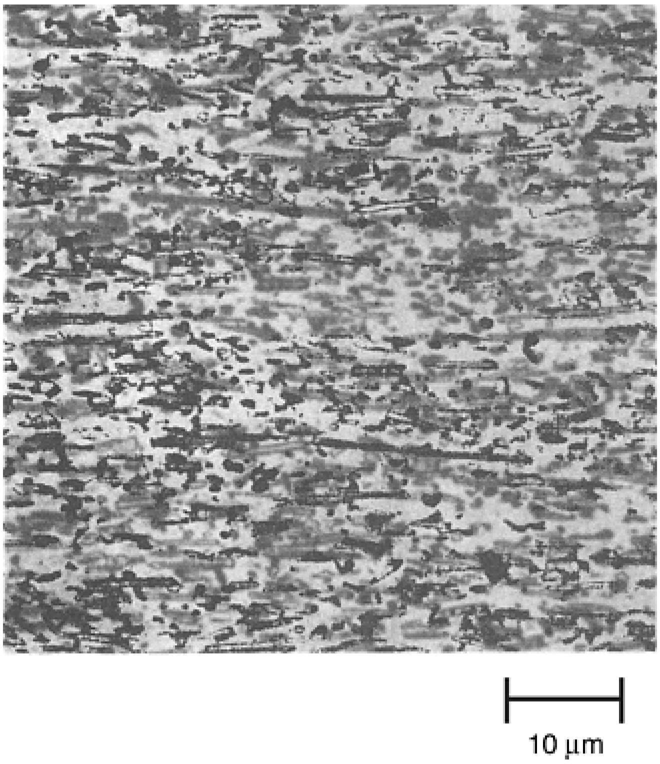

Fig. 4 SiC whisker-reinforced (20 vol% SiC) aluminum alloy sheet with the whiskers aligned in the direction of rolling

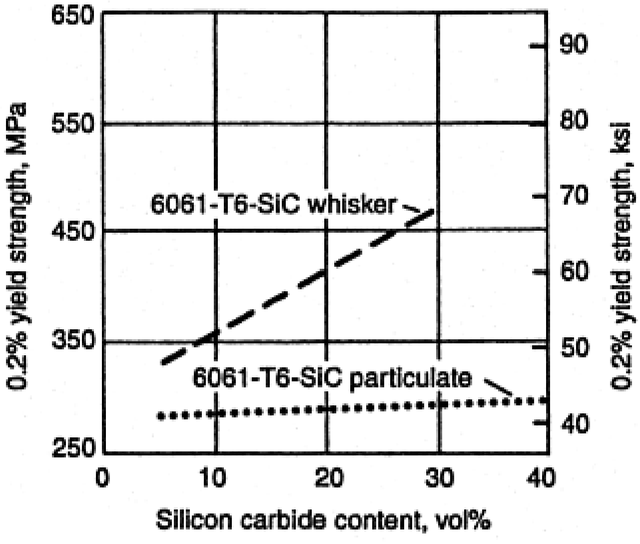

Fig. 5 Yield strength comparison between whisker- and particulate-reinforced aluminum MMCs

Powder metallurgy methods involving cold pressing and sintering, or hot pressing, to produce MMCs are shown in Fig. 6 and 7 (Ref 48, 49, and 50). The matrix and the reinforcement powders are blended to produce a homogeneous distribution. The blending stage is followed by cold pressing to produce what is called a *green body*, which is about 80% dense and can be easily handled. The cold pressed green body is canned in a sealed container and degassed to remove any absorbed moisture from the particle surfaces. The final step is hot pressing, uniaxial or isostatic, to produce a fully dense composite. The hot pressing temperature can be either below or above that of the matrix alloy solidus.

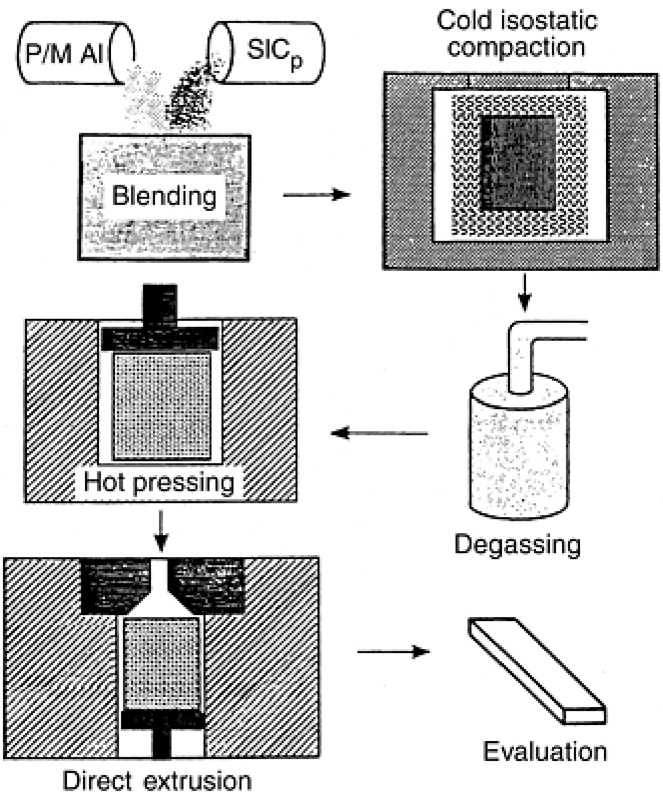

Fig. 6 Schematic interpretation of the processing route for P/M Al-SiC$_p$ composites. Source: Ref 48

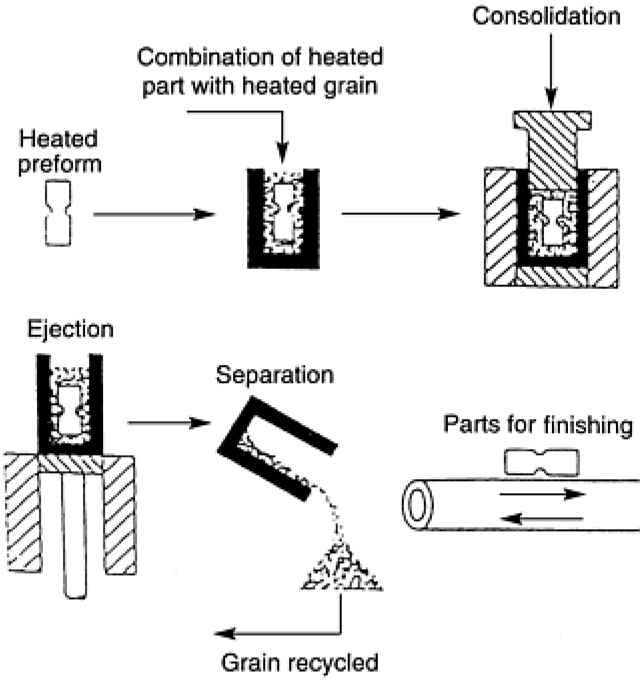

Fig. 7 Schematic illustration of the Ceracon technique for fabricating P/M MMCs. Source: Ref 49, 50

The P/M hot pressing technique generally produces properties superior to those obtained by casting and by liquid metal infiltration (squeeze casting) techniques. Because no melting and casting are involved, the powder process for MMCs is more economical than many other fabrication techniques and offers several advantages, including the following:

- A lower temperature can be used during preparation of a P/M-based composite compared to preparation of a fusion metallurgy-based composite. This results in less interaction between the matrix and the

reinforcement, consequently minimizing undesirable interfacial reactions, which leads to improved mechanical properties.

- The preparation of particulate- or whisker-reinforced composites is, generally speaking, easier using the P/M blending technique than it is using the casting technique.

This method is popular because it is reliable compared with alternative methods, but it also has some disadvantages. The blending step is a time-consuming, expensive, potentially dangerous operation. In addition, it is difficult to achieve an even distribution of particulate throughout the product, and the use of powders requires a high level of cleanliness, otherwise inclusions will be incorporated into the product with a deleterious effect on fracture toughness and fatigue life.

Processing of Continuous Fiber-Reinforced Aluminum

As shown in Fig. 1, aluminum MMCs reinforced with continuous fibers provide the highest performance/strength. Because of their high cost, however, most applications have been limited to the aerospace industry.

Aluminum-boron is a technologically mature continuous fiber MMC (Fig. 8). Applications for this composite include tubular truss members in the midfuselage structure of the space shuttle orbiter and cold plates in electronic microchip carrier multilayer boards. Fabrication processes for aluminum-boron composites are based on hot press diffusion bonding of alternating layers of aluminum foil and boron fiber mats (foil-fiber- foil processing) or plasma spraying methods.

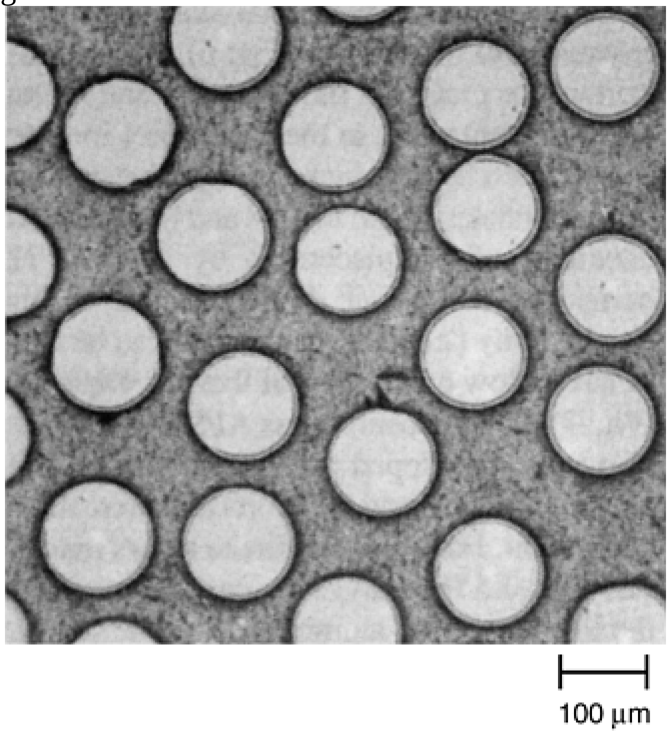

Fig. 8 Cross section of a continuous fiber-reinforced aluminum-boron composite. Shown here are 142 μm diam boron filaments coated with B_4C in a 6061 aluminum alloy matrix.

Continuous SiC fibers are often used as replacements for boron fibers, because they have similar properties (e.g., a tensile modulus of 400 GPa, or 60×10^6 psi) and offer a cost advantage. One such SiC fiber is the SCS series, which can be manufactured with any of several surface chemistries to enhance bonding with a particular matrix, such as aluminum or titanium.

Hot molding is a low-pressure, hot pressing process designed to fabricate Al-SiC parts at significantly lower cost than is possible with a diffusion-bonding/solid-state process. Because the SCS-2 fibers can withstand molten aluminum for long periods, the molding temperature can be raised into the liquid-plus-solid region of

the alloy to ensure aluminum flow and consolidation at low pressure, thereby eliminating the need for high-pressure die molding equipment.

The hot molding process is analogous to the autoclave molding of graphite/epoxy, in which components are molded in an open-faced tool. The mold in this case is a self-heating, slip cast ceramic tool that contains the profile of the finished part. A plasma-sprayed aluminum preform is laid into the mold, heated to near molten aluminum temperature, and pressure-consolidated in an autoclave by a metallic vacuum bag.

Aluminum-SiC MMCs exhibit increased strength and stiffness as compared with unreinforced aluminum, with no weight penalty. In contrast to the base metal, the composite retains its room-temperature tensile strength at temperatures up to 260 °C (500 °F).

Aluminum-graphite MMC development was initially prompted by the commercial appearance of strong and stiff carbon fibers in the 1960s. Carbon fibers offer a range of properties, including an elastic modulus up to 966 GPa (140×10^6 psi) and a negative CTE down to $–1.62 \times 10^{-6}$/°C ($–0.9 \times 10^{-6}$/°F). However, carbon and aluminum in combination are difficult materials to process into a composite. A deleterious reaction between carbon and aluminum, poor wetting of carbon by molten aluminum, and oxidation of the carbon are significant technical barriers to the production of these composites. Two processes are currently used for making commercial aluminum MMCs: liquid metal infiltration of the matrix on spread tows and hot press bonding of spread tows sandwiched between sheets of aluminum. With both precursor wires and metal- coated fibers, secondary processing, such as diffusion bonding or pultrusion, is needed to make structural elements. Squeeze casting also is feasible for the fabrication of this composite. Precision aerospace structures with strict tolerances on dimensional stability need stiff, lightweight materials that exhibit low thermal distortion. Aluminum-graphite MMCs have the potential to meet these requirements. Unidirectional P100 Gr/6061 aluminum pultruded tube exhibits an elastic modulus in the fiber direction significantly greater than that of steel, and it has a density approximately one-third that of steel.

Aluminum-Al_2O_3 MMCs can be fabricated by a number of methods, but liquid or semi-solid- state processing techniques are commonly used. A fiber-reinforced aluminum MMC is now used in pushrods for high-performance racing engines. The 3M Company produces the material by infiltrating Nextel 610 (3M Corporation) alumina fibers with an aluminum matrix (fiber volume fraction is 60%). Hollow pushrods of several diameters are made, where the fibers are axially aligned along the pushrod length. Hardened steel end caps are bonded to the ends of the MMC tubes. Additional information is available in the article “Automotive Applications of Metal-Matrix Composites” in this Volume.

Diffusion Bonding and Filament Winding. Fabrication of complex-shaped components is commonly achieved by diffusion bonding of monolayer composite tapes. The tapes may be prepared by a number of methods, but the most commonly used is filament winding, where the matrix is incorporated in a sandwich construction by laying up thin metal sheets between filament rows or by the arc spraying technique developed by the National Aeronautics and Space Administration (NASA) Lewis (now NASA Glenn) Research Center. In the latter process, molten matrix alloy droplets are sprayed onto a cylindrical drum wrapped with fibers. The operation is carried out in a controlled atmosphere chamber to avoid problems of oxidation and corrosion. The drum is rotated and passed in front of an arc spray head to produce a controlled porosity monotape. When lamination of the fibers between matrix alloy sheets is adopted to produce the monotape, a binder is used to hold the fibers in place prior to consolidation. This technique can also be combined with consolidation by hot isostatic pressing (HIP). Filament winding and monotape lay-up into multiple layers permit close control over the position and orientation of the fibers in the final composite.

A combination of the arc spray technique and diffusion bonding using SCS-6 SiC monofilament fibers was used to produce composites for various prototype applications in the aerospace and defense sectors of the market. In one example, a rocket motor shell was produced by filament winding of SCS-6 fibers and plasma spraying with an aluminum alloy. The rocket motor was reported to have been successfully fired and to have withstood the extreme temperatures, pressures, and vibrations associated with missile firing. In addition, the assembled motor, using the MMC shell, weighed about 10% less than a conventional steel motor.

Processing of Discontinuously Reinforced Titanium

Since the late 1980s, the unique benefits of the solid-phase processing of P/M titanium alloys have been used in the development of discontinuously reinforced titanium-matrix composites. For example, titanium carbide and titanium diboride powders have been added to both commercially pure titanium and the common titanium alloys using the blended elemental (BE) technique (Ref 51, 52, 53, 54, and 55). The BE technique is a pressing and sintering P/M technique. It involves cold pressing or cold isostatic pressing a blend of fine elemental titanium and master alloy powders that have been sintered. Ceramic particles are included in the blend to produce particulate- reinforced metal-matrix composites (PR- MMCs); the reinforcements provide improved wear resistance, elastic modulus, creep, fatigue, and corrosion properties with less than a 3% change in alloy density. Elongation and, to a lesser extent, fracture toughness decrease in the trade-off. The following examples typify several titanium PR-MMCs, both in current production and under development; however, it should be noted that most of these examples are research projects and have not achieved commercial use.

Among the first titanium-base PR-MMC materials introduced to the commercial market was CermeTi-C (Dynamet Technology Inc.). These composites are created by the BE technique with the addition of titanium carbide (TiC) to prominent titanium alloys, such as Ti-6Al-4V and Ti- 6Al-6V-2Sn. The titanium alloy matrix is formed during sintering by diffusion-driven solid-state alloying, typically at temperatures less than 250 °C (450 °F) above the β transus, or 1230 °C (2245 °F) for Ti-6Al-4V. As opposed to melt processing, the thermal decomposition of the TiC reinforcing particulate (melting point 3065 °C, or 5550 °F) can be limited to a practical extent during the sintering cycle. The resultant PR- MMC displays improved strength and elastic modulus, reflecting the load-sharing contribution of the tightly-bonded TiC particulate (density of 4.48 g/cm^3, elastic modulus of 145 GPa, or 21 × 10^6 psi, and hardness of 44 HRC) (Ref 56).

From 5 to 20 wt% TiC is added to commonly used titanium alloys. As an alternative to HIP or in addition to HIP operation, hot working (including forging, rolling, and extrusion) further increases the density and mechanical properties of the titanium alloy PR-MMC. The mechanically homogenized particulate distribution and the refined acicular α-β microstructure are retained by air cooling from the forging or extrusion temperature with a commensurate increase in tensile strength and ductility.

The addition of TiB_2 particulate by the BE technique is also done (Ref 57, 58). During normal sintering at 1200 °C (2190 °F), the TiB_2 particulate, in contact with the elemental titanium powder, reacts extensively or completely to form TiB. On cooling, the resultant TiB phase platelets extend beyond the boundaries of the prior titanium particles and bridge multiple α-β colonies.

At the Toyota Central Research and Development Laboratories, Inc., Saito et al. have continued efforts to reduce the cost of BE TiB_2- based PR-MMCs of titanium alloys (Ref 59, 60, 61, 62, 63, 64, and 65). When 5 wt% TiB_2 is added to BE-derived, metastable β matrix, composed of Ti-4.3Fe-7.0Mo- 1.4Al-1.4V, a derivative of Timetal LCB (TIMET, Denver, CO), the resultant 10% TiB_2 reinforcement forms a stable, crystallographically-oriented, coherent interface boundary, increasing the strength, stiffness, hardness, fatigue properties, and heat resistance of the matrix. Deformation flow stress of this material at 700 °C (1290 °F) approximates that of medium carbon steel, aiding producibility. This material is used for automotive engine valves and is the most commercially significant application of titanium PR-MMCs. Additional information is provided in the article “Automotive Applications of Metal-Matrix Composites” in this Volume.

Processing of Continuous Fiber-Reinforced Titanium*

Continuous fiber-reinforced titanium-matrix composites (CF-TMCs) offer the potential for strong, stiff, lightweight materials for usage temperatures as high as 800 to 1000 °C (1500 to 1800 °F). The principal applications for this class of materials would be for hot structure, such as hypersonic airframe structures, and for replacing superalloys in some portions of aerospace engines. The use of CF-TMCs has been somewhat restricted by both the high cost of the materials and the fabrication and assembly procedures.

Foil-Fiber-Foil Process

One method that has been used to fabricate CF-TMCs is the “foil-fiber-foil” method, depicted in Fig. 9. In this method, the silicon-carbide fiber mat (Fig. 10) is held together with a cross weave of molybdenum, titanium, or titanium-niobium wire or ribbon. The fabric is a uniweave system in which the relatively large-diameter SiC monofilaments are straight and parallel and held together by a cross weave of metallic ribbon. The Ti-15V-3Cr-3Sn-3Al foil is normally cold rolled down to a thickness of 0.11 mm (0.0045 in.). The plies are cut, laid up on a consolidation tool, and consolidated by either vacuum hot pressing or HIP.

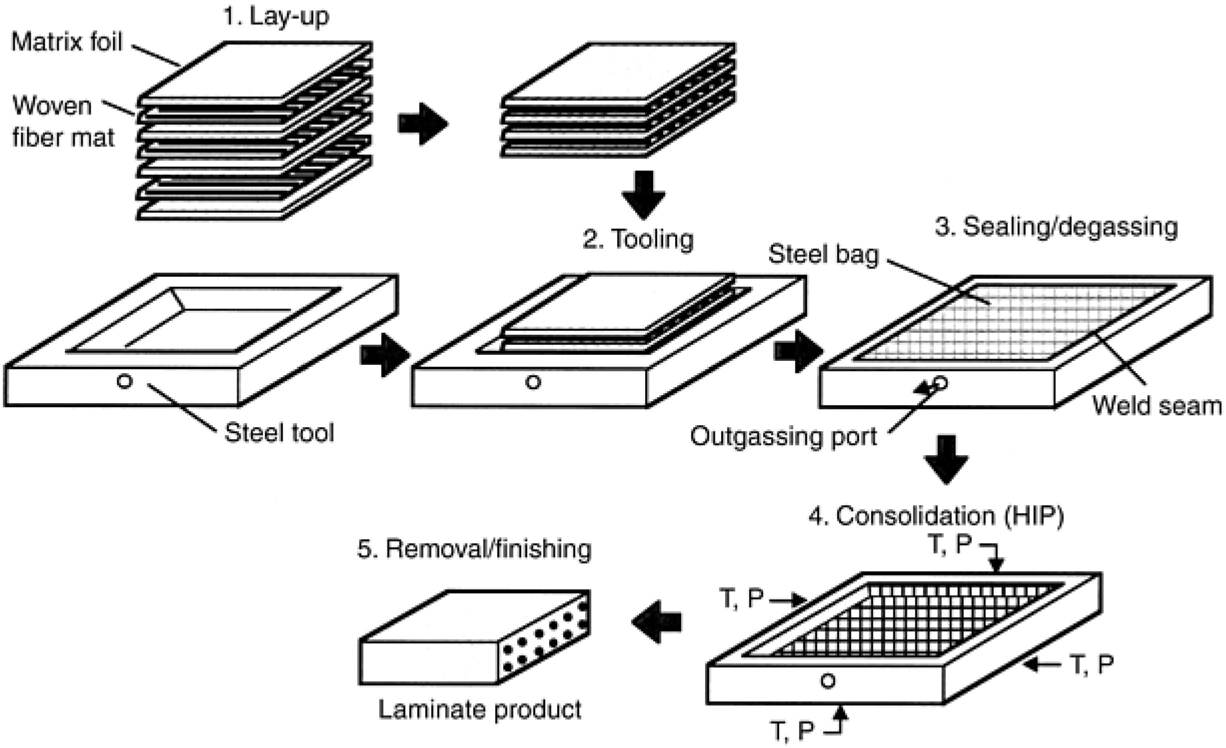

Fig. 9 Foil-fiber-foil method for titanium-matrix composite fabrication. HIP, hot isostatic pressing; P, pressure; T, temperature

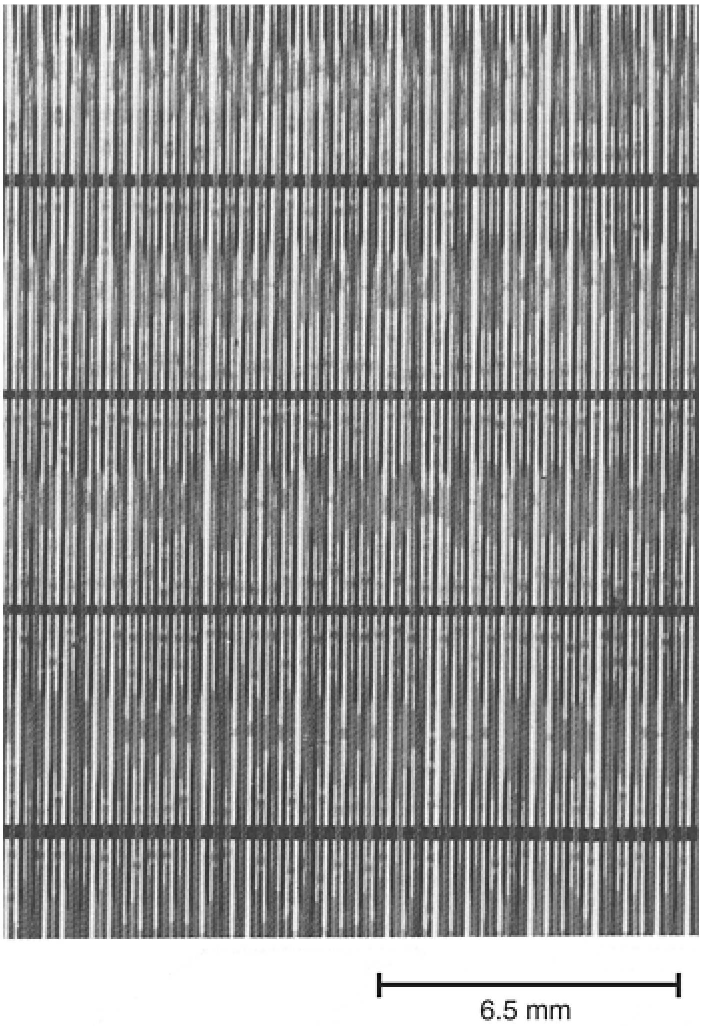

Fig. 10 SiC uniweave fabric showing cross weave

Consolidation Procedures. The two primary consolidation procedures are vacuum hot pressing and HIP. High-temperature/short-time roll bonding was used some years ago, but only to a very limited extent. Typical fiber contents for CF-TMC laminates range from 35 to 40 vol%.

Vacuum Hot Pressing. In the vacuum hot pressing technique, the lay-up is sealed in a stainless steel envelope and placed in a vacuum hot press. After evacuation, a small positive pressure is applied via the press platens. This pressure acts to hold the filaments in place during the initial 450 to 550 °C (800 to 1000 °F) soak used to decompose the binder and remove it under the action of a dynamic vacuum. The temperature is then gradually increased to a level where the titanium flows around the fibers under an increased pressure and the foil interfaces are diffusion bonded together. Each fabricator uses a specific set of consolidation parameters, although a typical range is 900 to 950 °C (1650 to 1750 °F) at 41 to 69 MPa (6 to 10 ksi) pressure for 60 to 90 min.

Hot isostatic pressing has largely replaced vacuum hot pressing as the consolidation technique of choice. The primary advantages of HIP consolidation are that the gas pressure is applied isostatically, alleviating the concern about uneven platen pressure; and the HIP process is much more amenable to making complex structural shapes. Typically, the part to be hot isostatically pressed is canned (or a steel bag is welded to a tool), evacuated, and then placed in the HIP chamber. For titanium, typical HIP parameters are 850 to 950 °C (1600 to 1700 °F) at 103 MPa (15 ksi) gas pressure for 2 to 4 h. Since HIP processing is a fairly expensive batch processing procedure, it is normal practice to load a number of parts into the HIP chamber for a single run.

Green Tape Process

Another method for making CF-TMCs involves placing a layer of titanium foil on a mandrel and filament winding the silicon-carbide fiber over the foil in a collimated manner, as to produce a unidirectional single ply. An organic fugitive binder, such as an acrylic adhesive, is used to maintain the fiber spacing and alignment

once the preform is cut from the mandrel. In this method (Fig. 11), often called the "green tape" method, the fibers are normally wound onto a foil-covered rotating drum, oversprayed with resin, and the layer cut from the drum to provide a flat sheet of monotape. The organic binder is "burned off" prior to the HIP cycle or during the early portions of the vacuum hot pressing cycle.

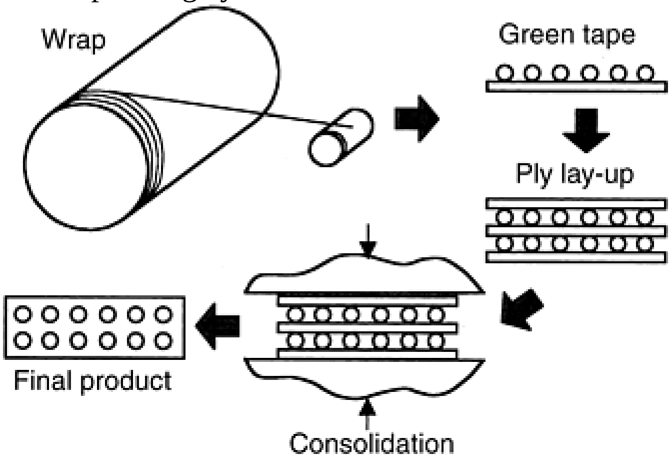

Fig. 11 Green tape method for titanium-matrix composite fabrication

Plasma spraying replaces the resin binder with a plasma-sprayed matrix. Plasma spraying removes the potential of an organic residue causing contamination problems during the consolidation cycle and speeds the process by not having to outgas an organic binder. One potential disadvantage of plasma spraying is that titanium, being an extremely reactive metal, can pick up oxygen from the atmosphere, potentially leading to embrittlement problems. This method has been primarily evaluated for titanium-aluminide- matrix composites, due to the difficulty of rolling these materials into thin foil.

Metal Wire Process

A CF-TMC manufactured by a novel metal wire process has been developed to replace stainless steel in a piston actuator rod in Pratt and Whitney F119 engine for the F-22 aircraft. A Ti- 6Al-2Sn-4Zr-2Mo (Ti-6242) alloy is hot drawn in a conventional wire drawing process to a diameter of 178 μm (0.007 in.). The Trimarc-1 SiC monofilament reinforcement is 129 μm (5.07×10^{-3} in.) in diameter and is produced by a chemical vapor deposition process on a tungsten wire core. An outer carbon-base coating protects the fiber from chemical interaction with the matrix during consolidation and service. The Ti-6242 metal wire is combined with 34 vol% of the SiC monofilament by wrapping on a rotating drum. The wires are held together with an organic binder and are then cut and removed from the drum to make a preform "cloth." This cloth is wrapped around a solid titanium mandrel, so that the SiC and Ti-6242 wires are parallel to the long axis of the mandrel. A short Ti-6242 cylinder, with an outer diameter of 10 cm (4 in.) and 5 cm (2 in.) high, is placed around one end of the cloth-wrapped mandrel, from which the piston head will be formed. After HIP consolidation, the piston head is machined from the stocky cylinder at one end of the piston, and a threaded connection is machined from the titanium mandrel at the other end. The remainder of the mandrel is removed by gun drilling. The final component is 30.5 cm (12 in.) long, and the shaft is 3.79 cm (1.49 in.) in diameter (see Fig. 6a in the article "Aeronautical Applications of Metal-Matrix Composites" in this Volume). The use of a titanium-matrix composite in the actuator piston is a landmark application and represents the first production aerospace application of TMCs.

Based on the experience gained from the success of the TMC actuator piston rod, TMCs have been certified as nozzle links on the General Electric F110 engine, which is used for F-16 aircraft. The original link was produced from a square tube of Inconel 718, which was formed from sheet and welded along it length. The manufacturing process for the TMC nozzle links begins by winding Trimarc-2 SiC monofilament, which is similar to Trimarc-1 but is produced on a carbon core, on a drum as for the piston rod. Rather than using metal wire, Ti-6242 powder is sprayed with an organic binder over the wound SiC fibers to produce a preform cloth. This cloth is then cut and removed from the drum, as before, and wrapped around a mandrel. Ti-6242 fittings are added at each end for a clevis attachment and a threaded end, and the entire assembly is consolidated via HIP. After machining the clevis and the threaded end, the mandrel is removed. (A finished part is shown as Fig. 6b in the article "Aeronautical Applications of Metal- Matrix Composites" in this Volume.)

Processing of Other Metal-Matrix Composites

In addition to aluminum and titanium, several other metals and alloys have been investigated as matrix alloys for MMCs. This section describes work done to develop magnesium, copper, and superalloy MMCs. These MMCs have found only limited commercial application to date.

Magnesium-Matrix Composites

Magnesium-matrix composites are being developed to exploit essentially the same properties as those provided by aluminum MMCs: high stiffness, light weight, and low CTE. In practice, the choice between aluminum and magnesium as a matrix is usually made on the basis of weight versus corrosion resistance. Magnesium is approximately two-thirds as dense as aluminum, but it is more active in a corrosive environment. Magnesium has a lower thermal conductivity, which is sometimes a factor in its selection. Magnesium MMCs include continuous fiber graphite/magnesium for space structures, short staple fiber Al_2O_3/Mg for automotive engine components, and discontinuous SiC or B_4C/Mg for engine components and low-expansion electronic packaging materials. Matrix alloys include AZ31, AZ91, ZE41, QE22, and EZ33. Processing methods parallel those used for the aluminum MMC counterparts.

Copper-Matrix Composites

Copper-matrix composites have been produced with continuous tungsten, silicon carbide, and graphite-fiber reinforcements. Of the three composites, continuous graphite/copper MMCs have been studied the most.
Interest in continuous graphite/copper MMCs gained impetus from the development of advanced graphite fibers. Copper has good thermal conductivity, but it is heavy and has poor elevated-temperature mechanical properties. Pitch- based graphite fibers have been developed that have room-temperature axial thermal conductivity properties better than those of copper. The addition of these fibers to copper reduces density, increases stiffness, raises the service temperature, and provides a mechanism for tailoring the CTE. One approach to the fabrication of graphite/copper MMCs uses a plating process to envelop each graphite fiber with a pure copper coating, yielding MMC fibers flexible enough to be woven into fabric. The copper-coated fibers must be hot pressed to produce a consolidated component. Graphite/copper MMCs have the potential to be used for thermal management of electronic components, satellite radiator panels, and advanced airplane structures.

Superalloy-Matrix Composites

In spite of their poor oxidation resistance and high density, refractory metal (tungsten, molybdenum, and niobium) wires have received a great deal of attention as fiber-reinforcement materials for use in high-temperature superalloy MMCs. Although the theoretical specific strength potential of refractory alloy fiber-reinforced composites is less than that of ceramic fiber-reinforced composites, the more ductile metal-fiber systems are more tolerant of fiber-matrix reactions and thermal expansion mismatches. When refractory metal fibers are used to reinforce a ductile and oxidation-resistant matrix, they are protected from oxidation, and the specific strength of the composite is much higher than that of superalloys at elevated temperatures.

Fabrication of superalloy MMCs is accomplished via solid-phase, liquid-phase, or deposition processing. The methods include investment casting, the use of matrix metals in thin sheet form, the use of matrix metals in powder sheet form made by rolling powders with an organic binder, P/M techniques, slip casting of metal alloy powders, and arc spraying.

Processing of Ceramic-Matrix Composites

K.K. Chawla, University of Alabama at Birmingham; N. Chawla, Arizona State University

Introduction

CERAMIC-MATRIX COMPOSITES (CMCs) have ability to withstand high temperatures and have superior damage tolerance over monolithic ceramics (Ref 1, 2). A significant hurdle in realizing the full potential of CMCs, however, has been in the area of processing and manufacturability. Ceramic-matrix composites can be processed either by conventional powder processing techniques, used to process polycrystalline ceramics, or by newer techniques developed specifically for CMCs. Several of the most important or promising techniques are summarized in Table 1. In this article, the term “ceramic” encompasses crystalline ceramics, glass-ceramics, and amorphous materials, such as silica-based glasses. Some of the important processing techniques for CMCs are described, and the advantages and disadvantages of each technique are highlighted to provide a comprehensive understanding of the achievements and challenges that remain in this area.

Table 1 Summary of CMC fabrication processes and examples of typical composite systems fabricated by these processes

Process	Examples
Slurry infiltration (ply stacking and hot pressing)	**SiC/glass ceramic, carbon/glass-ceramic, C/glass, mullite/glass**
Powder processing and hot pressing	**SiC/Al_2O_3, Al_2O_3/Al_2O_3**
Gas-liquid metal reaction (Lanxide)	**SiC/Al_2O_3, SiC/SiC**
Sol-gel (infiltration and sintering/hot pressing)	**C/glass, mullite/mullite**
Chemical vapor infiltration (infiltration of a woven	**SiC/SiC, C/SiC**

preform)	
Polymer conversion (infiltration and pyrolysis)	**C/C, C/SiC, SiC/Si-C-N**

Cold Pressing and Sintering

Cold pressing of a matrix powder and fiber mixture followed by sintering is a natural extension from conventional processing of ceramics. Shrinkage is a common problem associated with sintering of most ceramics. This problem is exacerbated when a glass-or ceramic-matrix is combined with a reinforcement material. Thus, after sintering the matrix generally shrinks considerably, and the resulting composite exhibits a significant amount of cracking. One of the reasons for high shrinkage after sintering is that fibers and whiskers—that is, reinforcements with high aspect ratio (length/diameter)—can form a network that may inhibit the sintering process. Depending on the difference in thermal expansion coefficients of the reinforcement and matrix, a hydrostatic tensile stress can develop in the matrix on cooling, which will counter the driving force (surface energy minimization) for sintering (Ref 3, 4). Thus the densification rate of the matrix will, in general, be retarded in the presence of reinforcement (Ref 5, 6, 7, 8, and 9).

Hot Pressing

Hot pressing is frequently used in a combination of steps or in a single step in the consolidation stage of CMCs. Hot pressing is an attractive technique because the simultaneous application of pressure and high temperature can significantly accelerate the rate of densification, resulting in a pore-free and fine-grained compact. An example of a common hot-pressed composite is silicon carbide (SiC) whisker-reinforced Al_2O_3, used in cutting tool applications.

A common variant of conventional hot pressing is the slurry infiltration process. It is perhaps the most important technique used to produce continuous fiber reinforced glass and glass-ceramic composites (Ref 10, 11, 12, 13, and 14). The slurry infiltration process involves two main stages: (1) incorporation of the reinforcing phase into a “slurry” of the unconsolidated matrix and (2) matrix consolidation by hot pressing.

Figure 1 shows a schematic of the slurry infiltration process. The first stage involves some degree of fiber alignment, in addition to incorporation of the reinforcing phase in the matrix slurry. The slurry typically consists of the matrix powder, a carrier liquid (water or alcohol), and an organic binder. The organic binder is burned out prior to consolidation. Wetting agents may be added to ease the infiltration of the fiber tow or preform. The fiber tow or fiber preform is impregnated with the matrix slurry by passing it through a slurry tank. The impregnated fiber tow or preform sheets are similar to the prepregs used in fabrication of polymer-matrix composites (PMCs) (Ref 2). The impregnated tow or prepreg is wound on a drum and dried. This is followed by cutting and stacking of the prepregs and consolidation by hot pressing. The process has the advantage that, just as in PMCs, the prepregs can be arranged in a variety of stacking sequences, for example, unidirectional, cross-plied (0°/90°/ 0°/90°, etc.), or angle-plied (+θ/–θ/+θ/–θ, etc.). Figure 2(a) shows an optical micrograph of a transverse section of a unidirectional alumina- fiber/glass-matrix composite (some residual porosity can be seen in this micrograph), while Fig. 2(b) shows the pressure and temperature schedule used during hot pressing of this composite.

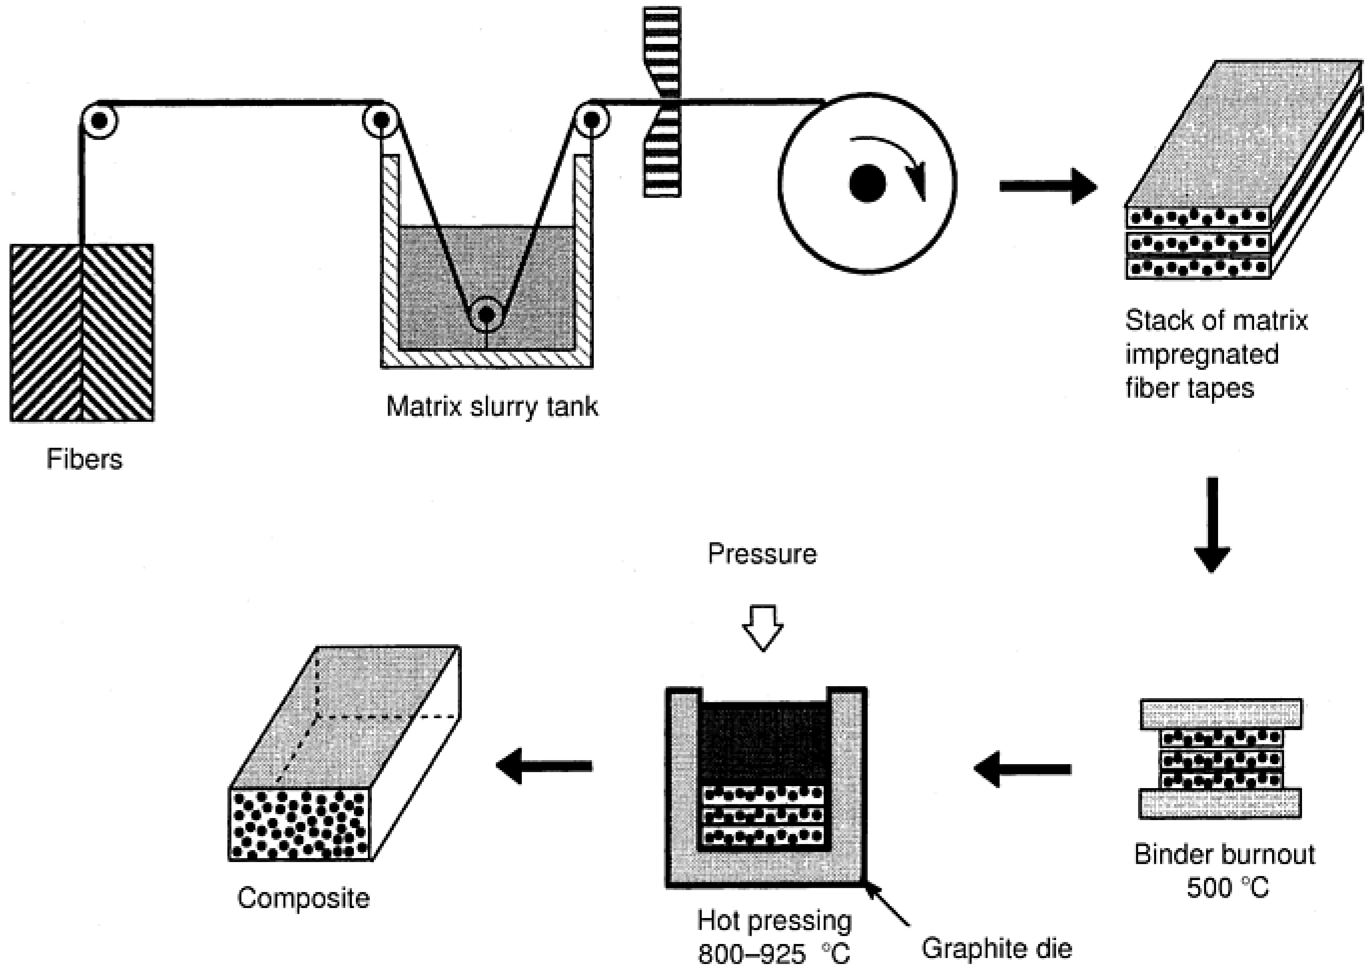

Fig. 1 Schematic of the slurry infiltration process followed by hot pressing

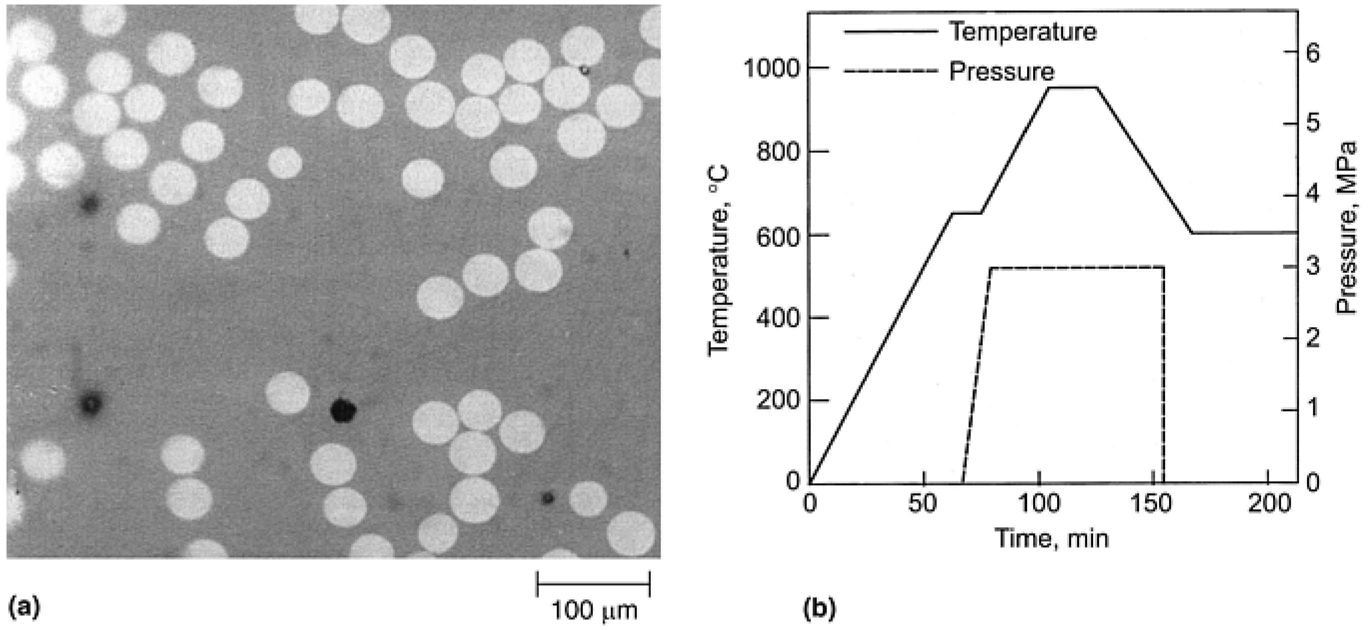

Fig. 2 Unidirectional alumina-fiber/glass-matrix composite formed by slurry infiltration followed by hot pressing. (a) Light micrograph of transverse section (some porosity can be seen in this micrograph). (b) Pressure and temperature schedule used during hot pressing of this composite

As mentioned above, the slurry infiltration process is well suited for glass- or glass-ceramic- matrix composites, mainly because the processing temperatures for these materials are lower than those used for crystalline-matrix materials. The hot-pressing process does have the limitation of not being able to produce complex shapes.

Application of a very high pressure during hot pressing can also easily damage the fibers and decrease the strength of the composite. The fibers may also be damaged by mechanical contact with refractory particles of a crystalline ceramic or from reaction with the matrix at very high processing temperatures. The matrix should have as little porosity as possible in the final product, as porosity in a structural ceramic material is highly undesirable. To this end, it is important to completely remove the fugitive binder and use a matrix powder particle smaller than the fiber diameter. The hot-pressing operational parameters are also important. Precise control within a narrow working temperature range, minimization of the processing time, and utilization of a pressure low enough to avoid fiber damage are important factors in this final consolidation part of the process. Fiber damage and any fiber/matrix interfacial reaction, along with its detrimental effect on the bond strength, are unavoidable attributes of the hot pressing operation.

In summary, the slurry infiltration process generally results in a composite with fairly uniform fiber distribution, low porosity, and relatively high strength. The main disadvantage of this process is that one is restricted to relatively low-melting or low-softening point matrix materials.

Whisker reinforced CMCs are generally made by mixing the whiskers with a ceramic powder slurry, dried, and hot pressed. Sometimes hot isostatic pressing (HIP) rather than uniaxial hot pressing is used. Whisker agglomeration in a green body is a major problem; mechanical stirring and adjustment of pH level of the suspension (matrix powder/whiskers in water) can help minimize this. Addition of whiskers to a slurry can result in very high viscosity. Also, whiskers with large aspect ratios (>50) tend to form bundles and clumps (Ref 15). Obtaining well-separated and deagglomerated whiskers is of great importance for reasonably high-density composites. Use of organic dispersants (Ref 16) and techniques such as agitation mixing assisted by an ultrasonic probe and deflocculation by a proper pH control (Ref 17) can be usefully employed.

Most whisker-reinforced composites are made at temperatures in the 1500 to 1900 °C (2730–3450 °F) range and pressures in the 20 to 40 MPa (3–6 ksi) range (Ref 18, 19). Figure 3 shows a scanning electron micrograph of a hybrid composite, consisting of SiC fibers (Nicalon) and whiskers in a glass-ceramic-matrix (Ref 20).

Reaction-Bonding Processes

Reaction-bonding processes similar to the ones used for monolithic ceramics can also be used to make ceramic-matrix composites. These have been used mostly with silicon carbide or silicon nitride matrices. The other advantages are:

- Little or no matrix shrinkage occurs during densification.
- Large volume fractions of whiskers or fiber can be used.
- Multidirectional, continuous fiber preforms can also be used.
- The reaction-bonding temperatures for most systems are generally lower than the sintering temperatures, so that fiber degradation can be avoided.

One great disadvantage of this process is that high porosity is hard to avoid.

A hybrid process involving a combination of hot pressing with the reaction-bonding technique can also be used (Ref 21, 22). Figure 4 shows the flow diagram for this process (Ref 22), while Fig. 5 shows a micrograph of a composite (SCS- 6 fiber/ Si_3N_4) made by this process (Ref 23). Silicon cloth is prepared by attrition milling a mixture of silicon powder, a polymer binder, and an organic solvent to obtain a "dough" of proper consistency. This dough is then rolled to make a silicon cloth of desired thickness. Fiber mats are made by filament winding of silicon carbide with a fugitive binder. The fiber mats and silicon cloth are stacked in an alternate sequence, debinderized, and hot pressed in a molybdenum die and in a nitrogen or vacuum environment. The temperature and pressure are adjusted to produce a handleable preform. At this stage, the silicon matrix is converted to silicon nitride by transferring the composite to a nitriding furnace between 1100 and 1400 °C (2010 and 2550 °F). Typically, the silicon nitride matrix has about 30% porosity, which is not unexpected in reaction-bonded silicon nitride. Note also the matrix-density variations around fibers in Fig. 5.

Infiltration

Infiltration of a preform made of a reinforcement can be done with a matrix material in solid (particulate), liquid, or gaseous form. Liquid Infiltration is very similar to liquid polymer or liquid metal infiltration (Fig. 6). Proper control of the fluidity of liquid matrix is, of course, the key to this technique. It yields a high-density matrix, that is, no pores in the matrix. Almost any reinforcement geometry can be used to produce a virtually flaw-free composite. The temperatures involved, however, are much higher than those encountered in polymer or metal processing. Processing at such high temperatures can lead to deleterious chemical reactions between the reinforcement and the matrix. Thermal expansion mismatch between the reinforcement and the matrix, the rather large temperature interval between the processing temperature and room temperature, and the low strain to failure of ceramics can add up to a formidable set of problems in producing a crackfree CMC. Viscosities of ceramic melts are generally very high, which makes the infiltration of preforms rather difficult. Wettability of the reinforcement by the molten ceramic is another item to be considered. Hillig (Ref 24) has discussed the melt

infiltration processing of ceramic-matrix composites in regard to chemical reactivity, melt viscosity, and wetting of the reinforcement by the melt. A preform made of reinforcement in any form (for example, fiber, whisker, or particle) having a network of pores can be infiltrated by a ceramic melt by using capillary pressure. Application of pressure or processing in vacuum can aid in the infiltration process.

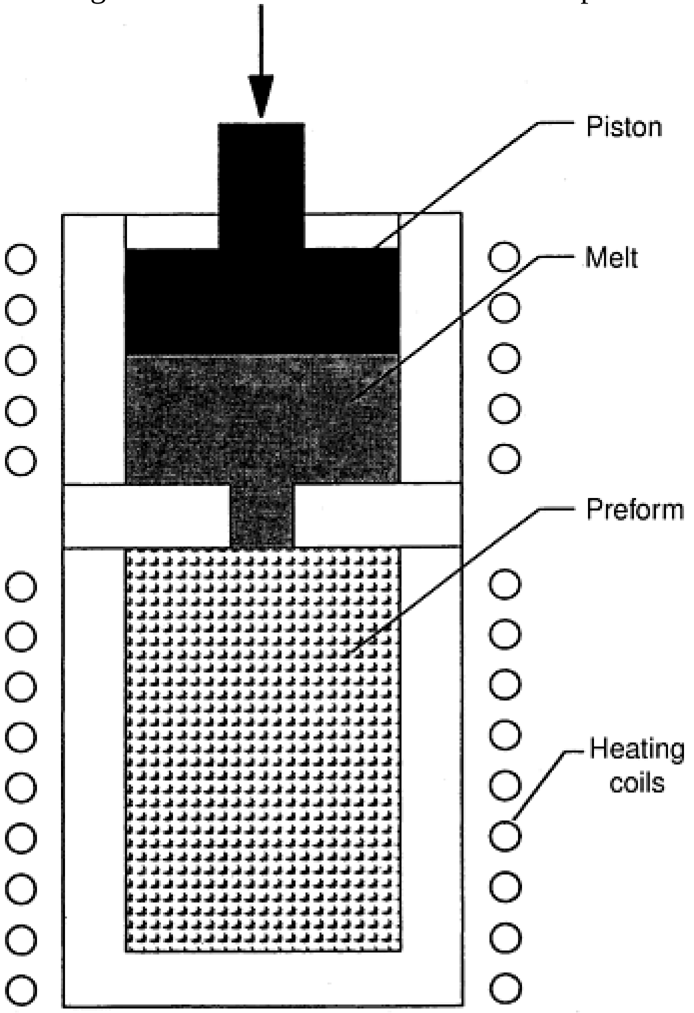

Fig. 6 Schematic of liquid infiltration processing. The technique is very similar to liquid polymer or liquid metal infiltration

Assuming that the preform consists of a bundle of regularly spaced, parallel channels, one can use Poissuelle's equation to obtain the infiltration height, *h*:

$$h = \sqrt{\frac{\gamma r t \cos\theta}{2\eta}}$$

where *r* is the radius of the cylindrical channel, *t* is the time, γ is the surface energy of the infiltrant, θ is the contact angle, and η is the viscosity. Note that the penetration height is proportional to the square root of time and inversely proportional to the viscosity of the melt. Penetration will be easier if the contact angle is low (i.e., better wettability), and the surface energy (γ) and the pore radius (*r*) are large. However, if the radius of the channel is made too large, the capillarity effect will be lost.

The advantages and disadvantages of different melt infiltration techniques can be summarized:

Advantages

- The matrix is formed in a single processing step.
- A homogeneous matrix can be obtained.

Disadvantages

- High melting points of ceramics mean a greater likelihood of reaction between the melt and the reinforcement.
- Ceramics have higher melt viscosities than metals; therefore, infiltration of preforms is relatively difficult.
- Matrix cracking is likely because of the differential shrinkage between the matrix and the reinforcement on solidification. This can be minimized by choosing components with nearly equal coefficients of thermal expansion.

Directed Oxidation (Lanxide) Process

A version of liquid infiltration is the directed oxidation process, or Lanxide process (Lanxide is a trademark of Advanced Materials Lanxide LLC, Newark, DE) (Ref 25). A schematic of the directed metal oxidation process called DIMOX is shown in Fig. 7. The first step in this process is to make a preform. In the case of a fibrous composite, filament winding or a fabric lay-up may be used to make a preform. A barrier to stop growth of the matrix material is placed on the preform surfaces. In this method, a molten metal is subjected to directed oxidation, that is, the desired reaction product forms on the surface of the molten metal and grows outward. The metal is supplied continuously at the reaction front by a wicking action through channels in the oxidation product. For example, molten aluminum in air will get oxidized to aluminum oxide. If one wants to form aluminum nitride, then molten aluminum is reacted with nitrogen. The reaction can be represented as:

$$Al + air \rightarrow Al_2O_3$$

$$Al + N_2 \rightarrow AlN$$

The end product in this process is a three-dimensional, interconnected network of a ceramic composite plus about 5 to 30% of unreacted metal. When filler particles are placed next to the molten metal surface, the ceramic network forms around these particles. As mentioned previously, a fabric made of a continuous fiber can also be used. The fabric is coated with a proprietary coating to protect the fiber from highly reducing aluminum and to provide a weak interface, which is desirable for enhanced toughness. Some aluminum (6–7 wt%) remains at the end of the process. This must be removed if the composite is to be used at temperatures above the melting point of aluminum (660 °C, or 1220 °F). On the other hand, the presence of a residual metal can be exploited to provide some fracture toughness in these composites.

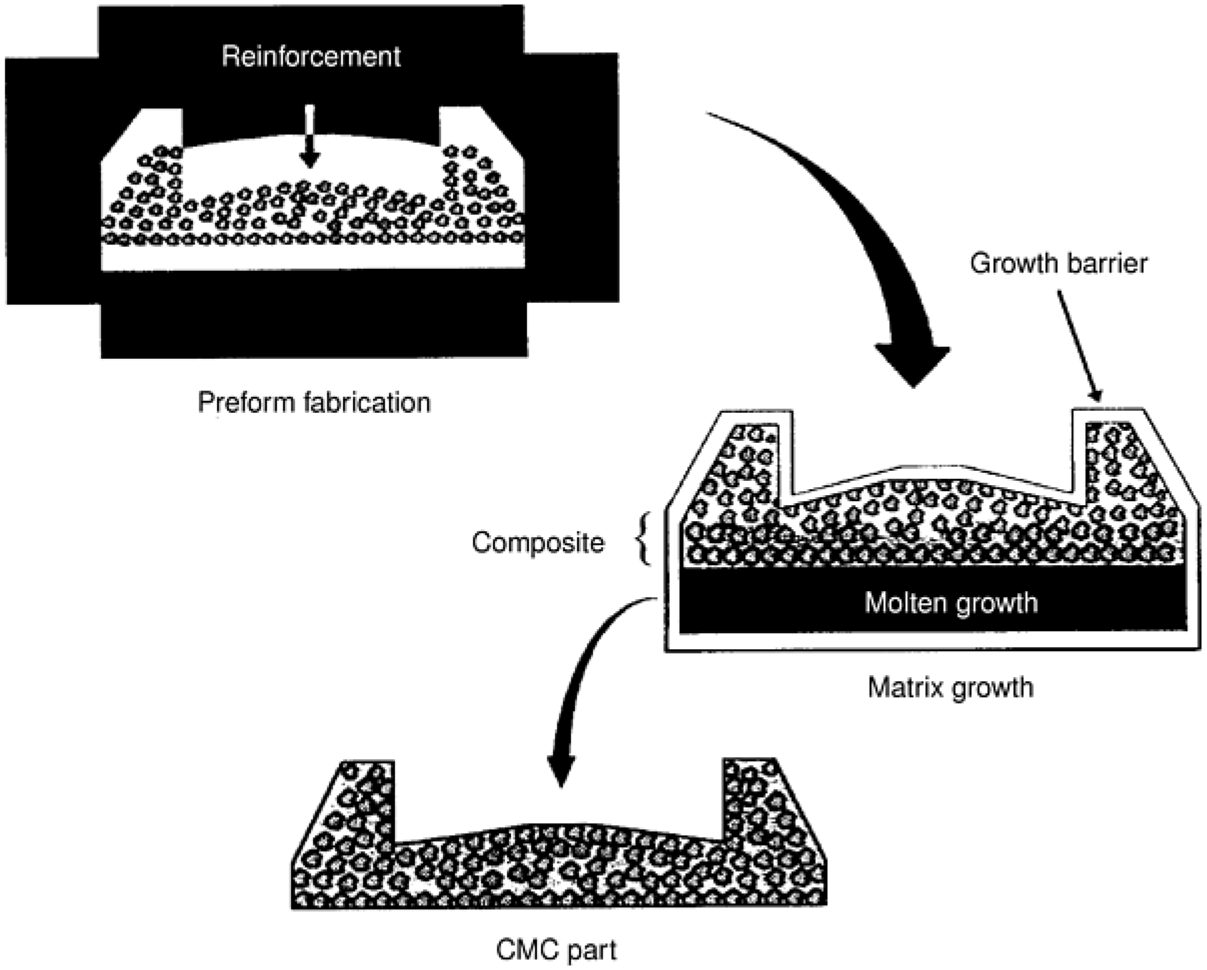

Fig. 7 Schematic of the directed metal oxidation (DIMOX) process. Courtesy of Lanxide Corporation

Proper control of the reaction kinetics is of great importance in this process. The process is potentially a low-cost process because near-net shapes are possible. Also, good mechanical properties (strength, toughness, etc.) have been reported (Ref 25). The main disadvantages of this process are:

- It is difficult to control the chemistry and produce an all-ceramic matrix by this method. There is always some residual metal that is not easy to remove completely.
- It is difficult to envision the use of such techniques for large, complex parts, such as those required, for aerospace applications.

In Situ Chemical Reaction Techniques

In situ chemical reaction techniques to produce CMCs are extensions of those used to produce monolithic ceramic bodies. The most important methods are chemical vapor infiltration (CVI) and different types of reaction-bonding techniques.

Chemical Vapor Infiltration (CVI). When chemical vapor deposition (CVD) is used for infiltration of rather large amounts of matrix material in fibrous preforms, it is called chemical vapor infiltration (CVI). Common ceramic-matrix materials used are SiC, Si_3N_4, and HfC. The CVI method has been successfully employed by several researchers to impregnate fibrous preforms (Ref 26, 27, 28, 29, and 30). The preforms can consist of yarns, woven fabrics, or three-dimensional shapes. Figure 8 shows a filament-wound Nicalon tube and a braided Nextel tube before CVI and after CVI.

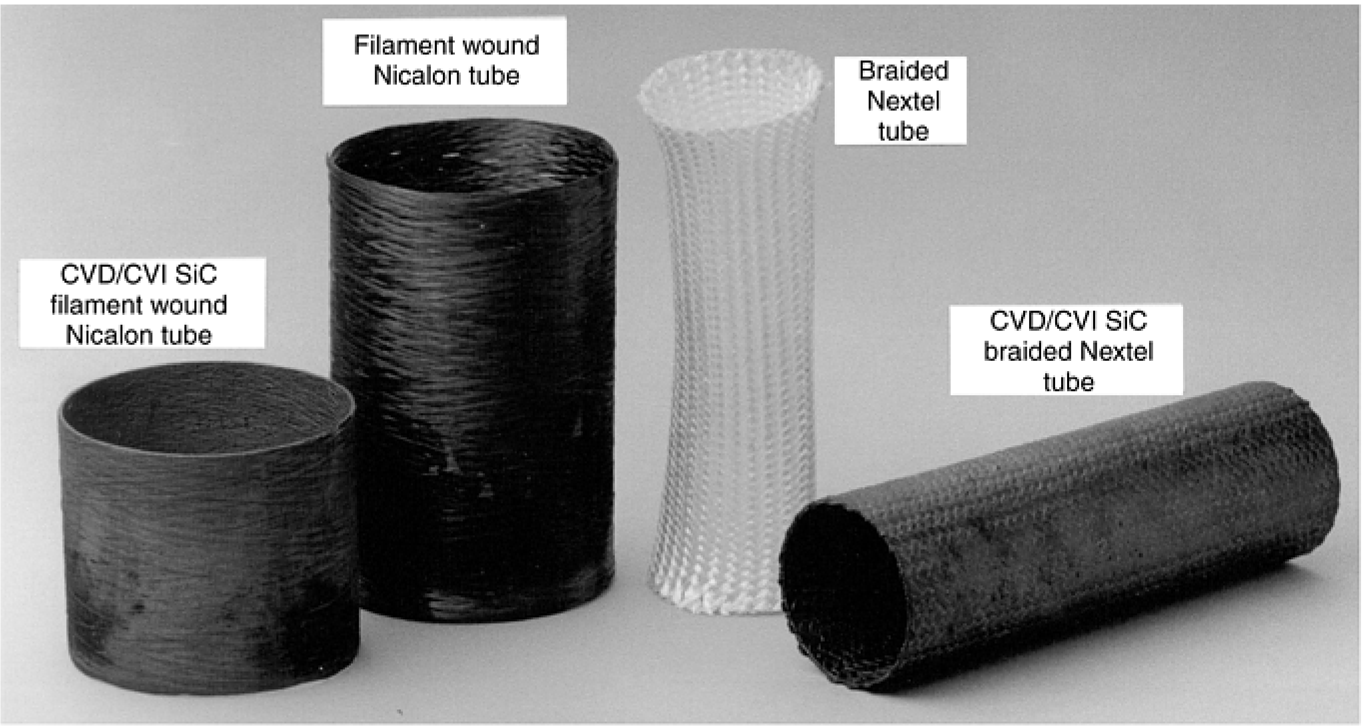

Fig. 8 Filament-wound Nicalon tube and a braided Nextel tube before and after being processed by chemical vapor infiltration. Courtesy of Thermo Electron Corporation

Chemical vapor infiltration has been used extensively for processing near net shape CFCMCs and CMCs. The first attempts at using CVI as a processing technique were in densifying porous graphite bodies with carbon (Ref 31). In fact, about half of the commercially available carbon- carbon composites today are made by CVI (Ref 32). Chemical vapor infiltration can be thought of as a bulk form of CVD, which is widely used in depositing thin coatings. The process involves deposition of the solid matrix over an open-volume, porous fibrous preform by the reaction and decomposition of gases. An example of a CVI reaction is the deposition of titanium diboride, which has a melting temperature of 3225 °C (5835 °F) but can be deposited at 900 °C (1650 °F) via CVI:

$$TiCl_4 + 2\ BCl_3 + 5\ H_2 \rightarrow TiB_2 + 10\ HCl$$

The resulting HCl by-product is very common in CVI-type reactions. The solid materials are deposited from gaseous reactants onto a heated substrate. A typical CVD or CVI process would require a reactor with the following parts:

- A vapor feed system
- A CVD reactor in which the substrate is heated and gaseous reactants are fed
- An effluent system where exhaust gases are handled

Figure 9 shows such a reactor in its simplest form. One can synthesize a variety of ceramic- matrices such as oxides, glasses, ceramics, and intermetallics by CVD. Table 2 shows several examples of ceramic composites fabricated by CVI (Ref 32). There are two main variations of CVI. Isothermal chemical vapor infiltration (ICVI) relies on diffusion for deposition (Ref 33, 34). The preform is maintained at a uniform temperature while the reactant gases are allowed to flow through the furnace and deposit the solid species. To obtain a

uniform matrix around the fibers, deposition is conducted at low pressures and reactant concentrations. When the CVI process is carried out isothermally, however, surface pores tend to close first, restricting the gas flow to the interior of the preform. This phenomenon, sometimes referred to as canning, necessitates multiple cycles of impregnation, surface machining, and reinfiltration to obtain an adequate density. One can avoid some of these problems by using a forced gas flow and a temperature gradient approach to chemical vapor infiltration (Ref 35, 36, and 37). Forced chemical vapor infiltration (FCVI) uses a combination of thermal gradients and forced reactant flow to overcome the problems of slow diffusion and permeability obtained in ICVI. This can eliminate, to some extent, the need for multiple cycles. Thus, FCVI processes typically yield much shorter infiltration times, while still obtaining uniform densification of the matrix and low residual porosity. As a comparison, a 3 mm (0.12 in.) part infiltrated by ICVI could take several weeks, while the same part infiltrated by FCVI would only take several hours. As is true with all CVI processes, with increasing densification a point of diminishing returns occurs, such that after a certain time the incremental increase in density is not proportional to the time required for deposition.

Table 2 Typical chemical reactions for a variety of matrix materials made by CVI

Matrix	**Fiber/reinforcement**	Typical reactions
SiC	Nicalon, Nextel, carbon, Al_2O_3, SiC	$CH_3SiCl_3 \overset{\text{in } H_2}{\rightarrow} SiC + 2HCl$
TiC	Carbon	$TiCl_4 + CH_4 \overset{\text{in } H_2}{\rightarrow} TiC + 4HCl$
B_4C	Carbon	$4BCl_4 + CH_4 \overset{\text{in } H_2}{\rightarrow} B_4C + 12HCl$
ZrC (HfC)	Carbon	$ZrCl_4 + CH_4 \overset{\text{in } H_2}{\rightarrow} ZrC + 4HCl$
Cr_3C_2	Al_2O_3	$CrCl_x + CH_4 \overset{\text{in } H_2}{\rightarrow} Cr_3C_2 + HCl$
TaC	Carbon	$TaCl_5 + CH_4 \overset{\text{in } H_2}{\rightarrow} TaC + HCl$
Si_3N_4	Carbon, Nicalon, Nextel	$3SiCl_4 + 4NH_3 \overset{\text{in } H_2}{\rightarrow} Si_3N_4 + 12HCl$
BN	BN, SiO_2, Nextel, carbon	$BX_3 + NH_3 \overset{\text{in } H_2}{\rightarrow} BN + 3HX (X = Cl, F)$
TiB_2	Carbon, Nicalon, Al_2O_3	$TiCl_4 + 2BCl_3 \overset{\text{in } H_2}{\rightarrow} TiB_2 + 10HCl$
ZrO_2	Al_2O_3, mullite, carbon	$ZrCl_4 + 2CO + 2H_2 \rightarrow ZrCl_4 + 2H_2O + 2CO \rightarrow ZrO_2 + 2CO + 4HCl$
Al_2O_3	**Nextel, Al_2O_3, carbon**	$2AlCl_3 + 3CO_2 + 3H_2 \rightarrow 2AlCl_3 + 3H_2O + 3CO \rightarrow Al_2O_3 + 3CO + 6HCl$

Source: After Ref 31

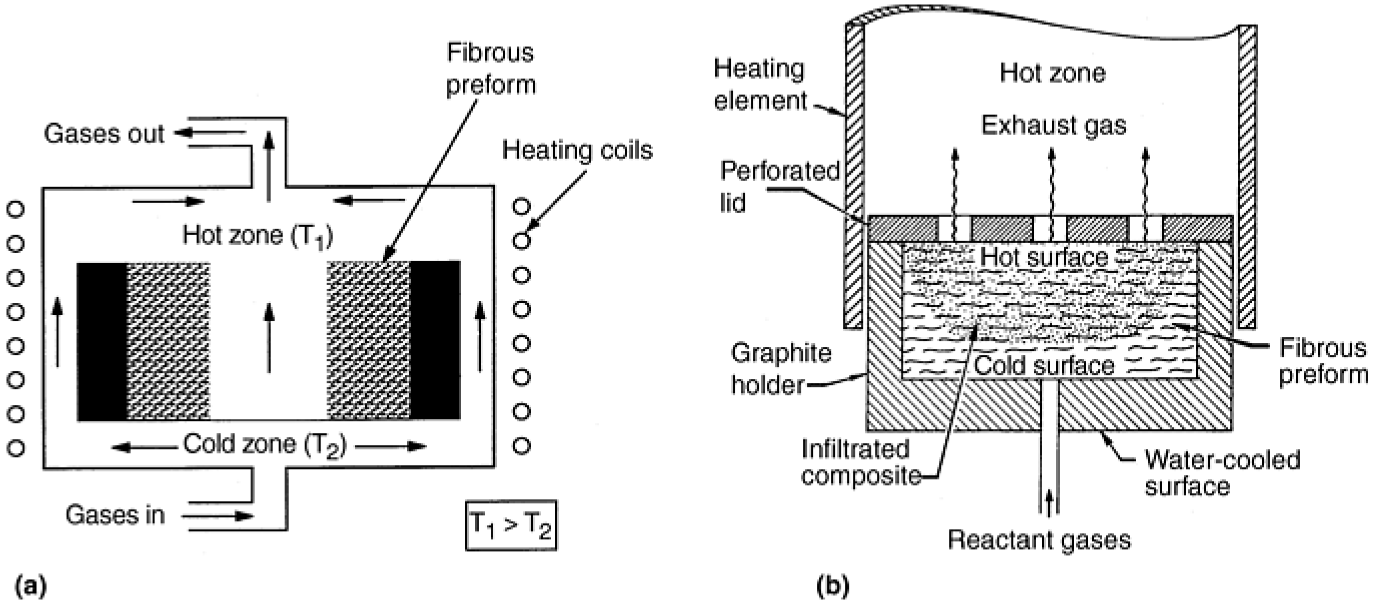

Fig. 9 Schematics of chemical vapor infiltration processes. (a) Isothermal chemical vapor infiltration. (b) Forced chemical vapor infiltration

In FCVI, a graphite holder in contact with a water-cooled metallic gas distributor holds the fibrous preform. The bottom and side surfaces thus stay cool, while the top of the fibrous preform is exposed to the hot zone, creating a steep thermal gradient. The reactant gaseous mixture passes unreacted through the fibrous preform because of the low temperature. When these gases reach the hot zone, they decompose and deposit on and between the fibers to form the matrix. As the matrix material gets deposited in the hot portion of the preform, the preform density increases, and the hot zone moves progressively from the top of the preform toward the bottom.

When the composite is formed completely at the top and is no longer permeable, the gases flow radially through the preform, exiting from the vented retaining ring. To control deposition, the rate of deposition must be maximized while minimizing density gradients. Deposition reaction rate and mass transport are competing factors, so very rapid deposition results in the exterior of the preform being well infiltrated, while severe density gradients and a large amount of porosity are present within the preform. Very slow deposition rates, on the other hand, require long times and are not economically feasible. A balance between the two factors is required for optimal infiltration.

Consider the process of decomposition of a chemical compound in the vapor form to yield SiC ceramic-matrix on and in between the fibers in a preform. For example, methyltrichlorosilane (CH_3SiCl_3), the starting material to obtain SiC, is decomposed between 1200 and 1400 K:

$$CH_3Cl_3Si \rightarrow SiC(s) + 3HCl(g)$$

The vapors of SiC deposit as solid phases on and between the fibers in a freestanding preform to form the matrix. The CVI process is very slow because it involves diffusion of the reactant species to the fibrous substrate, followed by outflow of the gaseous reactant products. The CVI process of making a ceramic-matrix is, indeed, a kind of low-stress and low-temperature CVD process and thus avoids some of the problems associated with high-temperature ceramic processing. Using CVI, when processing CFCMCs one can deposit the interfacial coating on the fibers as well as the matrix in situ. For example, for Nicalon/SiC composites with a carbon interface, the carbon layer is deposited first, and then the SiC matrix is infiltrated without changing the preform conditions. The fibrous preforms are stacked layer by layer between perforated plates, through which the gases pass during infiltration. The carbon coating is typically deposited by means of a hydrocarbon gas at around 1000 °C (1830 °F) and reduced pressure to protect the fibers.

The graphitic coating on the fibers has a characteristic aligned structure of the basal planes. These basal planes are parallel to the fiber direction, but perpendicular to the incoming crack front, so deflection of cracks at the weakly bonded basal planes takes place instead of fracturing the fibers. The softer *c*-axis of the graphite is also aligned in the perpendicular direction to accommodate the thermal residual stresses that arise from processing. The matrix consists of a nucleation zone in a small region at the coating/ matrix interface. After this, long columnar grains perpendicular to the surface of the fiber are seen. The preferred orientation is such that the (111) planes are aligned parallel to the fibers. The grains are composed predominantly of β-SiC with a cubic structure with small disordered regions of α-SiC. For CVI composites reinforced with woven fiber fabrics, the nature of the porosity is trimodal. Macroporosity is found between fiber bundles and between layers of fabric, with pore sizes less than 100 μm. Microporosity occurs between fibers in the fiber bundle, and the pore size is usually on the order of 10 μm. Lowden et al. (Ref 32), found that 70% of the pore volume was in the form of microporosity within the fiber bundle, 25% between the cloth layers, and 5% as holes between layers of the fabric.

This variant of CVI that combines forced gas flow and temperature gradient avoids some of the problems mentioned earlier. Under these modified conditions, 70 to 90% dense SiC and Si_3N_4 matrices can be impregnated in SiC and Si_3N_4 fibrous preforms in less than a day. Under conditions of plain CVI, it would take several weeks to achieve such densities; that is, one can reduce the processing time from several days to less than 24 h. One can also avoid using binders in this process with their attendant problems of incomplete removal. The use of a graphite holder simplifies the fabrication of the preform, and the application of a moderate pressure to the preform can result in a higher-than-normal fiber volume fraction in the final product. The final obtainable density in a ceramic body is limited by the fact that closed porosity starts at about 93 to 94% of theoretical density. It is difficult to impregnate past this point.

Advantages of a CVI technique or any variant thereof include:

- Good mechanical properties at high temperatures
- Large, complex shapes can be produced in a near-net shape
- Considerable flexibility in the fibers and matrices that can be used (oxide and nonoxide)
- It is a pressureless process, and relatively low temperatures are used, for example, compared to the temperatures involved in hot pressing.

Among the disadvantages, one should mention that the process is slow and expensive.
Reactive Consolidation or Liquid Phase Sintering. The term reaction bonding is used rather loosely in literature. Some researchers use it to encompass all processes not involving hot pressing. In this article the term is restricted to processes involving chemical reaction(s) between components to produce the desired end product. Reactive consolidation or liquid phase sintering are the other more descriptive terms of such processes. Some commercial success has been obtained in making silicon carbide based composites by reaction bonding. Siliconized silicon carbide is the name given to a composite of SiC grains in a silicon matrix. Commercially, such composites are available under different designations (e.g., K-T, Refel, and NC-435) from different producers.
Polymers are used to bond the preforms containing carbon in the form of carbon and silicon carbide, followed by pyrolysis of the polymer to give more carbon (Ref 38, 39). The Refel material, developed in the United Kingdom (Ref 38), is formulated to give a minimum of free silicon, which in practice is limited to about 10 vol%. The infiltration is done under reduced pressure at temperatures up to 1700 °C (3090 °F) and for several hours. Hillig et al. (Ref 40) used a low modulus carbon fiber instead of carbon powder in the preform. Molten silicon reacts with carbon fibers to form SiC. The original geometry of the carbon fibers is retained. A big advantage of SiC/Si composite is that the constituents are in chemical equilibrium, and they have closely matched thermal expansion coefficients. Carbon fiber in the form of cloth, tow, felt, or matte is used as a precursor. A preform is made of carbon fiber and infiltrated with liquid silicon. Silicon reacts with carbon fibers to form SiC fibers in a silicon matrix. Typical composition of the resultant composite is Si (30–50%) + SiC fiber. Silicon matrix limits the use temperature to about 1400 °C (2550 °F).
In another version of this process, a liquid phase forms as a result of an exothermic reaction between elemental powders. A good example is that from the field of intermetallics, for example, nickel aluminides. The following steps are involved:

1. Mix nickel and aluminum in stoichiometric proportions.
2. Cold isostatic press to 70% theoretical density to obtain a green body.
3. Vacuum encapsulate the green body in a 304 stainless steel can.
4. Subject the canned material to reactive HIP.

Processing of Ceramic-Matrix Composites

K.K. Chawla, University of Alabama at Birmingham; N. Chawla, Arizona State University

Sol-Gel Techniques

Sol-gel techniques, which have been used for making conventional ceramic materials, can also be used to make ceramic-matrix materials in the interstices of a fibrous preform. A solution containing metal compounds—for example, a metal alkoxide, acetate, or halide—is reacted to form a sol. The sol is converted to a gel, which in turn is subjected to controlled heating to produce the desired end product: a glass, a glass-ceramic, or a ceramic. Characteristically, the gel-to-ceramic conversion temperature is much lower than that required in a conventional melting or sintering process. A schematic of a typical sol-gel process for processing CMCs is given in Fig. 10. It is easy to see that many of the polymer handling and processing techniques can be used for sol- gel as well. Impregnation of fibrous preforms in vacuum and filament winding are two important techniques. In filament winding, fiber tows or rovings are passed through a tank containing the sol, and the impregnated tow is wound on a mandrel to a desired shape and thickness. The sol is converted to gel, and the structure is removed from the mandrel. A final heat treatment then converts the gel to a ceramic- or glass matrix.

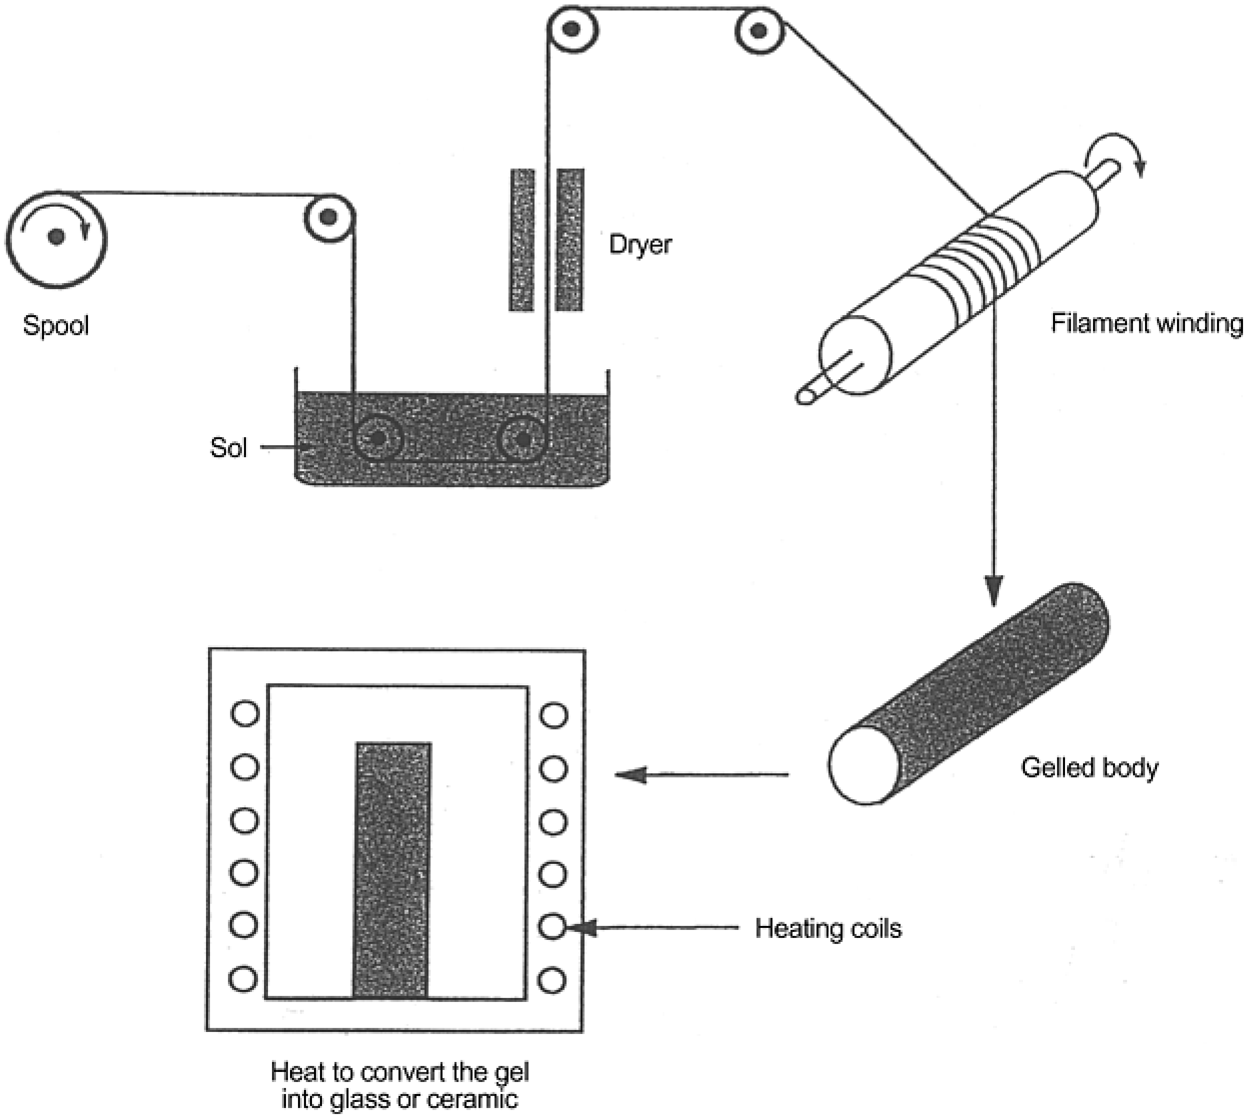

Fig. 10 Schematic of sol-gel process

Some of the advantages of sol-gel techniques for making composites are the same as those for monolithic ceramics, namely, lower processing temperatures, greater compositional homogeneity in single phase matrices, potential for producing unique multiphase matrix materials, and so forth. Specifically, in regard to composite material fabrication, the sol-gel technique allows processing via liquids of low viscosity such as the ones derived from alkoxides. Covalent ceramics, for example, can be produced by pyrolysis of polymeric precursors at temperatures as low as 1400 °C (2005 °F) and with yields greater than those in CVD processes. Among the disadvantages of sol-gel are high shrinkage and low yield compared to slurry techniques. The fiber network provides a very high surface area to the matrix gel. Consequently, the shrinkage during the drying step frequently results in a large density of cracks in the matrix. Generally, repeated impregnations are required to produce a substantially dense matrix.

The sol-gel technique can also be used to prepare prepregs by slurry infiltration. The sol in the slurry acts as a binder and coats fibers and glass particles. The binder burnout step is thus eliminated because the binder, being of the same composition as the matrix, becomes part of the glass matrix.

Processing of Ceramic-Matrix Composites

Polymer Infiltration and Pyrolysis

Polymeric precursors can also be used to form a ceramic-matrix in a composite. Because of the generally high cost of processing CMCs, polymer infiltration and pyrolysis (PIP) is an attractive processing route because of its relatively low cost while maintaining small amounts of residual porosity and minimal degradation of the fibers (Ref 41, 42, and 43). Moreover, this approach allows near-net-shape molding and fabrication technology that is able to produce nearly fully dense composites (Ref 44, 45). In PIP, the fibers are infiltrated with an organic polymer, which is heated to fairly high temperatures and pyrolyzed to form a ceramic-matrix. Due to the relatively low yield of polymer to ceramic, multiple infiltrations are used to densify the composite.

Polymeric precursors for ceramic-matrices allow one to use conventional polymer composite fabrication technology that is readily available and to take advantage of processes used to make polymer-matrix composites (Ref 42, 43). These include complex shape forming and fabrication. Furthermore, by processing and pyrolyzing at lower temperatures (compared to sintering and hot pressing, for example) one can avoid fiber degradation and the formation of unwanted reaction products at the fiber/matrix interface. French (Ref 42) lists some desirable characteristics in a preceramic polymer:

- High ceramic yield from polymer precursor
- Precursor that yields a ceramic with low free- carbon content (which will oxidize at high temperatures)
- Controllable molecular weight, which allows for solvent solubility and control over viscosity for fabrication purposes
- Low-temperature cross-linking of the polymer that allows resin to harden and maintain its dimensions during the pyrolysis process
- Low cost and toxicity

Most preceramic polymer precursors are formed from chloro-organosilicon compounds to form poly(silanes), poly(carbosilanes), poly(silazanes), poly(borosilanes), poly(silsesquioxanes), and poly(carbosiloxanes) (Ref 41). The synthesis reaction involves the dechlorination of the chlorinated silane monomers. Since a lot of the chlorosilane monomers are formed as by- products in the silicone industry, they are inexpensive and readily available. The monomers can be further controlled by an appropriate amount of branching, which controls important properties such as the viscosity of the precursor as well as the amount of ceramic yield.

All silicon-based polymer precursors lead to an amorphous ceramic-matrix, where silicon atoms are tetrahedrally arranged with nonsilicon atoms. This arrangement is similar to that found in amorphous silica (Ref 42). High-temperature treatments typically lead to crystallization and slight densification of the matrix, which results in shrinkage. At high temperatures, the amorphous ceramic begins to form small domains of crystalline phase, which are more thermodynamically stable (Ref 46). Silicon-carbide matrices derived from polycarbosilane begin to crystallize at 1100 to1200 °C (2010–2190 °F) while Si-C- O (polysiloxanes) and Si-N-C (polysilazanes) remain amorphous to 1300 to 1400 °C (23670–2550 °F).

Typically, the molecular weight range of the polymer is tailored, followed by shaping of the product (Ref 41). The polymer is then cross- linked and finally pyrolyzed in an inert or reactive atmosphere (e.g., NH_3) at temperatures between 1000 to1400 °C (1830 and 2550 °F). The pyrolysis step can be further subdivided into three steps. In the first step, between 550 and 880 °C (1020 and 1620 °F), an amorphous compound of the type $Si(C_aO_bN_cB_d)$ is formed. The second step involves nucleation of crystalline precipitates such as SiC, Si_3N_4, and SiO_2 at temperatures between 1200 and 1600 °C (2190 and 2910 °F). Grain coarsening may also result from consumption of any residual amorphous phase and reduction of the amount of oxygen due to vaporization of SiO and CO. Porosity is typically of the order of 5 to 20 vol% with pore sizes of the order of 1 to 50 nm. It should be noted that the average pore size and volume fraction of pores decrease with increasing pyrolysis temperature, since the amount of densification (and shrinkage) becomes irreversible at temperatures above the maximum pyrolysis temperature.

The main disadvantage of PIP is the low yield that accompanies the polymer-to-ceramic transformation and the resulting shrinkage, which typically causes cracking in the matrix during fabrication (Ref 41, 42, 43, 44, 45, 47, and 48). Due to shrinkage and weight loss during pyrolysis, residual porosity after a single impregnation is of the order of 20 to 30%. To reduce the amount of residual porosity, multiple impregnations are needed. Reimpregnation is typically conducted with a very-low-viscosity prepolymer, so that the slurry may wet and infiltrate the small micropores that exist in the preform. Usually, reimpregnation is done by immersing the part in the liquid polymer in a vacuum bag, while higher- viscosity polymers require pressure impregnation. Typically, the amount of porosity will reduce from 35% to less than 10% after about five impregnations.

Significant gas evolution also occurs during pyrolysis (Ref 42). Thus, it is advisable to allow these volatile gases to slowly diffuse out of the matrix, especially for thicker parts. Typically, pyrolysis cycles ramp to 800 to 1400 °C (1470–2550 °F) over periods of 1 to 2 days to avoid delamination. Recall that pyrolysis must be done at a temperature below the crystallization temperature of the matrix (or large volume changes will occur) and below the degradation temperature of the reinforcing fibers. The pyrolysis atmosphere is most commonly argon or nitrogen, although in ammonia a pure amorphous silicon nitride with low amounts of free carbon can be obtained (Ref 49). Such an atmosphere may also lead to the formation of nitrides from the reaction of filler particles (Ref 50). With the formation of the ceramic, the gaseous by-product reaction can be written as (Ref 41):

$$P(\mathrm{s,l}) \xrightarrow{\Delta} C(\mathrm{s}) + G(\mathrm{g})$$

where *P* is the polymer, *C* is the ceramic, and *G* is the gaseous by-product. With the loss of the volatile gaseous products, the ceramic yield, α, is just the ratio of ceramic formed and the initial amount of polymer:

$$\alpha = \frac{m(C)}{m(P)} = 1 - \frac{m(G)}{m(P)}$$

where *m* represents the mass of a component (ceramic, polymer, or gas). The density ratio of the ceramic product, $\rho(C)$, to that of the polymer precursor, $\rho(P)$, is given by:

$$\beta = \frac{\rho(P)}{\rho(C)}$$

Two extreme cases of polymer-ceramic conversion can be considered. If the volume is not constrained, then diffusional flow will cause the pores to be filled, but a high amount of shrinkage will take place. The maximum volume change that occurs during conversion can be written as:

$$\psi = \alpha\beta - 1$$

If the volume is constrained (i.e., $\psi = 0$) then shrinkage does not occur, but a large amount of residual porosity is present. The maximum amount of porosity can be written as:

$$\pi = 1 - \alpha\beta$$

It has been reported that for filler-free pyrolysis of poly(silazane) to form bulk Si_3N_4, either a large amount of porosity (>8%) or a large amount of shrinkage (20%) took place (Ref 51). Fitzer and Gadow (Ref 28) used repeated infiltration and in situ thermal decomposition of porous reaction-bonded ceramics, such as silicon carbide and silicon nitrate with silazanes and polycarbosilanes, to process Si_3N_4/SiC composites. A typical sequence of steps taken in processing the composites is as follows:

1. Porous SiC or Si_3N_4 fibrous preform with some binder phase is prepared.
2. Fibrous preform is evacuated in an autoclave.
3. Samples are infiltrated with molten precursors—silazanes or polycarbosilanes—at high temperature (780 K), and the argon or nitrogen pressure is slowly increased from 2 to 40 MPa (0.3–5.8 ksi). The high temperature results in a transformation of the oligomer silane to polycarbosilane and simultaneous polymerization at high pressures.
4. Infiltrated samples are cooled and treated with solvents.
5. Samples are placed in an autoclave, and the organosilicon polymer matrix is thermally decomposed in an inert atmosphere at a high pressure and at temperature in the 800 to 1300 K range.
6. Steps 2 through 5 are repeated to obtain an adequate density. To produce an optimal matrix crystal structure, the material is annealed in the 1300 to 1800 K range.

Polymer-derived ceramic-matrix composites, similar to carbon/carbon composites, typically have a cracked matrix from processing as well as a number of small voids or pores. The large amount of shrinkage and cracking in the matrix can be contained, to some extent, by the additions of particulate fillers to the matrix, which, when added to the polymer reduce shrinkage and stiffen the matrix material in the composite (Ref 41). Figure 11 shows a schematic of filler-free versus active filler pyrolysis. Figure 12 shows the microstructure of a PIP CMC, indicating some residual porosity and a clear “filler network” in the matrix of the composite (Ref

52). Particulate or whisker ceramics used as fillers in the polymeric matrix can serve a variety of purposes (Ref 42):

- Reduce and disrupt the formation of matrix cracks that form during shrinkage of the polymer
- Enhance ceramic yield by forming reaction products during pyrolysis
- Strengthen and toughen the weak amorphous matrix and increase the interlaminar shear strength of the composite

The filler must be submicrometer in size in order to penetrate the tow bundle, and the coefficient of thermal expansion of the filler must match that of the polymeric matrix. It should be noted that the filler must not be used in very high fractions, and the slurry should not be forced into the reinforcing fibers since abrasion of the fiber fabric may take place. This is especially true with hard, angular fillers or ceramic whiskers. Typically, the volume fraction of filler is 15 to 25% of the matrix volume fraction. High filler loading may result in an increase in interply spacing and lower volume fraction of fibers.

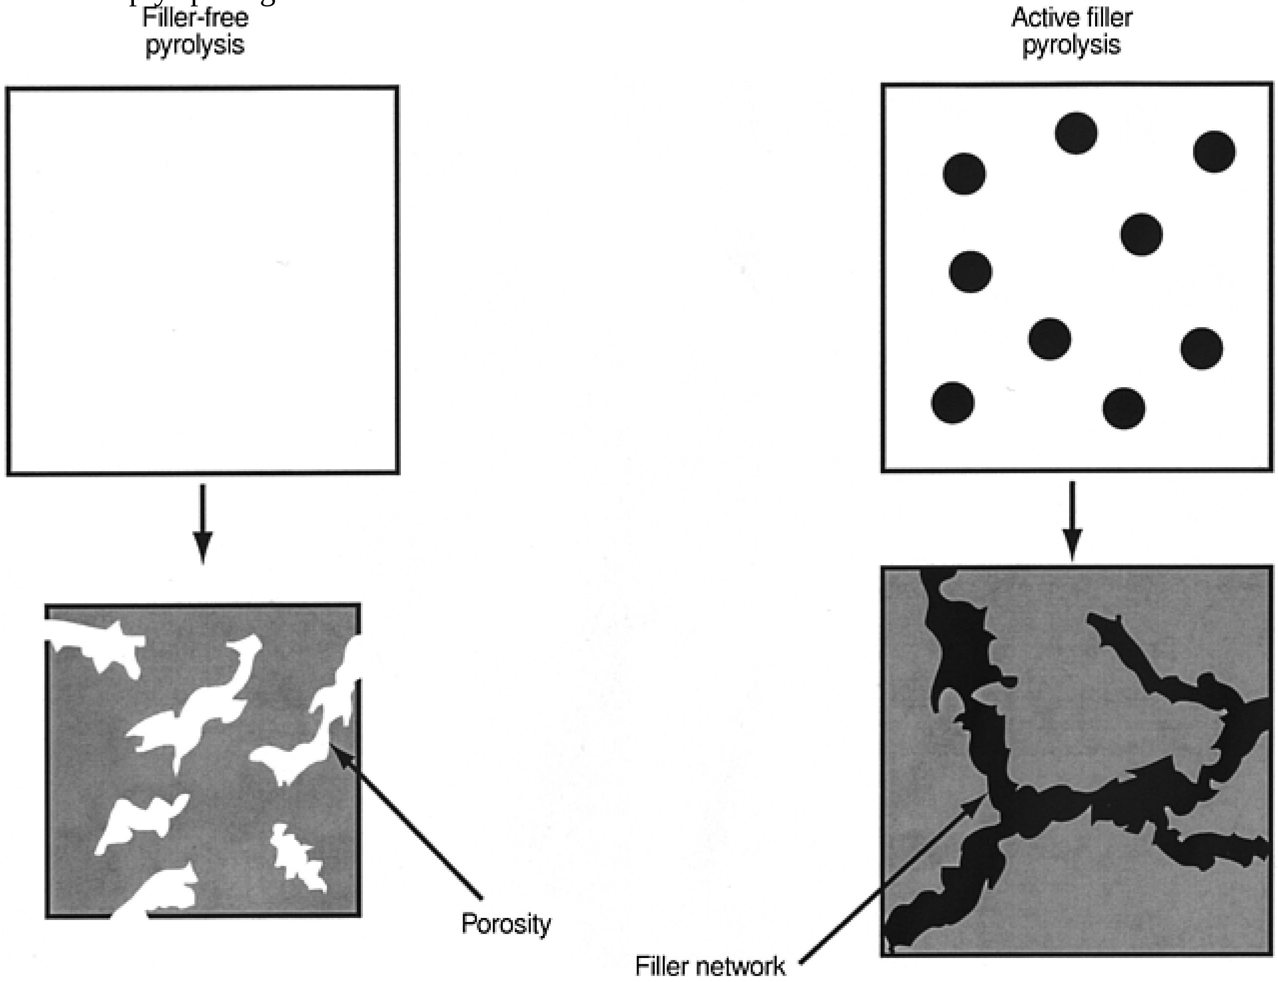

Fig. 11 Schematic of filler-free versus active filler pyrolysis. Source: Ref 52

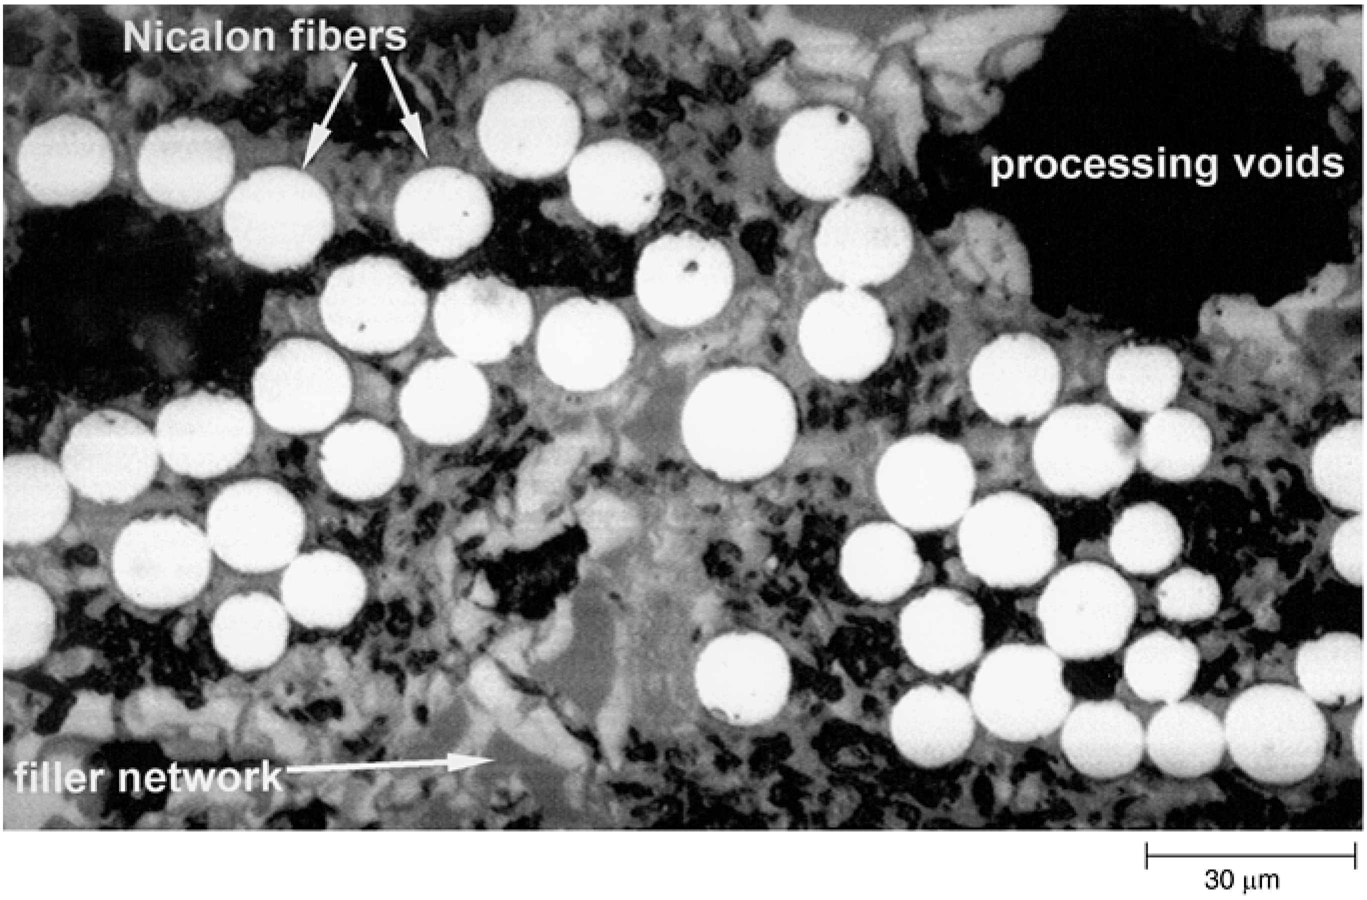

Fig. 12 Microstructure of a woven Nicalon/Si-C-O-N matrix composite with a SiC filler. Small amounts of residual porosity and a clear filler-free network can be seen in the matrix of the composite.

When an “active” filler phase is added to the polymer, it reacts with solid or gaseous decomposition products to form new carbide phases (Ref 41):

$$P(\mathrm{s,l}) + T(\mathrm{s}) \xrightarrow{\Delta} C(\mathrm{s}) + M(\mathrm{s}) + G(\mathrm{g})$$

where *T* is the active filler, and *M* is the carbide phase formed. The other symbols have the same meaning as described in the previous expression. The maximum volume change of a precursor containing an active filler, ψ^*, can be expressed as (Ref 41):

$$\psi^* = \left(1 - \frac{V_T}{V_T^*}\right)(\alpha\beta - 1) + V_T\,(\alpha^{TM}\beta^{TM} - 1)$$

where V_T^* is the critical volume fraction of filler that determines maximum particle packing density of the reacted filler phase in the pyrolyzed product, α^{TM} and β^{TM} describe mass change of the filler phase and density ratio. For α^{TM} and $\beta^{TM} > 1$, volume expansion of the filler phase may compensate for polymer shrinkage during pyrolysis.

If one assumes isotropic dimensional changes, the linear shrinkage ϵ is related to the volume shrinkage ψ by (Ref 41):

$$\varepsilon = (\psi + 1)^{1/3} - 1$$

Thus, by controlling the amount of filler, the degree of shrinkage can be controlled.

Fiber architecture may have an impact in regard to PIP. One of the key factors is wetting of the fiber bundles. During pyrolysis, the precursor shrinks around the fibers, so cracks are introduced. For example, two-dimensional woven fabrics seem to have less propensity in developing interlaminar cracks than do cross-ply or unidirectional architectures. Satin weaves are preferred versus plain weaves because more uniform cracking is achieved and large cracks between weave crossover points are avoided (Ref 53). Due to the looser nature of the

satin weave (it is more drapable), better wetting and densification may take place, although the loose nature of the weave also makes it more difficult to handle.

Self-Propagating High-Temperature Synthesis

Self-propagating high-temperature synthesis (SHS) can be used to produce a variety of refractory materials. The main disadvantage is that SHS products are very porous because of the fairly large porosity present in the original mix of reactants and because of the large volume change that results when the reactants transform to the products. Any adsorbed gases at the elevated temperatures used during this process can also add to the porosity of the final product. Synthesis concomitant with densification can improve the situation to some extent. This involves application of high pressure during the combustion or immediately after the completion of the combustion reaction when the product temperature is still quite high. Hot pressing, rolling, and shock waves are some of the techniques used to apply the necessary pressure.

The SHS technique involves synthesis of compounds without an external source of energy. One exploits exothermic reactions to synthesize ceramic compounds, which are difficult to fabricate by conventional techniques. For example, one can mix titanium powder and carbon black, cold press the mixture, and ignite the compact at the top in a cold-walled vessel. A combustion wave will pass through the compact, giving titanium carbide.

Among the salient features of SHS are:

- High combustion temperature (up to 4000 °C, or 7230 °F)
- Simple, low-cost equipment
- Good control of chemical composition
- Ability to obtain different shapes and forms

Many ceramics such as borides, carbides, nitrides, silicides, and sialons as well as composites such as SiC_w+ Al_2O_3 have been synthesized by means of SHS. The SHS process gives a weakly bonded compact. Therefore, the process is generally followed by breaking the compact, milling, and consolidation by some technique such as HIP. Explosive or dynamic compaction can result in a relatively dense product. A good example of an SHS process to make composites is the proprietary process of Martin Marietta Corporation (Baltimore, MD), called the XD Process, wherein exothermic reactions are used to produce multiphase alloy powders. These are hot pressed at 1450 °C (2640 °F) to full density. Reinforcement in the form of particles, whiskers, and platelets can be added to the master alloy to make a composite. A good example is that of TiB_2 particles, about 1 μm diameter, distributed in intermetallic matrixes such as TiAl, TiAl + Ti_3Al, NiAl, and so forth.

Electrophoretic Deposition

The phenomenon of electrophoresis has been known since the beginning of the 19th century, but its applications in processing of ceramics and ceramic composites is relatively recent. Electrophoretic deposition (EPD) should not be confused with electroplating. In electroplating, ions are the moving species and they undergo ion reduction on deposition. In EPD, on the other hand, solid particles migrate with no charge reduction on deposition. Also, the deposition rate in EPD is ~1 mm/min while in electroplating it is ~0.1 μm/min. Electrophoretic deposition is a relatively simple and inexpensive technique, which can be profitably exploited for infiltration of tightly woven fiber preforms (Ref 54). Electrophoretic deposition makes use of nanoscale ceramic particles in a stable nonagglomerated form (such as in a sol or colloidal suspension) and exploits their net surface electrostatic charge characteristics while in suspension. On application of an electric field the particles will migrate toward and deposit on an electrode. If the deposition electrode is replaced by a conducting fibrous preform, the suspended particles will be attracted into and deposited within it, providing an appropriate means of effectively infiltrating densely packed fibrous bundles. A schematic diagram of the basic EPD cell is shown in Fig. 13. The movement of ceramic sol particles in an aqueous suspension within an electric field is governed by the field strength, and the pH, ionic strength, and viscosity of the solution (Ref 54). The electrophoretic mobility of charged particles in a suspension is given by the Smoluchowski equation (Ref 55):

$$\text{Electrophoretic mobility} = \frac{U}{E} = \frac{\varepsilon\zeta}{4\pi\eta}$$

where U is the velocity, E is the field strength, ϵ is the dielectric constant, ζ is the zeta potential, and η is the viscosity. The zeta potential is a parameter for characterizing a suspension. It can be determined by measuring particle velocity in an electric field. According to the Smoluchowski equation, a suitable suspension for EPD should have a high particle surface charge, a high dielectric constant of the liquid phase, and a low viscosity. In

addition, a low conductivity of the suspending medium to minimize solvent transport would be desirable (Ref 56).

Processing of Carbon-Carbon Composites

Introduction

CARBON-CARBON COMPOSITES (CCCs), high-density carbon fibers in a carbon matrix, began replacing fine-grained graphite as nose tips in rockets in the mid-1960s. They were subsequently introduced for applications that require their high specific strength and stiffness, in combination with their thermoshock resistance, chemical resistance, and fracture toughness, especially at high temperatures.

This article describes the manufacture, post- processing, fabrication, and properties of CCCs. Detailed information about CCC constituent materials is provided in the articles “Carbon Fibers” and “Carbon Matrices” in this Volume. Information about applications is provided in the article “Applications of Carbon-Carbon Composites” in this Volume.

Processing of Carbon-Carbon Composites

Preform Fabrication

All types of carbon fibers can be used as reinforcements in many different architectures: random fibers; two-directional fabrics in stacked, stitched, or pierced configurations; three-directional geometries (cartesian or cylindrical coordinates) to increase the off-axis strength; or three-directional and multidirectional (4 to 11) weaves to minimize the empty spaces between the rod junctions. Unidirectional orientation has no importance for technical applications, but many basic investigations have been carried out using unidirectional composites as models (Ref 1, 2, 3, 4, 5, and 6).

Both three-directional and multidirectional composites are generally too expensive for industrial applications. Two-directional and multiaxial fibers usually suffice. Manufacturing techniques are listed in Table 1 with respect to the processibility of different geometries. In some cases, combinations of the main processing techniques are reasonable for manufacturing complex structures.

Multidirectional Woven Preforms

The main advantage of multidirectional CCCs is the freedom to orient selected fiber types and amounts to accommodate the design loads of the final structural component. Multidirectional fabrication technology provides the means to produce tailored composites.

The simplest type of multidirectional preform is based on a three-directional orthogonal construction, which is normally used to weave rectangular, block-type preforms. As shown in Fig. 1, this preform type consists of multiple yarn bundles located on cartesian coordinates. Each of the yarn bundles is straight in order to achieve the maximum structural capability of the fiber.

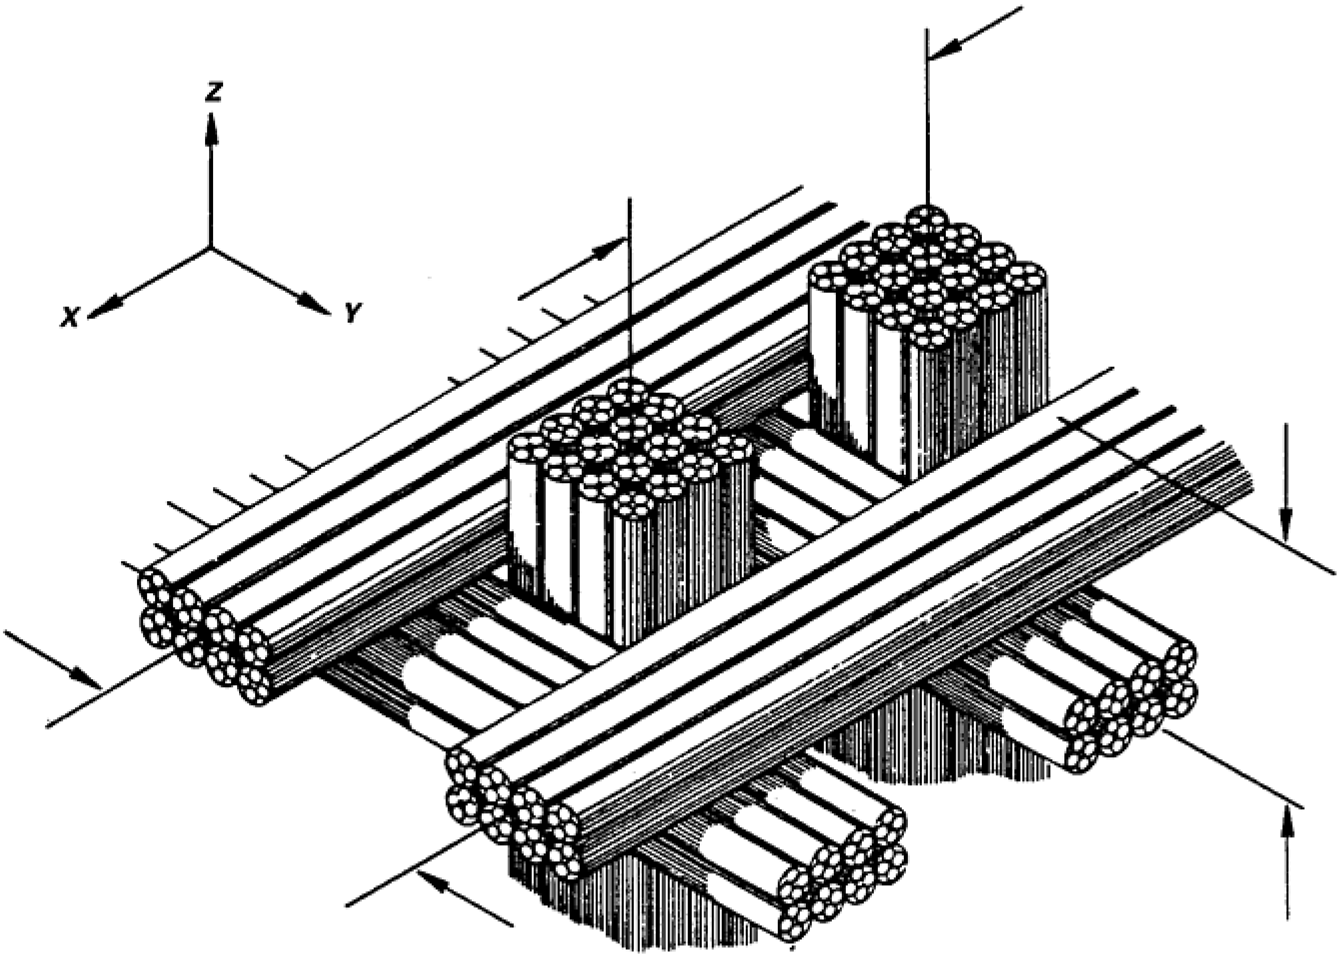

Fig. 1 Three-directional orthogonal preform construction. Source: Ref 7

Preforms are described by yarn type, number of yarns per site, spacing between adjacent sites, volume fraction of yarn in each direction, and preform density.

Several modifications of the basic three-directional orthogonal construction are available in order to achieve more isotropic preforms. This is accomplished by introducing yarns in additional directions. For example, a five-directional construction can be achieved by adding two reinforcement directions that are ±45° with respect to the yarns within the *X-Y* plane of the preform. Another option is to introduce diagonal yarns across the corners and/or across the faces of a rectangular three-directional preform to achieve a nonplanar multidirectional construction (Ref 7).

The type of multidirectional preform construction typically used for cylinders and other shapes of revolution (shown in Fig. 2) is a three- directional construction with yarns oriented on polar coordinates in the radial, axial, and circumferential directions. As with orthogonal block preforms, yarn type, spacing, and volume fraction can be varied in all three directions.

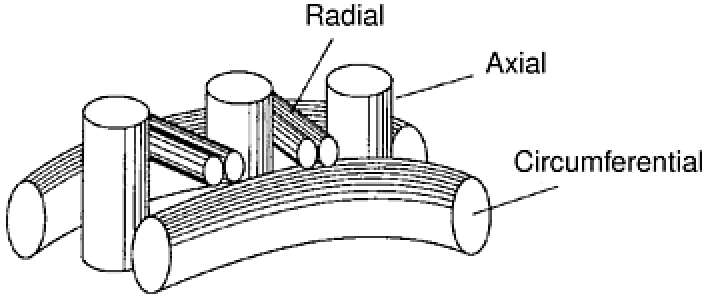

Fig. 2 Three-directional cylindrical preform construction. Source: Ref 7

Fiber Selection. Fibers are normally available as yarns or tows containing 1000 to 12,000 filaments per strand. Fibers selected must be compatible with the weaving and densification process and must provide the physical and structural properties required in the composite.

The highest-modulus fibers have been subjected to the highest heat treatment temperature during manufacture. The properties of these high-modulus fibers are less affected by temperature exposure during carbon-carbon processing than high-strength intermediate-modulus fibers that have not been previously exposed to graphitizing temperatures.

In most cases, fiber properties are degraded by various handling and processing steps that occur during CCC fabrication. Small amounts of polymeric coatings or finishes are used to reduce handling damage and to improve fiber-matrix compatibility.

Manufacturing. The original multidirectional preforms used precise tooling to locate yarns, but the weaving operations were performed manually. Weaving operations have now been automated, but many details regarding equipment and procedures are proprietary.

Most multidirectional preforms used for CCCs are represented by the orthogonal or polar constructions shown in Fig. 1 and 2, respectively, or by some modification of these constructions. The techniques used to manufacture these preforms include weaving dry yarns (Ref 8), piercing fabrics (Ref 9, 10), assembling resin-rigidized yarns (Ref 11), and filament winding (modified) (Ref 12).

Block Preforms. One method of weaving three-directional orthogonal block preforms involves setting up a precisely spaced rectangular array of thin-walled metal tubes or solid rods representing the location of each *Z* direction reinforcing yarn (Ref 8, 13). Alternate *X* and *Y* layers of yarn are built up between the rows of metal tubes, as illustrated in Fig. 3. After the height of the preform has been established by *X*- *Y* layers, each *Z* direction tube (or rod) is replaced by yarn to establish the *Z* direction of the preform.

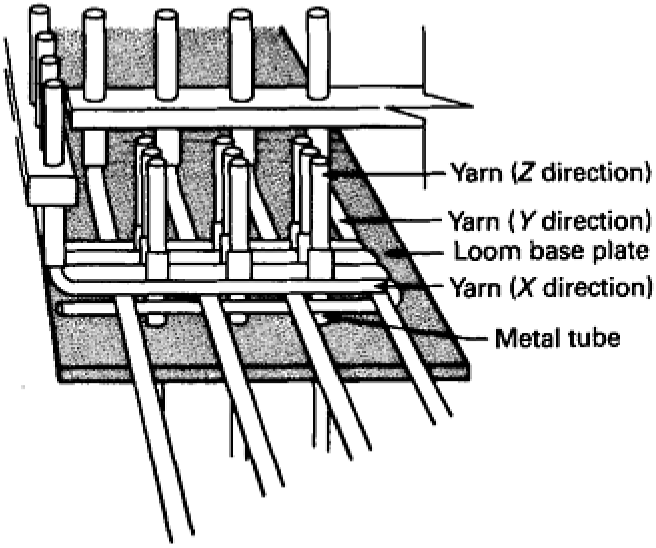

Fig. 3 Three-directional orthogonal weaving. Source: Ref 8

A modified three-directional orthogonal block construction is produced by using a two-directional woven fabric instead of *X*-*Y* yarn layers. These preforms are fabricated by piercing multiple layers of fabric over a precisely spaced rectangular array of metal rods. These metal rods, which represent the *Z* direction of the preform, are replaced with carbon yarns or precured (rigidized) yarn-resin rods as the final step of the process (Ref 10).

Shapes of Revolution. Fully automated computer-controlled equipment for fabricating three- directional cylindrical, conical, and contoured preforms has been developed both in the United States and in France. One version of this type of equipment is three-axis computer numerically controlled to define the preform configuration accurately and to place reinforcing fibers in the radial, axial, and circumferential directions (Ref 14). The outside surface defines the inside surface of the preform. Such machines can make preforms up to 2000 mm (84 in.) in diameter.

Automated equipment has also been developed to fabricate cylindrical preforms completely from dry yarns (Ref 13, 15). To weave preforms, this type of loom locates yarns in the circumferential and radial directions within an array of axial metal rods, which are then replaced by dry yarns.

Processing of Carbon-Carbon Composites

Densification Processing

Generally, the best CCCs result from a densification process that fills the open volume of the preform with a dense, well-bonded carbon- graphite matrix. The actual densification process is dictated by the characteristics

of the preform (Fig. 4). Four of the most important factors are carbon fiber type, fiber volume, preform thickness, and void size distribution within the preform.

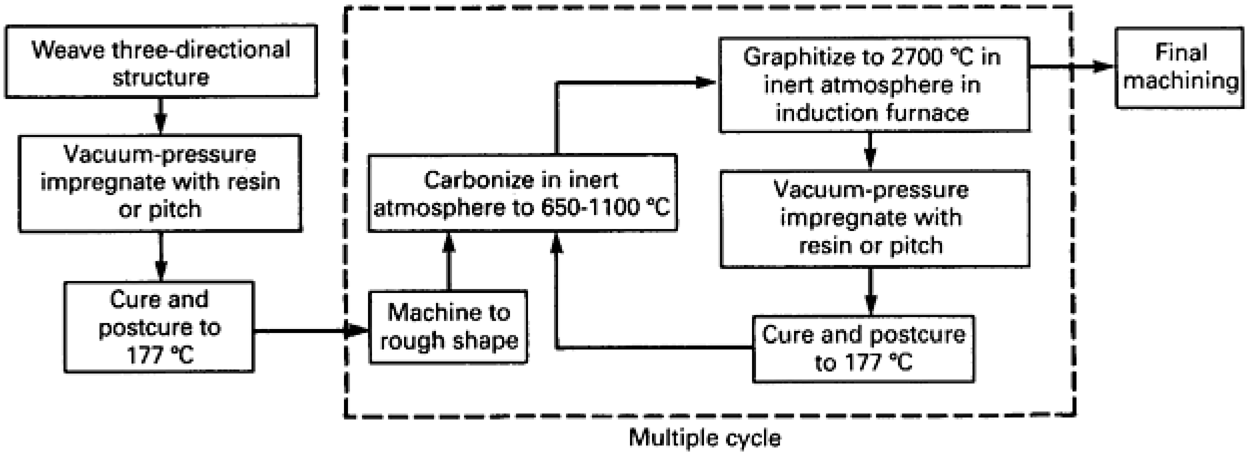

Fig. 4 Typical carbon-carbon densification process. Source: Ref 16

Matrix Precursor Impregnants. The two general categories of matrix precursors used for carbon-carbon densification are thermosetting resins, such as phenolics and furfurals, and pitches based on coal tar and petroleum. The thermosetting resins polymerize to form cross- linked, infusible solids. As a result of pyrolysis, these resins form amorphous (glassy) carbon. The carbon yield at 800 °C (1470 °F) is about 50 to 60 wt%.

The coal tar and petroleum pitches are mixtures of polynuclear aromatic hydrocarbons. From their softening point up to about 400 °C (750 °F), the liquefied pitches undergo various changes, including volatilization of low-molecular-weight fractions, polymerization, cleavage, and rearrangements of the molecular structure. At temperatures above 400 °C (750 °F), mesophase spheres are formed in the isotropic liquid pitch. These mesophase spheres deform, coalesce, and solidify to form regions of extended order. The lamellar arrangement of the molecular structure in these regions favors the formation of a graphitic structure on further heating to above 2000 °C (3630 °F).

Coke yield from coal tar and petroleum pitches is about 50 wt% after pyrolysis at atmospheric pressure. However, pyrolysis of coal tar pitch at 600 °C (1110 °F) under 6.9 MPa (1 ksi) of pressure gives a coke yield of 90% (Ref 17). An increase in pyrolysis pressure does not increase coke yield over the 90% level.

Liquid Impregnation. The general processing technique using organic liquid impregnants as carbon matrix precursors involves multiple cycles of preform impregnation and heat treatment to produce a densified composite. Impregnant viscosity and coke yield, density, microstructure, and degree of graphitization must be considered (Ref 18). All of these factors are influenced by the time-temperature-pressure relationships encountered during processing.

The process can be modified by performing the carbonization step under pressures ranging from 6.8 to 103 MPa (1 to 15 ksi). This modified process has been designated as the pressure-impregnation-carbonization (PIC) process. Modified hot isostatic pressing equipment is used to impregnate and densify the composite effectively during the melting and coking stages of the carbonization process (Ref 19, 20). Isostatic pressure forces pitch into the small pores that are not filled during initial vacuum impregnation. As the pitch begins to pyrolyze, high isostatic pressure maintains the more volatile fractions of the pitch in a condensed phase. This reduces the amount of liquid forced out of the composite by pitch pyrolysis products.

The curves in Fig. 5 illustrate the advantage of PIC versus atmospheric-pressure carbonization to achieve high-density, multidirectional CCCs.

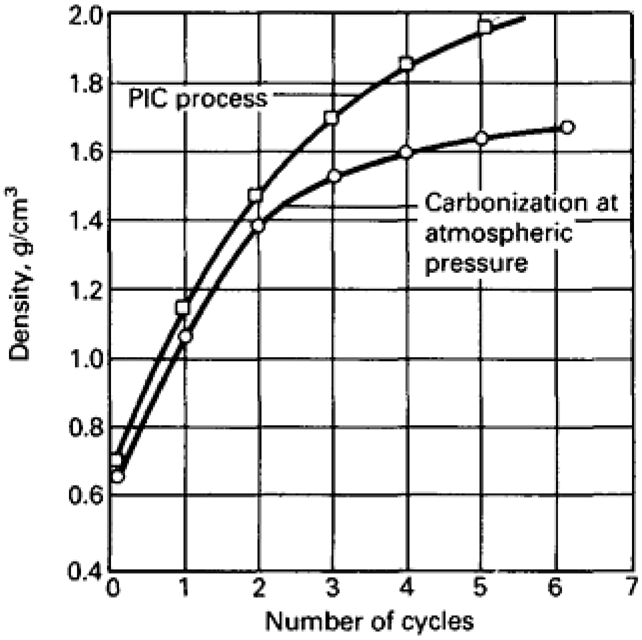

Fig. 5 Comparison of the pressure-impregnation-carbonization (PIC) process with carbonization at atmospheric pressure. Source: Ref 7

Chemical vapor infiltration (CVI) (Ref 21) of carbon uses gaseous hydrocarbons such as methane, propane/propylene, and benzene to deposit a carbon matrix internally in a carbon fiber preform. The process can be performed using three different methods. In the most commonly used technique (Fig. 6a), natural gas or other carbonaceous gases are flowed past and through a carbon fiber preform located in a low-pressure isothermal furnace. Uniform deposition throughout the preform can be achieved by operating at a temperature sufficiently low to permit rapid gaseous diffusion, compared to deposition of carbon. However, the deposition time is usually very long. Mass transfer through the fiber preform can be improved by inducing a pressure gradient through it (Fig. 6b). The deposition rate can be much higher. Enhanced deposition rates can be achieved also by using a temperature gradient deposition process (Fig. 6c).

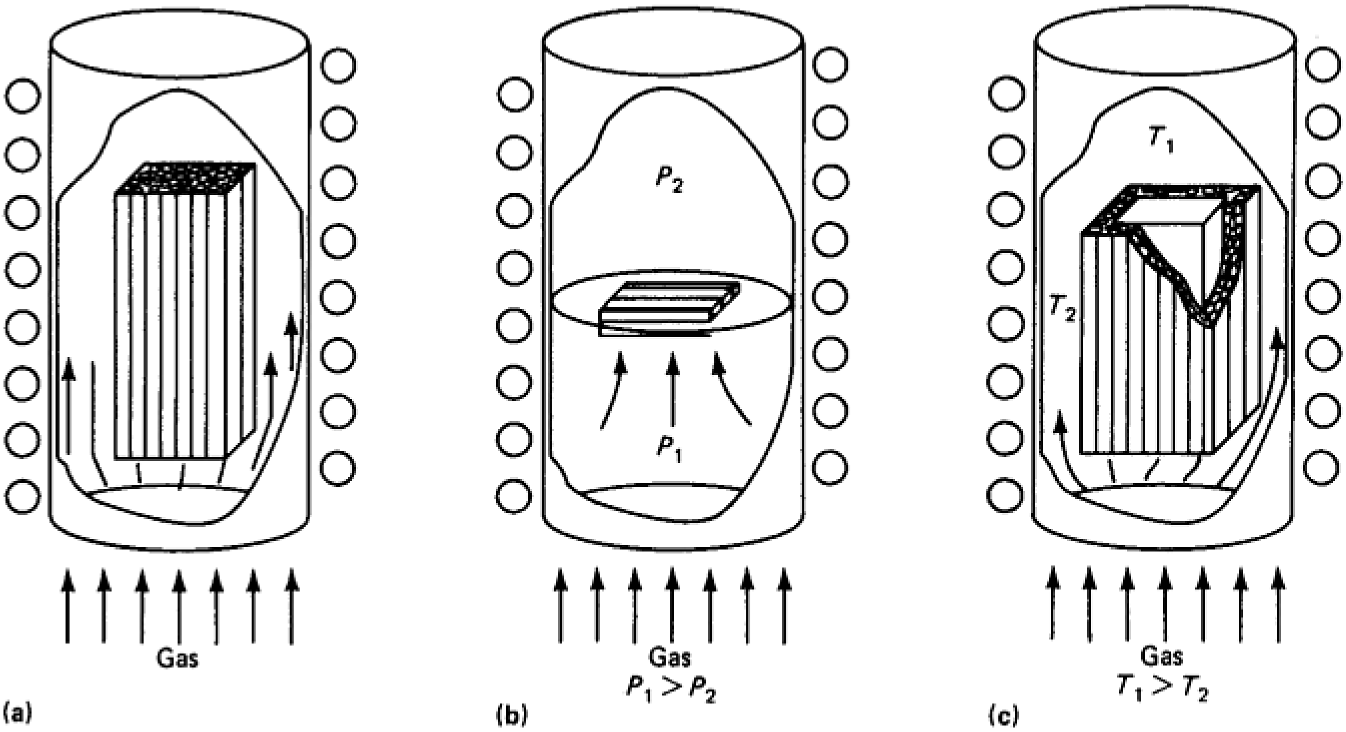

Fig. 6 Chemical vapor infiltration process

A major problem with CVI is to achieve the uniform deposition of the carbon matrix throughout a thick preform. Mass transfer from the bulk gas must be sufficiently high in the fiber preform to keep a relatively constant concentration of carbon-containing molecules throughout. Hence, the rate at which carbon is deposited must be slow compared to the mass transfer of carbon into and throughout the preform.

Mass transfer of carbon-containing molecules into the preform is usually by diffusion, which slowly increases with temperature. The deposition of carbon is complex, but the overall process has a high temperature coefficient. Hence, the relative rates of the two processes can be varied by adjusting the temperature. A temperature of 1000 to 1100 °C (1830 to 2010 °F) is commonly used, along with a pressure of 500 to 3000 Pa (5 to 30 mbar), to achieve a relatively uniform deposition of carbon throughout a part 10 mm (0.40 in.) thick.

More rapid mass transfer can be achieved by placing a pressure drop across the fiber preform (Fig. 6b). However, the deposition rate decreases as the pressure decreases, which produces nonuniform deposition through the preform. A pressure gradient process can be used at the end of a conventional cycle when mass transfer through tiny pores is extremely slow.

An alternative is to use a temperature gradient, such that carbon is deposited at a moving boundary that sweeps through the thickness (Fig. 6c). The deposition time can be significantly decreased, because mass transfer of the deposition gases is mostly through parts of the preform that have not yet been deposited upon. Unfortunately, the technique produces a variation in microstructure because deposition occurs at different temperatures.

A problem with all present CVI processes is closed pore formation caused by the sealing off of bottleneck pores, and, more insidiously, delaminated regions. However, high-temperature heat treatment may be employed to induce microcracks in the matrix to be filled in the subsequent CVI process. Using liquid impregnation to produce relatively uniform open pores, followed by CVI, is another attractive alternative.

Protective Coatings

Coating technology for carbon-carbon has been driven primarily by the aerospace and defense industries, in applications where the composite is exposed to high-temperature oxidizing environments. Advanced applications include hot-section components for limited-life missile engines, exhaust components for fighter aircraft, hypersonic vehicle fuselage and wing components, and structures for space defense satellites (Ref 22). The most notable application of coated carbon-carbon is for the nose cap and wing leading edges of the Shuttle Orbiter vehicle (Ref 23, 24, and 25). Several dozen successful missions have been flown, demonstrating the flight worthiness of coated carbon-carbon in reentry applications. Ref 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, and 37 provide information about the historical development of methods for protecting carbon bodies.

Fundamentals of Protecting Carbon-Carbon

Carbon-Carbon Constituents and Microstructure. Applications requiring coatings typically use carbon fibers in laminated woven cloth or three-dimensional woven reinforcements. The fibers used are derived from rayon, polyacrylonitrile (PAN), or petroleum pitch and have a wide range of properties. For example, the elastic modulus along the fiber axis ranges from approximately 41.4 GPa (6×10^6 psi) for rayon fibers to 414 GPa (60×10^6 psi) for heat-stabilized PAN to 690 GPa (100×10^6 psi) for pitch fibers. The axial fiber expansion coefficients become lower as the fiber modulus increases.

The characteristics of the matrix vary, depending on the method of densification. Generally, the matrix microstructure spans a range from being glasslike, with small, randomly oriented crystallites of turbostratic carbon, to having strongly oriented and highly graphitized large crystallites. Weak interfaces usually exist between the fibers and matrix, because strong covalent atomic bonding prevents the carbon constituents from sintering, even at very high temperatures. Because the mechanical properties of the matrix are substantially inferior to those of the fibers, the fibers generally control the mechanical performance and expansion characteristics of the composites. A rayon-fabric-reinforced laminated construction typically exhibits the following in-plane properties: a tensile strength of 51.7 MPa (7.5 ksi), a tensile elastic modulus of 13.8 GPa (2×10^6 psi), and a coefficient of thermal expansion (CTE) of 2.4×10^{-6}°C^{-1} (1.3×10^{-6}°F^{-1}). Laminated constructions that have high-performance fibers exhibit the following typical in-plane properties: a tensile strength of 276 MPa (40 ksi), a tensile elastic modulus of 90 GPa (13×10^6 psi), and a CTE of 1.4×10^{-6}°C^{-1} (0.8×10^{-6}°F^{-1}).

Matrix Inhibition. Carbon begins to oxidize at measurable rates at approximately 371 °C (700 °F). Carbon-carbon composites exhibit high internal surface areas due to the porous nature of the structure (typical levels of interconnected porosity are 10 to 15%). Adding inhibitor phases to the matrix has become an important facet of an overall oxidation protection system, because inhibitors allow some control of oxidation that can occur through defects in coatings. Inhibitors can also prevent catastrophic oxidation failure due to coating spallation at high temperatures.

Additions of boron, boron compounds, and phosphorus compounds have been effective in protecting carbon bodies (Ref 38, 39, 40, 41 , 42, and 43) by true chemical inhibition and by formation of internal and external glass layers that act as diffusion barriers. The practice of making boron additions to carbon-carbon for improved oxidation resistance was first disclosed in a 1978 patent (Ref 44). Since that time, many improvements and variations on this theme have been reported (Ref 45, 46, 47, 48, 49, 50, 51, 52, 53, and 54).

Internal chemical modifications can be made either by mixing the carbonaceous and nonoxide inhibitor powders and consolidating the constituents to form the carbon body, or by impregnating the porous body with liquids that contain the inhibitors, usually in oxide form. Boron and many nonoxide boron compounds are quite refractory, so the powder mixing and carbon processing route has often been used (Ref 41, 42, and 43). In composite fabrication, submicron refractory compound additives are normally carried within impregnating resins and are dispersed through the fiber tows as well as between the fabric plies.

Coating Selection Principles. The most critical component of any coating architecture is the primary oxygen barrier. The oxygen barrier prevents oxygen ingress to the underlying composite by providing a physical

permeation barrier and, in some cases, by gettering oxygen in the process. The critical parameters that guide the selection of the oxygen barrier are its oxidation characteristics, CTE, and inherent oxygen permeability. A material that forms an adherent, low-permeability oxide scale is preferred as an oxygen barrier because it oxidizes slowly and has the potential to self-heal. An Arrhenius plot of rate constants for oxidation of refractory materials typically considered for coating applications (Ref 55, 56) is presented in Fig. 7. Scale growth as a function of time can be estimated from Fig. 7 using the relationship $x^2=Kt$, where x is the scale thickness, K is the parabolic rate constant, and t is time in hours. The silicon- based ceramics exhibit substantially lower oxide growth kinetics than the aluminum-, hafnium-, or zirconium-based ceramics. Time and temperature of service dictate material selection and coating thickness. However, from the standpoint of forming thin protective scales in thermal cycles with peak temperatures in the range of 1400 to 1700 °C (2550 to 3090 °F), only Si_3N_4 and SiC exhibit sufficiently low-rate constants for oxide growth over extended time periods.

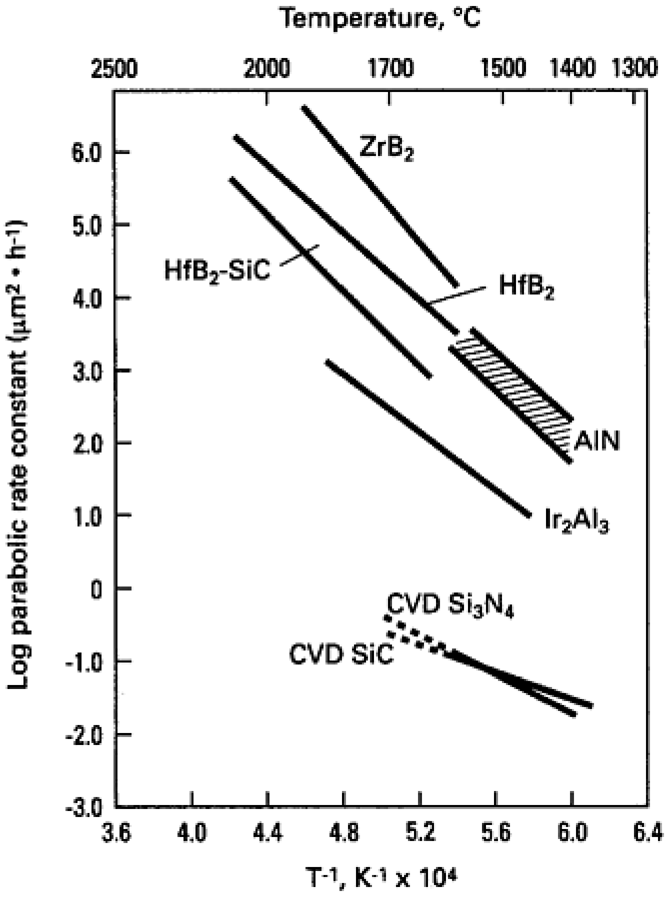

Fig. 7 Oxidation kinetics of refractory materials. CVD, chemical vapor deposition

Figure 8 compares the thermal expansion behavior of refractory coating candidates with that measured for high-performance, fabric-reinforced carbon-carbon (Ref 55, 56, and 57). The expansion of carbon-carbon in the in-plane directions is substantially lower than that for any of the refractory ceramics. This expansion difference, coupled with the high modulus of the refractory materials, results in significant thermal mismatch stresses when they are employed as coatings.

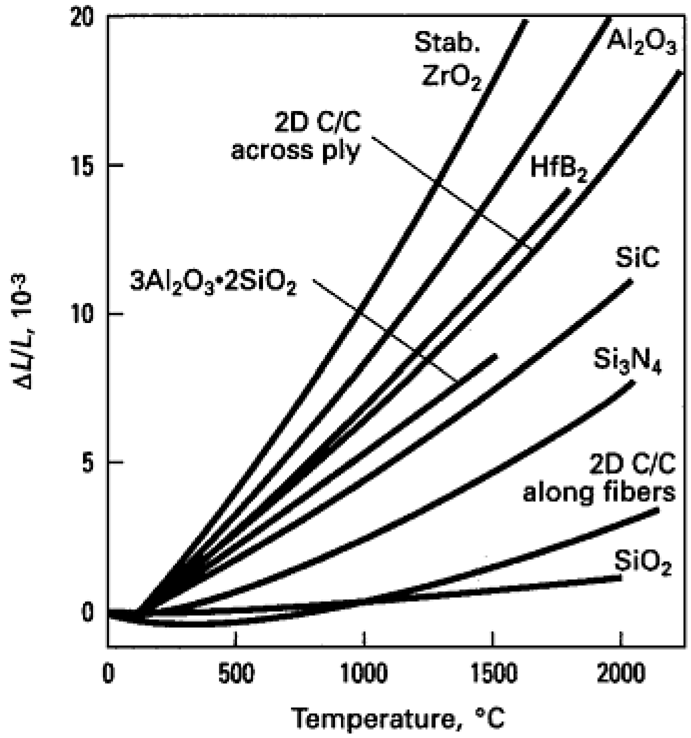

Fig. 8 Thermal expansion characteristics of ceramics and carbon-carbon laminates. 2D, two-directional; C/C, carbon-carbon laminae; *L*, specimen length

The properties of refractory materials that have been used in deposition studies are summarized in Table 2. Figure 9 presents the thermal stresses calculated as a function of temperature when these coatings were deposited onto high- performance, two-dimensional carbon-carbon laminates. For the refractory ceramics, Si_3N_4 provides the lowest thermal mismatch stresses of any of the ceramic coating candidates, but these stresses are still high enough to cause cracking. Therefore, it is usually found that deposited ceramic coatings exhibit microcracking and that the crack pattern depends on the coating thickness and deposition temperature. Iridium metal deposited by electron beam physical vapor deposition techniques can have low thermal mismatch stresses upon cooling. However, such a coating must then be able to withstand extremely high compressive stresses upon heating. In previously reported work (Ref 56), it has been shown that iridium-based coatings deposited by this technique onto high-performance carbon- carbon fail by compressive spalling at elevated temperatures.

Table 2 Properties of refractory materials deposited on carbon-carbon composites

Material	**Deposition process**	**Deposition temperature**		Bulk properties				
				Modulus		**Poisson's ratio**	CTE (20–1900 °C)	
		°C	**°F**	**GPa**	**10^6 psi**		**10^{-6}/°C**	10^{-6}/°F
SiC	CVD	1050	1920	448	65	0.19	5.2	**9.4**

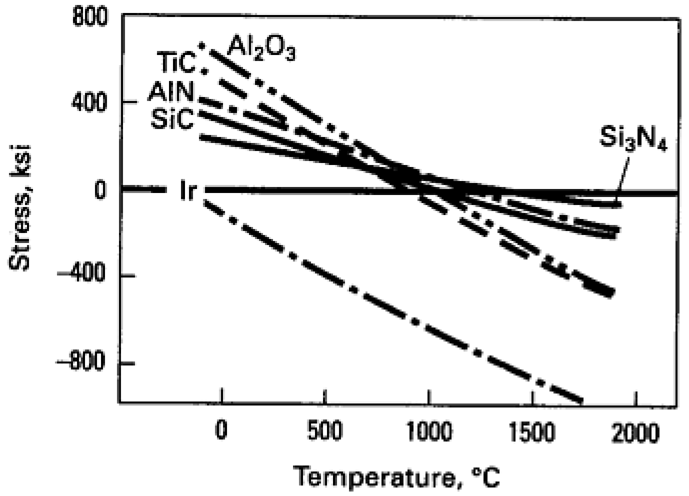

Fig. 9 Calculated thermal stresses for thin coatings on high-performance carbon-carbon laminates. Ratio of substrate thickness to coating thickness = 20.

Preferred Coating Approaches

Coating approaches are dictated by application requirements and fundamental behavior. Generally speaking, SiC- and Si_3N_4-based coatings have found broad use at temperatures below 1700 °C (3090 °F) because of minimum thermal mismatch stresses and low oxide-scale growth kinetics. In the higher temperature range, 1700 to 2200 °C (3090 to 3990 °F), refractory carbides and borides have been used for short time periods. Coating deposition techniques that have been used include pack cementation, CVD, and slurry processes. Coating architectures are normally built using combinations of these techniques. In the following sections, typical coating architectures are discussed in accordance with the process used to deposit the primary oxygen barrier.

Pack Cementation. The coating system used on the Shuttle Orbiter vehicle is the preeminent example of the use of a pack process to create an oxidation protection system for carbon-carbon (Ref 25). In this process, the carbon-carbon part is packed in a retort with a dry pack mixture of alumina, silicon, and SiC. The retort is placed in a furnace, and under argon atmosphere a stepped time-temperature cycle is used to activate conversion of the carbon-carbon surface to SiC. Peak process temperature is approximately 1760 °C (3200 °F). This creates a porous SiC surface nominally 1.0 to 1.5 mm in thickness. Multiple impregnation and curing with an acid- activated tetraethoxysilicate liquid produces SiO_2 coating of the porous surfaces. A surface sealant consisting of a mixture of a commercial alkali silicate bonding liquid filled with SiC powder is then applied.

This system was designed to provide protection during multiple reentry cycles where surface temperatures of 1540 °C (2800 °F) are anticipated. The success of the shuttle missions and further testing (Ref 23, 24, and 25) have proven this to be an effective approach for low-performance rayon-based composites. Attempts to use similar coatings modified with boron (Ref 58, 59) for other aerospace applications requiring high-performance carbon-carbon have met with only limited success.

Chemical Vapor Deposition. Attempts to expand carbon-carbon use to turbine engine hot- section and exhaust components fostered the need for protective coatings that could be applied as thin layers over the structural components without compromising mechanical performance. The coating architectures developed have been dependent on the application lifetime as well as on dynamic or static structural requirements. The CVD coatings are normally applied in multiple cycles to ensure even deposition rates over curved surfaces. A substrate pretreatment is normally used to enhance adherence. Silicon nitride overlay coatings have been shown to be effective for limited-life (<20 h) cycles where heating above the deposition temperature occurs rapidly and peak temperatures reach 1760 °C (3200 °F) (Ref 55, 56, and 60). For these coatings a thin reaction layer of SiC (formed in a pack process, of the order of 5 μm) has been used as a reaction barrier and to enhance adherence. The Si_3N_4 has been applied in thicknesses ranging from 125 to 250 μm (0.005 to 0.010 in.) in a multiple-step process.

Other applications require that carbon-carbon withstand hundreds of hours of exposure to peak temperatures in the range of 1400 to 1500 °C (2550 to 2730 °F) and undergo thermal cycling to temperatures in the range of

600 to 1200 °C (1110 to 2190 °F). In these extended-life applications, a boron-rich inner layer is used to provide a glassy phase to seal microcracks in the outer coatings. Elemental boron, B_4C, and combinations of boron compounds mixed with SiC or silicon are inner layer approaches. These layers are deposited in thicknesses normally in the range of 25 to 50 μm (0.001 to 0.002 in.) using CVD, conversion of the carbon surface, and slurry coating (Ref 61, 62, and 63). Depositing SiC or Si_3N_4 by CVD is the preferred method to provide hard, erosion-resistant surfaces that cover the boronated inner layers and inhibit vaporization of borate glass sealants (Ref 64, 65). Overlay thicknesses in the range of 200 to 300 μm (0.008 to 0.012 in.) are normally deposited in a multiple- step process. A typical coating architecture on an inhibited composite is shown schematically in Fig. 10.

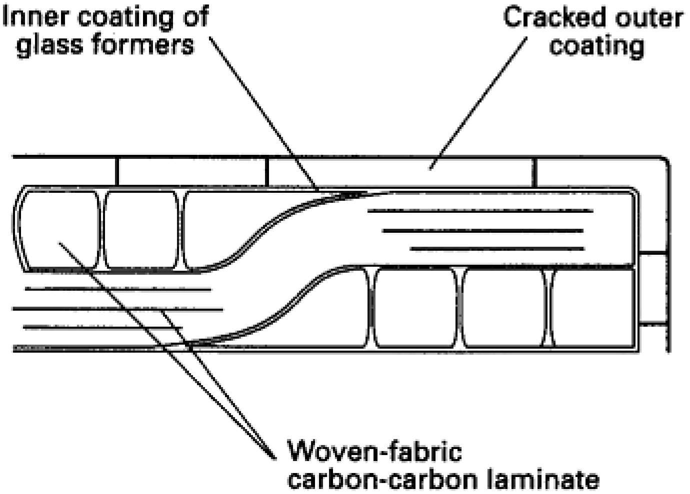

Fig. 10 Schematic of coating architecture used to protect carbon-carbon for extended-life applications

Silicate glazes are frequently applied to fill the microcrack network existing in SiC and Si_3N_4 coatings. Although the glaze is applied externally and is susceptible to vaporization and physical removal, it has been shown to improve cyclic oxidation lifetimes. Glaze overcoats are normally applied as aqueous sols incorporating boron and silicon that can be painted, sprayed, or dip coated. Typical processing involves air drying and firing above 1038 °C (1900 °F) in an argon atmosphere (Ref 64). The glaze can be periodically replenished.

Slurry coatings are produced by dispersing appropriate ceramic or metal powders in a liquid vehicle to make the slurry, applying the slurry as a paint to the component surface, evaporating or gelling the liquid to harden the coating, and then heating to a high temperature to stabilize and densify the coating. Slurries are applied by brushing, spraying, or dipping. The liquid can be water or volatile organics with organic binders in solution, inorganic or organic sols or solutions that form oxides, or thermosetting preceramic polymers or polymer solutions (Ref 66, 67).

Hardening produces a coating composed of powder particles, bound together and bonded to the substrate by the solid that is precipitated or condensed from the liquid. Heating to a high temperature decomposes the binder phase to form carbon or a ceramic. The shrinkage associated with binder decomposition and incomplete solid-state sintering of the powder particles produces a cracked, porous, and often weakly bonded coating unless a flowable and wetting liquid is formed by one of the constituents. This can be a glass, molten metal, or ceramic melt.

Coatings meant to provide oxidation protection for graphite and CCC articles at temperatures below 1000 °C (1830 °F) often contain large amounts of boron in the form of elemental boron, B_4C, BN, metal borides, or B_2O_3 (Ref 68, 69). Employing B_2O_3 glass provides a wetting liquid at low temperatures on initial heating, and the nonoxides rapidly oxidize in use to produce the same result. Coatings composed mostly of refractory oxide particles bound together with small amounts of borate glass have shown utility at temperatures in the range of 1200 to 1500 °C (2190 to 2730 °F) in configurations where evaporation of the B_2O_3 is inhibited (Ref 47). When such coatings are made, the boron can be present in the powder constituents, the liquid vehicle, or both. Water or alcohol solutions of boric acid and liquid boron alkoxides are often used (Ref 47, 53). Solutions of preceramic boron polymers are also a possibility (Ref 70, 71).

Slurry coatings meant for higher temperatures, in which borates are replaced by glassy alkali silicates or aluminum phosphate, are prominent (Ref 37, 58). The use of siloxane fluids as preceramic polymers has also been disclosed (Ref 72). Converting the carbon surface to SiC is often recommended as a pretreatment to ensure the adherence of glassy borate, silicate, and phosphate coatings (Ref 37, 58).

The bonding and densification of slurry coatings with molten metal and melted ceramic phases have been used to produce protective layers with intermediate to very high temperature capabilities. Dense, very adherent coatings capable of extreme-temperature service can be made from paints containing fine refractory boride particles (Ref 30). The coatings are fully stabilized by heating the borides in contact with the carbon surface to temperatures over 2000 °C (3630 °F) in an inert environment to form a boride-carbon eutectic liquid. Coatings made by melting certain combinations of metal powders and reacting these with the carbon surface to form refractory carbides (Ref 73) are protective to 1800 °C (3270 °F). Work of this type (Ref 74), using a mixture of silicon, hafnium, and chromium powders reacted with the carbon surface at 1450 °C (2640 °F), has produced carbide coatings that provide excellent oxidation protection for short times at 1200 °C (2192 °F).

Other Methods. Coatings have been applied using other techniques, including sputtering and plasma spraying. Plasma spraying has been used successfully to coat CCCs with HfC, with the goal of improving surface hardness and erosion or corrosion resistance (Ref 75). Mechanical properties of the composites are retained after a thermal treatment under vacuum of 2h at 1000 °C (1830 °F).

Practical Limitations of Coatings

As mentioned above, CCCs can be used as structural materials to at least 2200 °C (4000 °F). At the time of this writing, viable coating concepts to match this capability have not been consistently demonstrated, especially for times greater than a few hours. Silicon carbide and Si_3N_4 are limited thermodynamically to temperatures of approximately 1800 to 1815 °C (3270 to 3300 °F). At higher temperatures, the SiO_2 layers that form and protect these materials are disrupted by CO and N_2 interfacial pressures that become greater than 10^{-1} MPa (1 atm), causing the coatings to erode by uncontrolled oxidation (Ref 56, 57). Use of more refractory materials such as HfC or HfB_2 is limited by the very rapid oxidation rates pointed out in Fig. 7. Rapid conversion of these films to high-expansion oxides leads to severe spallation in thermal cycles. Thus, above approximately 1760 °C (3200 °F), coating lifetimes are currently limited to a few hours.

For the range of applications where coating architectures incorporating borate sealant glasses are used, coating use temperatures are limited to approximately 1500 to 1550 °C (2730 to 2820 °F). When B_2O_3 contacts carbon at atmospheric pressure, the CO reaction product pressure exceeds 10^{-1} MPa (1 atm) at approximately 1575 °C (2870 °F). Borate glasses also cause dissolution of the protective SiO_2 scale forming on SiC or Si_3N_4, leading to more rapid corrosion because of the high oxygen permeability of the mixed glass. Experience in test cycles with peak temperatures about 1400 °C (2550 °F) has shown that accelerated dissolution of coatings along microcrack boundaries eventually causes gross oxidation of boron-based inner layers, leading to massive dissolution of the silicon-based overlays.

Moisture sensitivity of borate glasses (Ref 76) can be a major limitation. Hydrolysis at low temperatures in moist air converts adherent B_2O_3 containing layers into loosely bonded boric acid particulate. Under long-term exposure, sealant glasses forming beneath the hard overlays undergo moisture attack that leads to spallation. Subsequent heating cycles that rapidly release moisture can cause catastrophic failure. Finally, high-temperature exposure to moist environments makes borate glass susceptible to vaporization by the formation of HBO_2 (Ref 53).

Processing of Carbon-Carbon Composites

Joining

Various aerospace systems, currently in the development stage, make use of structures and components that are fabricated from CCCs and monolithic graphite materials. These proposed systems use carbon-based materials for ground- and space-based interceptor propulsion components, satellite structural components, space truss structures, and hypersonic vehicle propulsion and skin assemblies. In all cases, advanced joining methods need to be developed in order to fully exploit the capabilities of the CCCs and graphite materials and to obtain the performance characteristics desired. During the last half decade, technological advancements in CCCs and their product forms have made the issue of component assembly and joining methods ever more important.
Depending on the specific application, joints accomplished by brazing methods can have a number of advantages over mechanically fastened joints, including:

- The size and weight of brazed assemblies can be significantly less.
- Brazing permits the use of designs involving small, compact, multipart components.
- The use of high-temperature braze materials allows components with brazed joints to function at higher operating temperatures.

Components assembled by brazing methods have been designed primarily for various rocket propulsion applications, including hot gas valve component joints and injector/thrust-chamber joints. Joining schemes for assembly of CCC parts for the national aerospace plane have also been developed, as have joining schemes to allow use of CCC and graphite armor tiles in the large vacuum vessel/plasma chamber for the Doublet 3 fusion research device (Ref 77).

These applications represent a wide range of operating temperatures, so a number of different braze materials and techniques have been developed in order to achieve system design requirements and enhance the capabilities of the joined components. Some of the materials investigated for brazing CCC and graphite include silver- based filler metals, gold-based filler metals, zirconium metal, hafnium metal, and hafnium diboride/hafnium carbide powder mixtures. Other researchers have investigated brazing and diffusion bonding of CCC using titanium metal, silver-based filler metals, copper-based filler metals, various silicides ($MoSi_2$, BSi_2, and $TiSi_2$), and various proprietary materials (Ref 78, 79, 80, and 81).

For moderate-temperature applications, both silver- and gold-based braze filler metals have been used to join CCC panels to other CCC panels and to join graphite materials to refractory metals. Typical brazing temperatures have ranged from roughly 800 to 1250 °C (1470 to 2280 °F) for such applications. For high-temperature applications, zirconium braze materials have been used successfully with both CCC and graphite materials; typically, braze temperatures of approximately 1850 °C (3360 °F) have been employed. Finally, for very high-temperature applications, joints have been fabricated using both hafnium metal and HfB_2 powder braze materials to join both CCC and graphite materials; brazing temperatures of approximately 2200 to 2550 °C (3990 to 4620 °F) have been used. These braze material/operating temperature combinations are summarized in Table 3.

Table 3 Carbon-carbon and graphite joining

Primary substrates joined	**Operating temperature**	**Braze material**	Temperature for initiation of melting	
			°C	°F
Graphite to refractory metal	Moderate	Silver, copper, titanium alloy	780	**1435**
Graphite to refractory metal	Moderate	Gold, palladium alloy	1190	**2175**
C-C to C-C, and graphite to graphite	High	Zirconium	1823	**3315**
C-C to C-C, and graphite to graphite	Very high	Hafnium	2180	**3955**
C-C to C-C, and graphite to graphite	**Very high**	**HfB_2, with and without HfC**	**2260**	**4100**

Source: Ref 77

Metals suitable for joining CCCs by graphite formation are those that react with carbon to form a carbide that decomposes upon heating to higher temperatures, leaving a metal-free carbon-carbon joint (Ref 82). However, metals with high vapor pressures, which readily oxidize at very low partial pressures of oxygen, and/or which form carbides that dissociate at very high temperatures (>2000 °C, or 3630 °F), seem to be unsuitable as interlayers for joining by this method.

One study (Ref 83) used brazing and solid- state diffusion bonding of three-dimensional CCC with silicon, Si_3N_4, SiB_4, boron, and $TiSi_2$ joining materials. The primary criteria for selecting these systems were:

- These materials and their carbides possess desirable high-temperature mechanical properties and thermal stability at temperature ranges greater than 1038 °C (1900 °F) and less than 1928 °C (3502 °F).
- Elements with low atomic numbers are involved in these systems.
- Joining by solid-state diffusion bonding and carbide formation was expected to be possible.
- Joining temperatures below 2205 °C (4000 °F) were expected.

The first three materials (silicon, Si_3N_4, and SiB_4) produced no bonding or very weak bonds. Thus, it was determined that only the latter two systems (boron and $TiSi_2$) were suitable for producing joints of sufficient

shear strength (γ> 3.4 MPa, or 0.5 ksi). Due to the difficulty of melting the boron interlayers, only solid-state diffusion bonding with boron was studied.

The optimum conditions for joining were determined to be 1995 °C (3625 °F), 15 min, and 7.2 MPa (1 ksi). The shear strengths of the joints made under optimum conditions increased with the testing temperature from an average value of 5.8 MPa (0.8 ksi) at room temperature to 18.1 MPa (2.6 ksi) at 1660 °C (3020 °F). $TiSi_2$ exhibited excellent wettability and penetrability during the brazing operations. The optimum temperature for brazing was 1490 °C (2715 °F). The maximum shear strength of an optimum joint was 406 MPa (59 ksi) at 1165 °C (2130 °F). The strength decreased at lower test temperatures, and at ambient temperature the average joint shear strength was 15.4 MPa (2.2 ksi) (Ref 83).

Another study investigated the solid-state diffusion bonding of CCCs by using boride and carbide interlayers (Ref 84). The maximum joint strength was achieved for CCCs bonded at 2000 °C (3630 °F) with a 2:1:1 mole ratio of titanium, silicon, and B_4C powders. These powders reacted in situ to produce interlayers of TiB_2+ SiC + B_4C. The joint shear strength increased with temperature, from 8.99 MPa (1.3 ksi) at room temperature to an average value of 14.51 MPa (2.1 ksi) at 2000 °C (3630 °F).

Properties of Carbon-Carbon Composites

Carbon-carbon composites have many of the desirable high-temperature properties of conventional carbons and graphites, including high strength, high modulus, and low creep. In addition, the high thermal conductivity and low CTE, coupled with high strength, produce a material with low sensitivity to thermal shock. Also characteristic of CCCs are a high fracture toughness and a pseudoplasticity, the latter of which bears a resemblance to fiber-reinforced polymers. These attributes make CCCs uniquely useful at temperatures as high as 2800 °C (5070 °F). The major problems have been high-temperature oxidation and off-fiber-axis properties.
Unidirectional CCCs can approach the same strengths and moduli as those achieved with resin matrix composites. Moreover, because their properties are maintained to 2000 °C (3650 °F), they represent the premier material for inert atmosphere or short-time high-temperature applications. Table 4 shows typical mechanical properties of unidirectional CCCs.

Decisive influences on the mechanical, thermal, and electrical properties of CCCs come from the fiber type, fiber volume fraction, fiber architecture, precursor, and processing cycle (Tables 5– 7). With an increasing number of redensification cycles, porosity decreases and density, strength, and stiffness increase (Fig. 11). The final heat treatment temperature influences fracture behavior and physical properties such as the CTE, resistivity, and conductivity (Table 7).

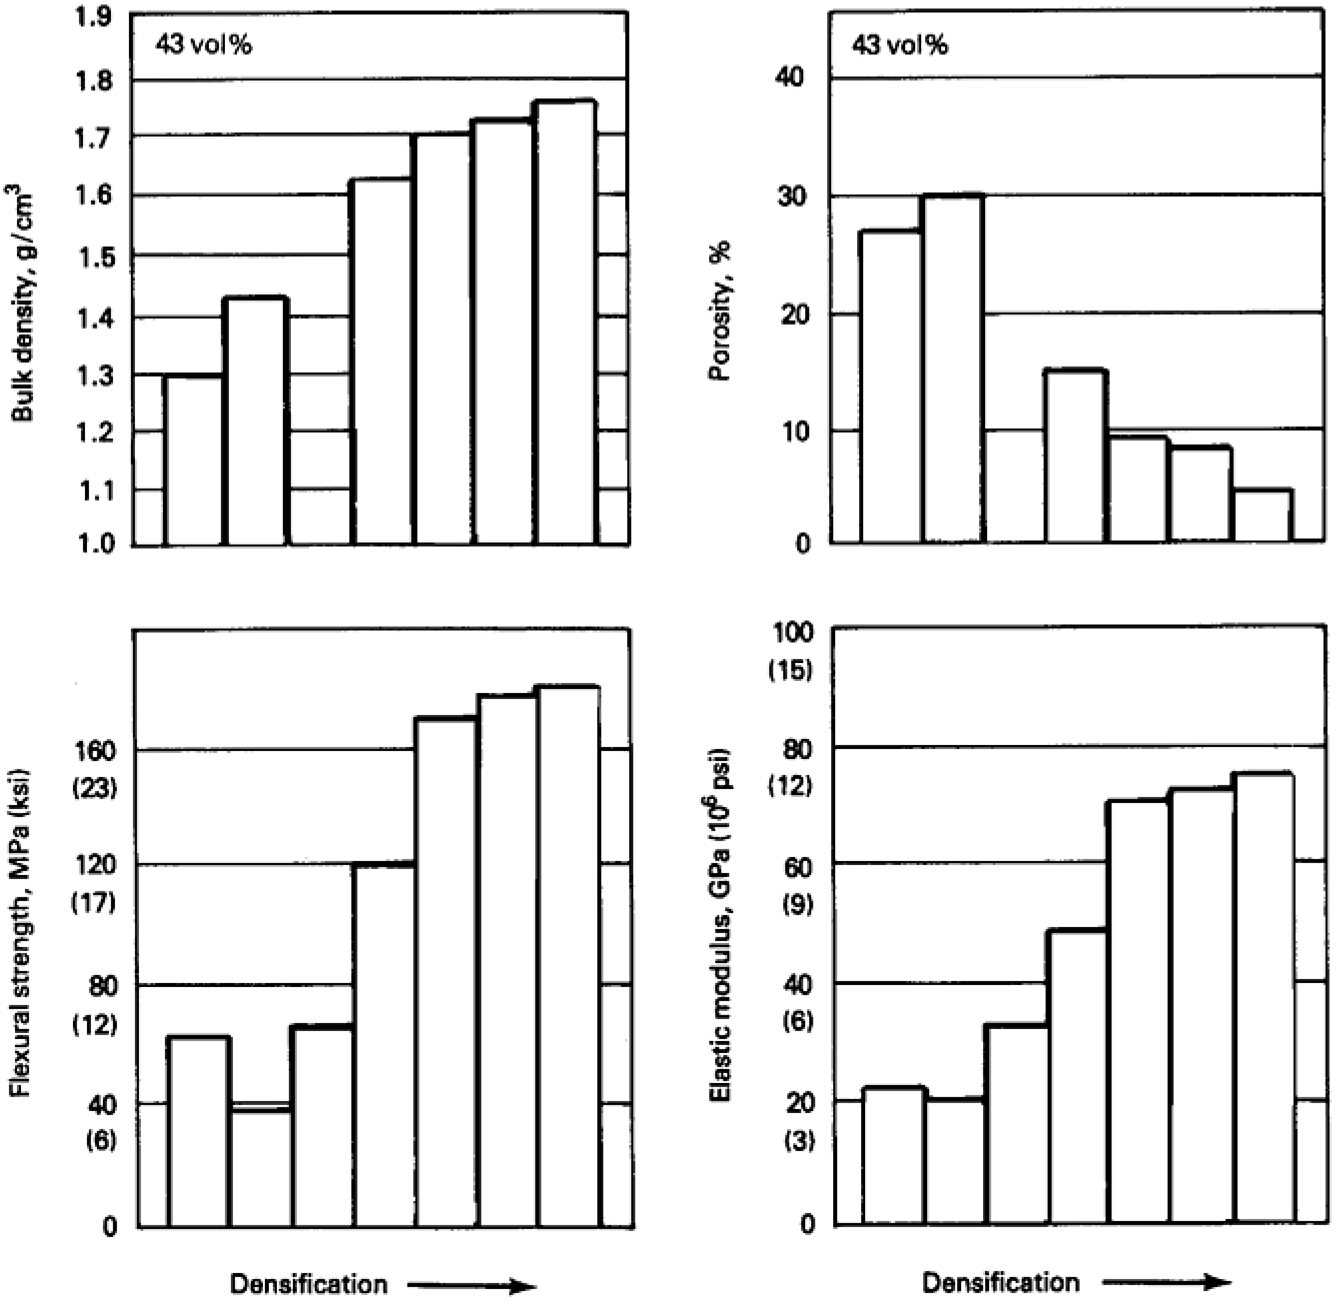

Fig. 11 Change of properties with number of redensifications (two-directional weave, 8 harness/satin)

All properties of CCCs are anisotropic. This originates from the carbon fibers, which are extremely anisotropic because of their graphite crystal lattice. Along the fiber axis, stiffness, strength, and electrical and thermal conductivity are excellent. Across the axis, these properties are poor. In the case of two-directional reinforcement, the ratio of anisotropy amounts to between 5/1 and 10/1.

The flexural strength of industrially manufactured CCCs with different fiber architectures varies between 100 and 600 MPa (15 and 90 ksi) (parallel to the laminates/fibers). A characteristic feature of carbon-carbon materials is that the ratio of flexural/tensile strength is 1/1.4. Wound tubes with fiber angles of ±15° and ±45° (normal to the axis) exhibit tensile strength values of 540 MPa (80 ksi) and 430 MPa (60 ksi), respectively. The strength values of three-directional reinforced weave structures range from 150 to 300 MPa (22 to 44 ksi). The strengths of felt and randomly oriented short fiber reinforcements are between 50 and 100 MPa (7.5 and 15 ksi). Fatigue behavior is very attractive. Under alternating flexural loads, 70 to 80% of the ultimate flexural strength is still available (Ref 86, 87). Moduli values range from 40 to 150 GPa (6 to 22 × 10^6 psi) for two-directional and three- directional weaves, respectively. Besides the fiber type and orientation, the type of matrix precursor and the final heat treatment temperature decisively influence the modulus value. If the graphite layers of the

matrix are oriented parallel to the fiber axis, then they can contribute to the composite modulus nearly in the same order of magnitude as the fibers.

A high-temperature strength capability is attractive for many structural applications. Although other high-temperature materials significantly lose strength at temperatures greater than 1300 °C (2370 °F), carbons and graphites keep their mechanical properties up to 2000 °C (3630 °F) (Ref 88). Ongoing tests clearly show increasing values up to the testing temperature of 1600 °C (2910 °F) in an order of magnitude of 40 to 50% (Ref 89), as shown in Fig. 12. The interlaminar shear strength increases about 70% (from room temperature to 1800 °C, or 3270 °F), and the modulus increases approximately 10%.

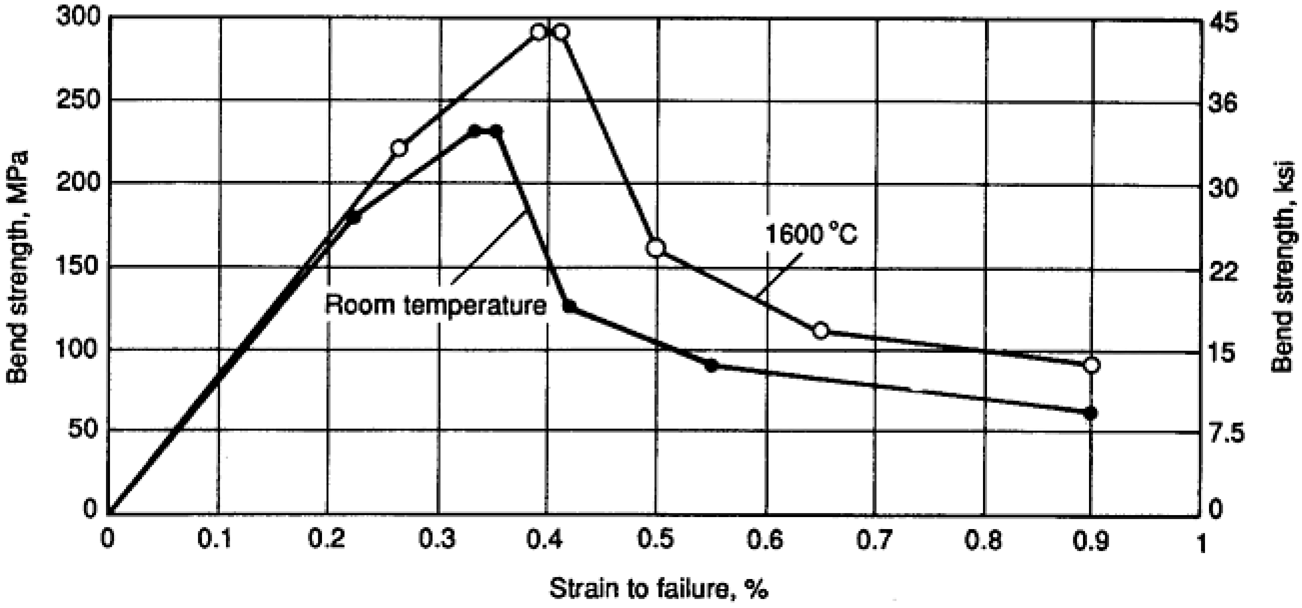

Fig. 12 Comparison of bend strength at room temperature and 1600 °C (2910 °F) (two-directional weave, 8 harness/ satin in inert atmosphere)

The physical and thermophysical properties of CCCs are also of great interest for specific applications. In one direction, along the fibers or laminates, the material acts as a heat conductor, but in the other direction (across) it acts as an insulator. The processing history of the composites is important to the final property values. Graphitization treatment increases conductivity and decreases resistivity (Table 7). This is still more pronounced if graphitizing matrices, such as pitch-based carbon or pyrolitic graphite, are used. In three-directional and multiaxial structures, the properties are balanced to a more isotropic behavior. However, the ratio of isotropy is dependent on the balance of fiber volume fraction in the *x*, *y*, and *z* directions. At high temperatures, electrical resistivity decreases and the composites show negative thermal conductivity behavior. Thermal conductivity also drops with higher temperatures.

Thermal expansion parallel to the laminates of two-directional CCCs is negative up to 800 °C (1470 °F). Across the laminates, a positive CTE is present. In general, however, the CTE data are low and can be tailored by the fiber architectures to a balanced expansion of nearly zero in the plane (Fig. 13).

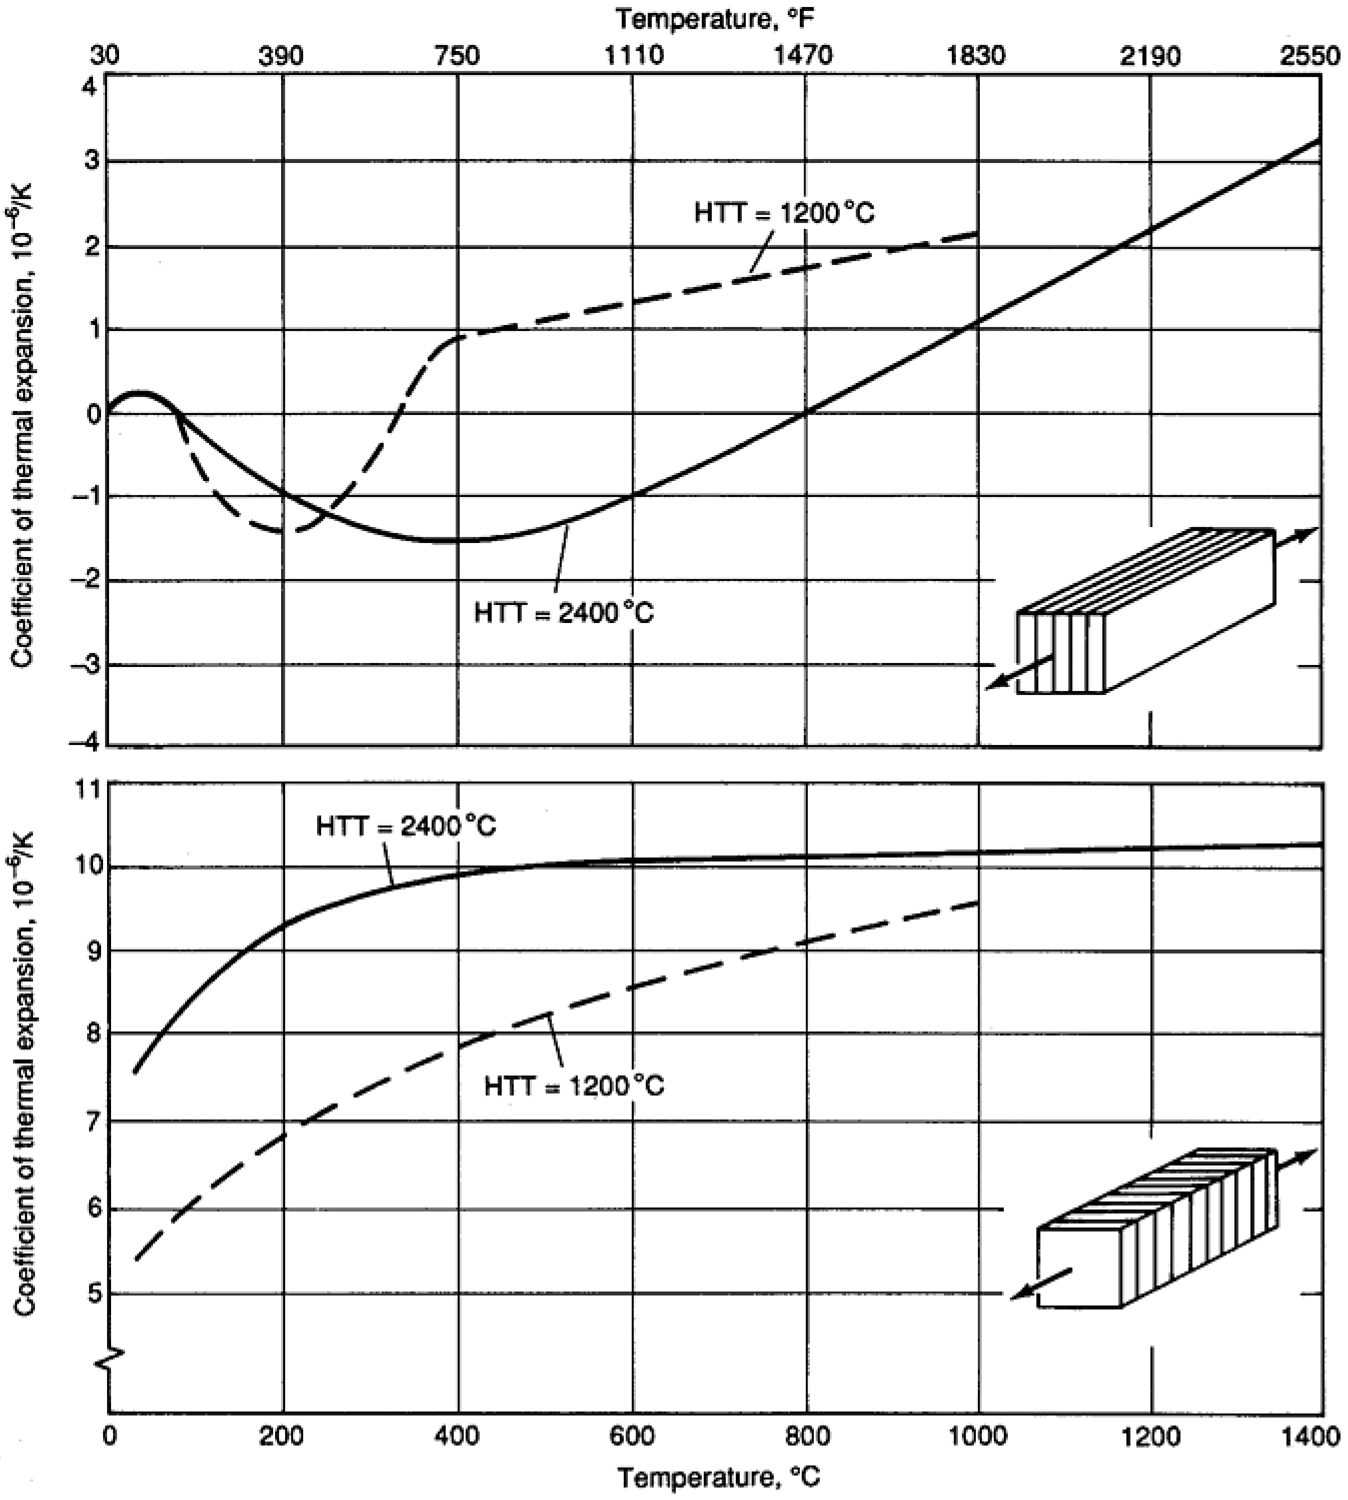

Fig. 13 Coefficient of thermal expansion, parallel and perpendicular to laminates of two-directional weave carbon- carbon composite with final heat treatment temperature (HTT) of 1200 and 2400 °C (2190 and 4350 °F)

Fracture Behavior. High fracture toughness values and pseudoplastic fracture behavior are most attractive for numerous applications. Both brittle, catastrophic failure by overstressing and critical stress concentrations at notches can be excluded. This high damage tolerance can be demonstrated by nailing a composite. No catastrophic, brittle failure occurs as one might expect for ceramic materials. Only the area around the nail shaft is delaminated. Bend tests on three- directional composites have shown enormous strains, up to 5% (Ref 90). The reasons originate from the complex minimechanical and micromechanical behavior of the several interfaces that are present in a CCC: fiber-fiber, fiber-matrix, and matrix-matrix interfaces (Ref 91). The crystalline structure of the matrix itself also influences toughness (Ref 92, 93). The micromechanics are not yet fully understood, but weak interfacial bondings seem to be a precondition for producing tough CCCs (Ref 1,

94). Bonds between fiber and matrix that are too good induce excessive damage and promote fast crack propagation through the fibers. The composite fails in a brittle mode, and no strengthening effect is achieved. The mechanism of load transfer is not well understood, either, but if the interfacial forces are low, no brittle fracture occurs. Because the shear and transverse strengths are very low, one could assume that the loads are transferred across the interfaces primarily by friction. In addition, mechanical interlocking of cracked matrix parts and particles can occur.

One can also assume that microcracking is still in service when loads are applied on the composite. However, the debonded and weak interfaces avoid the crack propagation through the fibers. The energy dissipation is additionally promoted by poorly bonded matrix-matrix interfaces, which act as a type of "duplex mechanism" (Ref 95) and increase the fracture toughness.

The influence of the graphitic matrix structure on toughness values was demonstrated in model experiments (Ref 96). Three-directional billets were graphitized to different extents to produce matrix structures that ranged from slightly to highly graphitic. In Fig. 14, the ability of the matrix to absorb energy is expressed as relative toughness. The maximum is reached at 2400 °C (4350 °F). The explanation for this is given by different lamellar structures of the pitch-based matrix. Less ordered microstructures allow crack propagation over long distances along the filaments, and energy dissipation is low with consequent low toughness. At 2400 °C (4350 °F), an intermediate stage exists where the microstructure is sufficiently ordered to accommodate some slip from shear forces, but is disordered enough to prevent long-range slip. Energy absorption and, therefore, toughness are high. A good graphitic order of the matrix decreases against toughness, because there is more extensive microcracking in the matrix and the chance for multiple fracturing is the greatest.

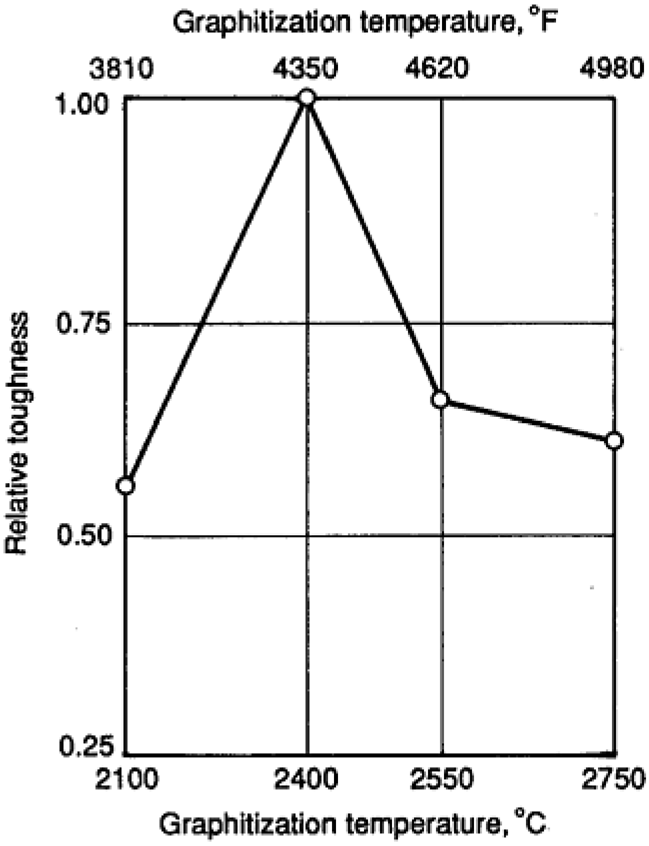

Fig. 14 Relative toughness as function of graphitization temperature (pitch-based matrix, three-directional, carbon-carbon). Source: Ref 97

Oxidation of CCCs can begin at temperatures as low as 400 °C (750 °F). The rate of oxidation depends on the perfection of the carbon structure and its purity. Highly disordered carbons, such as carbonized resins given low-temperature heat treatments, oxidize at appreciable rates at 400 °C (750 °F). Highly graphitic structures, such as pitch-based carbon fibers, can be heated as high as 650 °C (1200 °F) before extensive oxidation occurs. At these low temperatures, carbons are very susceptible to catalytic oxidation by alkali metals, such as sodium, and multivalent metals, such as iron and vanadium, at extremely low concentrations. Therefore, the oxidation rate often is determined by the initial purity of the CCC or by in-service contamination. Borates and particularly phosphates have been found to inhibit oxidation up to about 600 °C (1110 °F) (Ref 98). Oxidation at higher

temperatures becomes more rapid, and by 1300 °C (2370 °F), it is completely limited by mass transport of oxygen to the surface and transport of carbon monoxide and dioxide away from the surface.
Carbon-carbon composites can be attacked by strongly oxidizing acids, but they are inert to most other acids and to all alkalis, salts, and organic solvents.

Introduction to Post-Processing and Assembly

Flake C. Campbell, The Boeing Company

Introduction

ONE OF THE PRIMARY ADVANTAGES of composite designs is that they can achieve part- count reductions of up to 60% compared to equivalent metallic designs. However, even with these significant reductions, almost all composite structures require some type of post-processing and/or assembly operations. Since both of these operations add to the total cost of the final product in many instances, it is advantageous to minimize these operations if possible. In addition, many of the post-processing and assembly operations, such as trimming, drilling, and fastening, are more expensive for composites than metals. Trimming requires greater care because dull tools or incorrect feeds can cause heat damage or delaminations. Drilling is complicated by the abrasive nature of carbon fibers that can result in accelerated tool wear and splintering of the surface plies. During assembly, composites will tend to delaminate if excessive force is used to pull out gaps often encountered during assembly.

Introduction to Post-Processing and Assembly

Flake C. Campbell, The Boeing Company

Polymer-Matrix Composites

This Section starts with the overview article “Machining, Trimming, and Routing of Polymer-Matrix Composites.” This article is first because these are typical operations performed after composite curing but prior to other major post-processing or assembly operations. Machining of polymer-matrix composites (PMCs) can be accomplished using either traditional solid tools or with newer technologies, such as abrasive waterjet trimming. Even if traditional methods are used, special tools and parameters are required due to the abrasive nature of carbon fibers and the danger of overheating or delaminating the workpiece. Therefore, the tool materials, geometries, feeds, speeds, and rigidity requirements are generally more stringent and less forgiving than normally encountered in metallic structure.

The next two articles, “Secondary Adhesive Bonding of Polymer-Matrix Composites” and “Processing and Joining of Thermoplastic Composites,” cover major assembly operations. Secondary adhesive bonding can be used either as a structural fabrication process (e.g., for honeycomb structure) or as an assembly method for attachment to other structure. The two critical variables in secondary adhesive bonding are adhesive selection and surface preparation. Adhesive selection is driven by a rather extensive list of variables, such as static and dynamic strength, modulus, temperature capability, and operating environment (e.g., humidity and moisture). Surface preparation is absolutely critical to obtaining a high-strength durable bond. This includes not only the composite parts to be bonded, but also any core materials or metallic details as well.

Thermoplastic composite materials offer potential post-processing advantages compared to thermoset composites. As a natural result of their structure, thermoplastic composites can be reformed into structural shapes after their initial consolidation. In addition, novel joining technologies such as induction welding are available for assembly operations. “Processing and Joining of Thermoplastic Composites” covers the different types of thermoplastic composites, processing methods, thermoforming methods, and joining technologies.

Although secondary adhesive bonding and thermoplastic composite joining processes offer significant cost advantages compared to mechanical assembly, mechanical fastening is and will remain an important assembly method for composite structures. First, in many instances, mechanical fasteners are the only feasible method for assembling composite parts to other major pieces of structure, and second, mechanical fasteners are often the

only reliable method for highly loaded primary structure with complex load paths. Two articles cover this important assembly method for polymer-matrix composites—"Hole Drilling in Polymer Matrix Composites" and "Mechanical Fastener Selection." The article on hole drilling discusses shimming, drilling techniques (manual, power feed, and automated), reaming and countersinking operations, and hole-quality considerations. The article on mechanical fastener selection and installation covers fastener types and considerations, different types of fits, and special fasteners, such as blind fasteners, screws and nutplates, and temporary fasteners. It also covers a number of fastener installation methods and typical equipment.

The last article on post-processing and assembly of polymer-matrix composites, "Environmental Protection and Sealing," covers this important area with discussion of galvanic corrosion, thermal expansion considerations, different sealing methods, and painting. Although this article is the last article in this Section on polymer-matrix composites, environmental considerations and protection systems should be considered early in the design process to ensure success.

Flake C. Campbell, The Boeing Company

Metal-Matrix and Ceramic-Matrix Composites

The final two articles in this Section address post-processing and assembly of metal-matrix composites and ceramic-matrix composites. The article "Extrusion of Particle-Reinforced Aluminum Composites" addresses special considerations involved in extrusion operations for MMCs. The article "Post-Processing and Assembly of Ceramic-Matrix Composites" addresses finishing, coating, joining and other assembly methods, and nondestructive evaluation.

Machining, Trimming, and Routing of Polymer-Matrix Composites

Lawrence F. Kuberski, Fischer U.S.A.

Introduction

POLYMER-MATRIX STRUCTURES are commonly fabricated to near-net shape. Therefore, by far the highest percentage of machining operations are trimming or roughing operations to remove the undesirable edge material from the cured part. Actual machining operations such as milling are used much less frequently, occasionally to mill seal grooves in parts or machine parts for improved fit during assembly.

Thermoset and thermoplastic composite parts are similar in machining characteristics but do exhibit some differences. Both materials contain high-strength fibers in a resin matrix. Both materials require the use of carbide tools, as a minimum, due to the extremely abrasive nature of the carbon reinforcing fibers. Tool wear during machining of thermoplastic composites is actually more severe than when machining thermoset composites. However, the most obvious difference between the two materials is the chip form. Thermoplastics form a folded ribbon type of chip compared to the dust particulate produced by machining of thermoset composites. Both material classes are similar in that they are susceptible to surface and/or exit delaminations, especially when the cutting tool becomes dull.

Lawrence F. Kuberski, Fischer U.S.A.

Machining Operations

A significant amount of work has been conducted to understand the complete machining process; that is, drilling, reaming, routing, trimming, and machining (end milling, slot milling, and facing) of carbon fiber-reinforced epoxy, or carbon/epoxy, thermoset composite materials. Some general guidelines for machining of carbon/epoxy composites are the following:

- Carbon/epoxy is abrasive by nature. Therefore, precautions should be taken to ensure that the carbon/epoxy particulate does not propagate into the precision machine/ground ways of the machine tool. The carbon/epoxy particulates can cause not only premature tool wear but machine wear as well.
- Carbon/epoxy dust can cause electrical components to short out or malfunction. All electronic components should be tightly sealed and have filter systems installed to prevent problems. Since thermoplastic composites generally form chips rather than particulates, electrical problems have not been experienced with these materials.

The aforementioned machining processes can be completed dry (with vacuum) or wet. When machining dry, a vacuum system must be used to collect the dust particulates to prevent them from becoming airborne. The vacuum system normally used is an ultrahigh-efficiency cartridge- type dust collection system providing capacity of 8.5 m^3/min (300 ft^3/min, or CFM, at an external static pressure of 7.5 kPa at 20 °C (30 in. H_2O at 70 °F) with an overall efficiency of 99% down to a 0.5 μm particle size. Even with this high efficiency system, it is imperative to remain vigilant of heat buildup or baking of the carbon epoxy particulate to the cutting tool. This problem can cause catastrophic part failure due to degradation and delaminations.

Enhanced tool life results when these operations are accomplished wet. Typical coolants are tap water or Bio-Cool 500 (Westmont Products, Dallas, TX) mixed at a 20-to-1 ratio, applied as flood. Another very important point for consideration is how the coolant will be recirculated during the machining processes. If the machine is not going to be dedicated to carbon/epoxy machining, then every consideration should be given to an auxiliary tank. This will prevent contamination of the coolant tank of the machine, an important point because dust particulates and not a chip form are generated during machining. The particulates form a sludge clogging filters and impeding coolant flow.

If the machine is not dedicated and an auxiliary tank will be used, the tank should be designed to provide a sludge and filtration system that will ensure adequate particulate-free coolant to be delivered to the cutting tool. This type of system will prevent contamination of the primary coolant delivery system of the machine and will also prevent severe corrosion to internal components.

Machining, Trimming, and Routing of Polymer-Matrix Composites

Lawrence F. Kuberski, Fischer U.S.A.

Cutting Tools For Machining

Solid carbide cutting tools can be used; however, their life is very limited due to the abrasive nature of carbon/epoxy. Slot milling with solid carbide tools is not a cost effective process. During full slot milling of cuts with surface speeds in the range of 30.5 to 46 m/min (100 to 150 surface feet per minute, or sfm), overall tool life was typically less than 914 mm (36 in.) before delaminations occurred on the part surface. In addition,

no conventional coatings, such as titanium nitride (TiN), titanium carbon nitride (TiCN) or titanium aluminum nitride (TiAlN) have proved advantageous for machining carbon/epoxy.

Diamond plated cutting tools offer little advantage over carbide tools when machining carbon/epoxy. This can be best explained with a little understanding of the plating process. The plating process lays down a single layer of bonding material, usually tin. This layer almost encapsulates the diamond particles leaving approximately 10 to 20% of the diamonds exposed. The problem with this type of tool occurs when the tool begins to generate heat during the cutting process. Once the tin bonding layer becomes hot, the diamonds lose adhesion, and, consequently, the tool is left with no cutting edges.

Brazed diamond cutting tools do have a significant advantage over carbide and plated diamond tools. The diamond braze process is also a layer process; however, nickel is used rather than tin and the application temperature is much higher because of the nickel. In addition, bonding of the nickel to the diamond is quite good, requiring only 10 to 30% of the diamond particles to be encapsulated, leaving 70% or more of the diamond exposed for cutting purposes. These tools can be fabricated into a wide variety of shapes and diameters. In selected applications, tools of diameters 50.8 mm (2 in.) and greater can be operated above 1,070 m/min (3,500 sfm) and at 5,080 to 10,160 mm/min (200–400 in. per min, or ipm) feedrate or more. A diamond brazed cutting tool with slots to break up the constant contact of the tool to the part surface is shown in Fig. 1. These slots can also carry coolant to help keep the tool cool, reducing carbon/epoxy buildup on the surface and subsequent delaminations or catastrophic failure.

Fig. 1 Typical diamond brazed cutting tool

Diamond Coated Carbide Tools. The latest thin film diamond coatings have shown good potential for machining carbon/epoxy. However, it is important to point out that the life of these coated tools does not approach the life of solid polycrystalline diamond (PCD) tools. They can be used successfully in the range of 612 m/min (2,000 sfm) with 0.025 to 0.051 mm per tooth (0.001–0.002 in. per tooth, or ipt) feedrate and are substantially less expensive than polycrystalline diamond tools. In addition, they can be used in dry-machining operations, but a high capacity vacuum system is required to keep the carbon/epoxy particulates from becoming airborne. A mist type coolant will prolong the life of these tools if the coolant can be tolerated on the part piece. A typical solid carbide end mill with a thin film diamond coating is shown in Fig. 2.

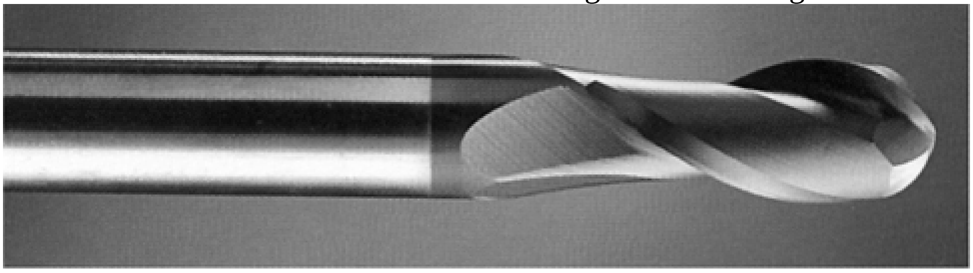

Fig. 2 Solid carbide end mill with thin film diamond coating

Polycrystalline cutting tools have a solid polycrystalline wafer brazed onto a high-speed steel (HSS) or carbide body. These tools present an interesting alternative to conventional cutting materials, such as carbides and brazed or plated tools, combining a very hard and wear resistant solid-diamond cutting edge. In many cases, their higher cost can be justified. Under certain conditions it is not unusual to experience 30 to 50 times longer tool life of solid carbide tooling. The main drawback to PCD tools is that the diamond is fragile and prone to chipping and breakage. They cannot be handled the way HSS, carbide, plated, or brazed tools are handled. Due to the fragile nature of these tools, extremely rigid setups, such as automated machine tools, are required.

Polycrystalline diamond tools can be operated at the higher surface speeds similar to brazed diamond tooling. However, polycrystalline tools have flutes rather than multiple cutting edges. Therefore, the surface finish obtained will be somewhat dependent on the feed rate or advance per revolution. Surface finishes of 40 R_a or better have been achieved.

Lawrence F. Kuberski, Fischer U.S.A.

Peripheral Milling

The cutting tool materials used for slot machining are also applicable to peripheral milling. Because the tool is not in constant contact with the workpiece, it is possible to achieve higher surface speeds during peripheral milling. However, increasing the surface speed also increases the incidence and severity of possible surface delaminations. Tool wear in all of these operations will cause delaminations and costly rework. Therefore, a thorough knowledge of the process and predictable tool life is extremely important to the end user. Ideally the surface produced by milling, routing, drilling, or countersink should be free of delaminations, as shown in Fig. 3. This carbon/epoxy sample had three machining operations performed–drilling, countersinking and milling of the top surface.

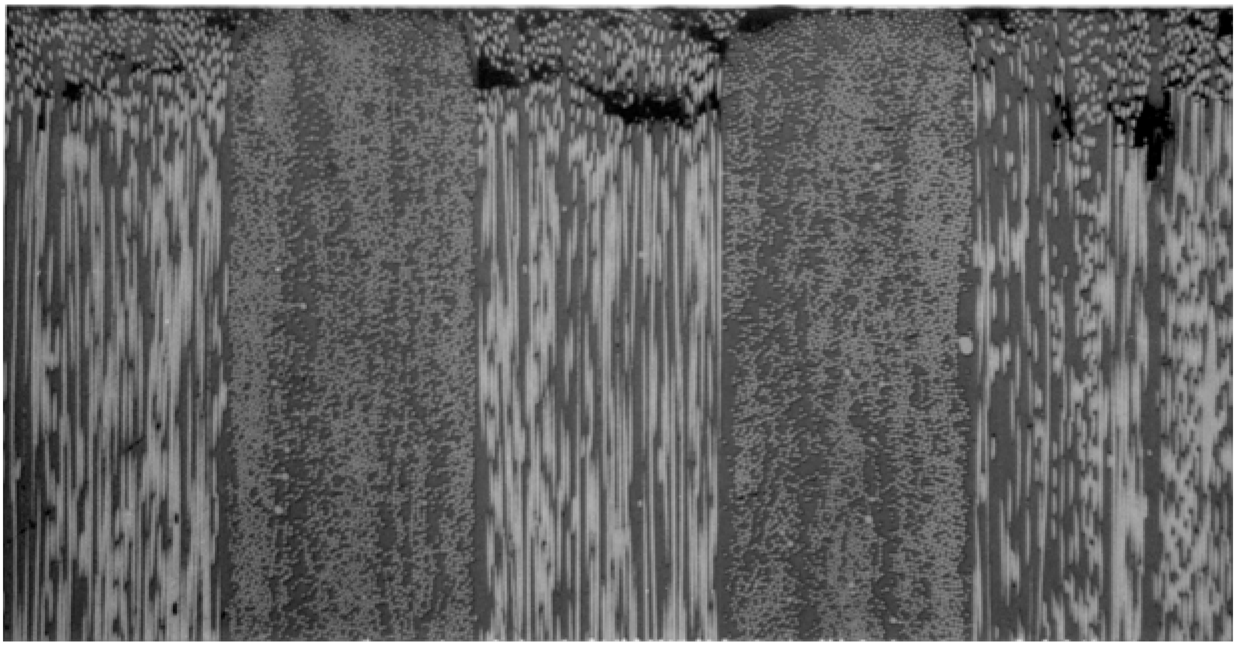

Fig. 3 Typical machined surface of carbon/epoxy composite

Machining, Trimming, and Routing of Polymer-Matrix Composites

Lawrence F. Kuberski, Fischer U.S.A.

Face Milling

As with peripheral milling, face milling can be accomplished with the same type of cutting tools. However, as described in the section on brazed diamond cutting tools, these tools can be produced in a wide variety of shapes and sizes and can be easily custom fitted to milling operations. However, PCD tools are not as readily shaped and are significantly more expensive. An example of the machining parameters for facing operations is shown in Table 1. However, the tool should be balanced when operating at high sfm because balance can become an issue. Vibrations, which are either self-excited (tool problem) or forced resonant vibration (part vibration), can damage the spindle and the workpiece. So, as in any other high-speed machining operation, these types of vibrations must be recognized and properly dealt with to prolong both spindle and tool life.

Table 1 Typical face-milling parameters for carbon fiber-reinforced epoxy composites

Tool diam		Speed[a]		Axial depth of cut		Radial depth of cut		Feed rate	
mm	in.	m/min	sfm	mm	in.	mm	in.	mm/min	in./min
63.5	2.5	320	1048	3.8	0.015	63.5	2.5	1524	60
		478	1572	2.54	0.100	63.5	2.5	1016	40
		638	2100	1.52	0.060	63.5	2.5	762	30
		638	2100	0.76	0.030	63.5	2.5	1016	40
101.5	4.0	510	1677	1.27	0.050	63.5	2.5	762	30

Note: Water used as flood coolant.

(a) Tools can be operated at higher surface-feet-per-minute values when lighter cuts are taken.

In summary, there are several important points to remember when machining carbon/epoxy composites.

- To prolong tool life, prevent heat damage, and contain the carbon/epoxy particulate, the machining operations must be accomplished wet. Always use sharp tools.
- It is extremely important for programmers and operators to be familiar with the geometry of plated or brazed diamond tool shapes. Never exceed the length of the cutting edge.
- If intricate part shapes are involved, use of carbide tooling may be necessary. Tool life with carbide tooling is short. Therefore, the operator/programmer must be prepared to change tools frequently to prevent delaminations and subsequent rework.
- Brazed diamond tools can be fabricated in a wide variety of shapes and sizes but require adequate lead-time for procurement.
- Brazed diamond tooling can be cleaned with a soft wire brush or wheel to extend tool life.
- If PCD tools are used, the operators must be properly trained regarding handling of these costly tools. Rigid setups are also needed with polycrystalline diamond tools to preclude edge chipping or breakage.

Machining, Trimming, and Routing of Polymer-Matrix Composites

Lawrence F. Kuberski, Fischer U.S.A.

Trimming

Abrasive waterjet is the preferred method for trimming carbon/epoxy composites. Cut quality and trim accuracy is best controlled using this method. A typical head configuration is shown in Fig. 4. These systems typically have 345 MPa (50 ksi) pressure capability at the pump. The orifice is made of sapphire that has a 1 mm (0.04 in.) diameter hole through which the high-pressure fluid flows. The 1 mm diameter hole typically diminishes pressure to 303 to 310 MPa (44–45 ksi) at the nozzle tip. The fluid is filtered to 0.05 μm and is pumped in relatively low volumes, typically 0.96 to 1.98 L/min (1–2 gal/ min). The system uses an abrasive material, such as a No. 80 garnet grit that is introduced into the waterjet after the primary jet is formed. Some typical examples of abrasive waterjet trimming parameters on carbon/epoxy materials are given in the following table:

Material thickness		Feed rate		Surface finish (R_a)
mm	in.	mm/min	in./min	
≤12.7	0.5	381	15	**50–70**
25.4	1.0	254	10	**50–70**
25.4–50.8	**1–2**	**127–152**	**5–6**	**50–70**

Waterjet cutting produces less cutting force than most of the mechanical machining methods and generally requires only clamping to secure the part, virtually eliminating the need for intricate fixturing methods. In addition, the waterjet produces no heat affected zone and can dwell in one spot for some time without widening the cut width. However, the process is quite noisy (requiring ear protection), requires good filtration equipment for the water, must be carefully monitored for jet wear (the most common jet material is sapphire), and has a

tendency to produce trailback, especially in thicker materials, as shown in Fig. 5. This trailback or deflection results in an angled cut on the edge of the workpiece but can usually be decreased to acceptable levels with a slower feed rate. As shown in the table above, the feed rates are significantly slower as the material thickness increases. This is to ensure that as little deviation as possible occurs from the top to the bottom of the part, as the waterjet has a tendency to spread as it penetrates thicker material. Also, as the feed rate increases, the waterjet can lag behind in thicker cuts. Several other difficult-to-machine material types are easily cut or trimmed by abrasive waterjet. A partial list is shown in Table 2.

Routing operations are conducted both by machine and by hand. When conducted by machine, routing by using PCD tools is possible. However, when the operation is conducted by hand, too many variables enter into the process to use PCD tools. Therefore, either a brazed diamond tool or a carbide router bit with diamond-shaped facets (Fig. 6) is often used.

Fig. 6 Typical router bit

Routers are frequently operated at speeds up to 30,000 rpm. In hand operations, the feed rate is adjusted by the individual operating the hand router. With sharp tool bits, this feed rate can be as much as 305m/min (1,000 ft/min). Using the same type tool in a robot or machine tool operation, the feed rate can be 610 m/min (2,000 ft/min) or more in trimming operations. In full slot cuts, the feed rate will drop approximately 50%. This is necessary to flush the particulate away from the tool. Unlike diamond brazed tools, which can be cleaned with a wire brush, or the PCD tools, which can be resharpened, these types of tools must be considered disposable. As with the other tool bits used for machining carbon/epoxy, the main criterion for tool life is evidence of any delaminations.

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Introduction

ADHESIVE BONDING frequently is used to assemble composite components into larger structures. In addition, finished components that are damaged during assembly or service are often repaired with adhesive-bonding techniques.

Adhesive bonding is used only if subsequent disassembly of the subcomponents is unlikely. Bonded joints may be preferred if thin composite sections are to be joined when bearing stresses in bolted joints would be unacceptably high, or when the weight penalty for mechanical fasteners is too high. In general, thin structures with well-defined load paths are good candidates for adhesive bonding, while thicker structures with complex load paths are better candidates for mechanical fastening.

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Adhesive Joint Design

In a structural adhesive joint, the load in one component must be transferred through the adhesive layer to another component. The efficiency with which this can be done depends on the joint design, the adhesive characteristics, and the adhesive/substrate interface. In order to transfer loads through the adhesive, the substrates (or adherends) are overlapped to place the adhesive in shear. Figure 1 shows some typical joint designs for adhesively bonded joints of composite-to-metal substrates.

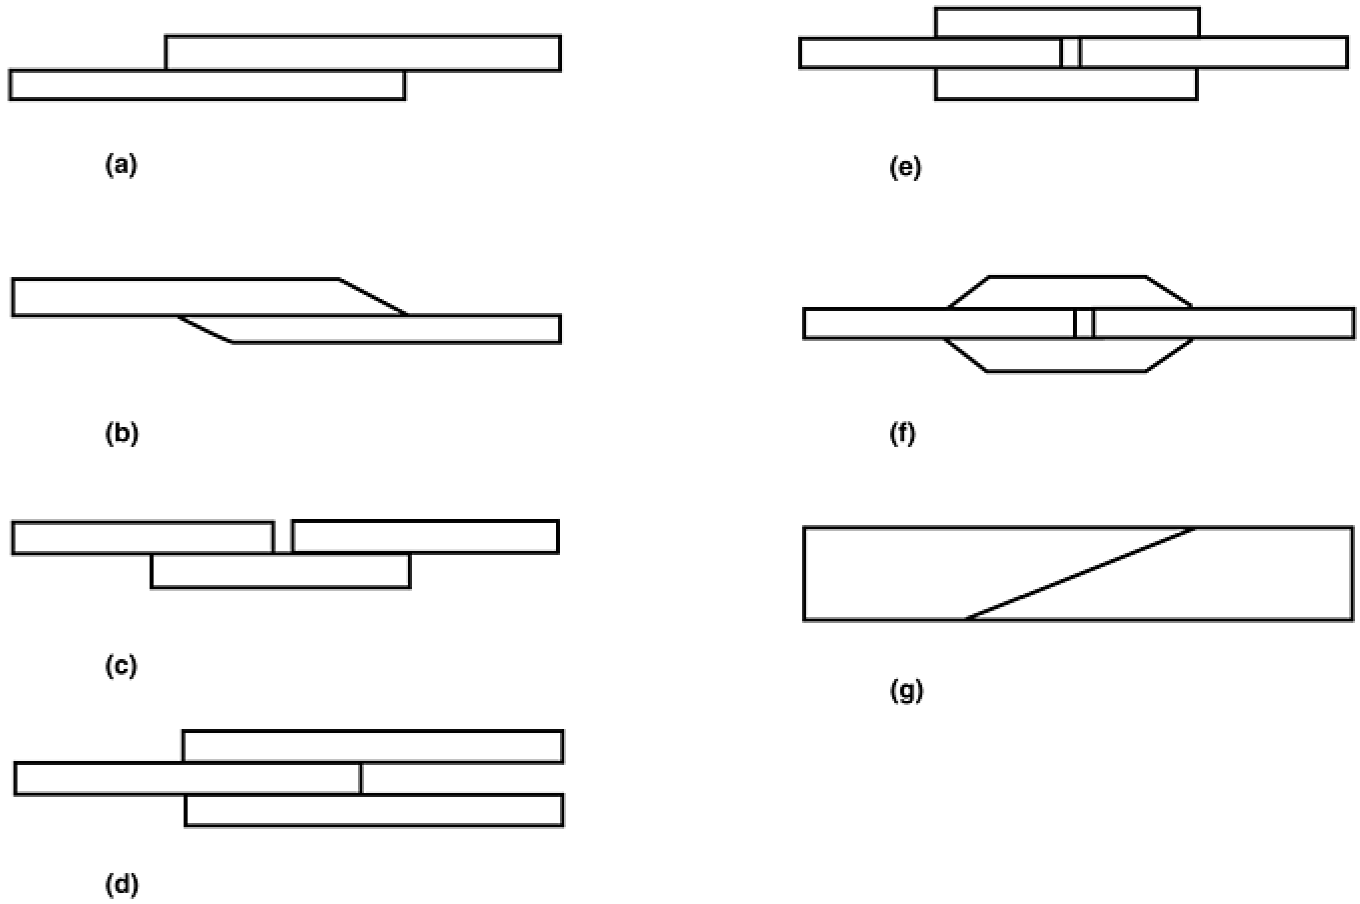

Fig. 1 Typical secondary adhesively bonded joint configurations. (a) Single lap joint. (b) Tapered single lap joint. (c) Single strap joint. (d) Double lap joint. (e) Double strap joint. (f) Tapered double strap joint. (g) Scarf joint

Figure 2 shows a typical stress distribution for a double lap shear joint. Note that the adhesive is required to withstand relatively high local loads near changes in the joint section (i.e., at the ends). Therefore, adhesives designed to carry high loads need to be strong and tough, especially if there is any bending in the joint that would induce peel loads. Adhesives are frequently rubber modified; this practice sacrifices modulus in order to improve fracture toughness and fatigue life. However, in well-designed, toughened adhesives (e.g., second-phase toughening), only moderate reductions of the continuous-phase modulus occurs.

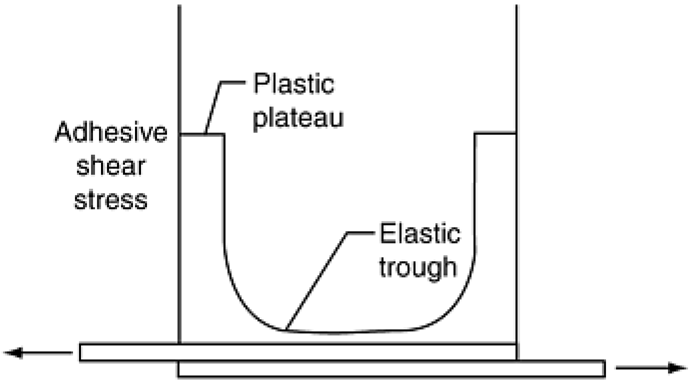

Fig. 2 Typical bondline shear stress distribution

The criteria for selecting an adhesive must be considered in view of the joint design. The joint design must ensure that the adhesive is loaded in shear as far as possible. Tension, cleavage, and peel loading (Fig. 3) should be avoided when using adhesives.

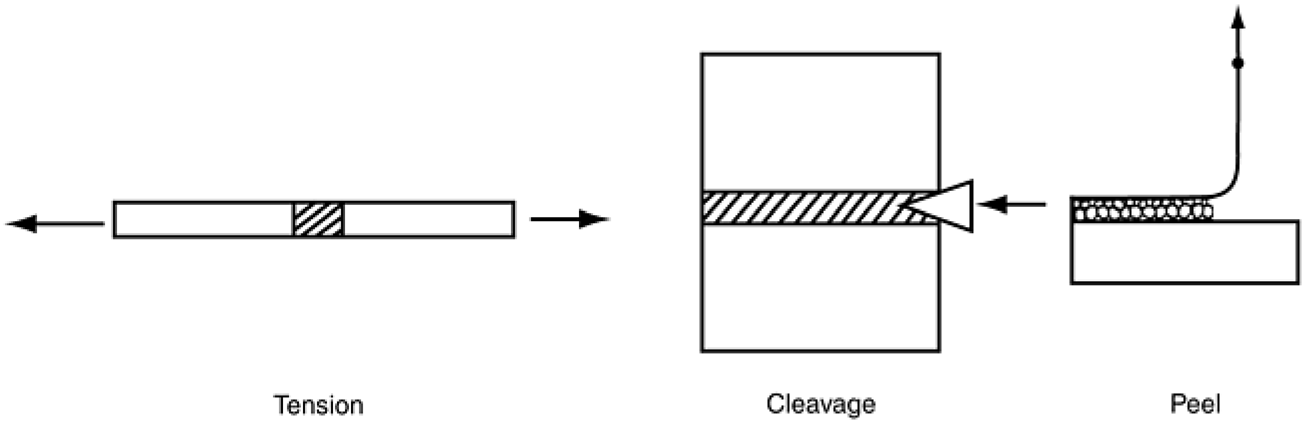

Fig. 3 Load paths to avoid in adhesive use

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Selection Criteria

The first criterion for selecting an adhesive is the capability to withstand the required stresses in the full range of environmental conditions to which the component may be exposed. The class of adhesive may be dictated by the loading conditions. For example, if high peel loads are unavoidable, a highly flexible adhesive would probably be more suitable than a rigid epoxy.

In-service environmental conditions should also be considered as a selection criterion because, for example, flexible polyurethane adhesives are more sensitive to moisture degradation than the equivalent polychloroprene (neoprene) rubber formulations.

Long-term stress conditions can also affect adhesive selection. Thermoplastic adhesives and highly flexibilized epoxy systems may be susceptible to creep under sustained load. On the other hand, rigid, glassy adhesives may have limited resistance to cyclic load conditions.

The practicality of the application process must also be considered, specifically, the method of surface preparation; the restriction on handling prepared surfaces before bonding; the method of mixing (if necessary) and applying the adhesive to the joint; the procedure for melting or curing the adhesive; the tooling necessary for support of the joint during bonding; and the methods for cleaning the joint after bonding, if necessary, and cleaning application equipment. Adhesive characteristics are listed in Tables 1 and 2. Adhesive selection and use criteria are summarized as follows:

- The adhesive must be compatible with the adherends and able to retain its required strength when exposed to in-service stresses and environmental factors.
- The joint should be designed to ensure a failure in one of the adherends rather than a failure within the adhesive bondline.
- Thermal expansion of dissimilar materials must be considered. Due to the large thermal expansion difference between graphite composite and aluminum, adhesively bonded joints between these two materials have been known to fail during cool-down from elevated-temperature cures as a result of the thermal stresses induced by their differential expansion coefficients.
- Proper joint design should be used, avoiding tension, peel, or cleavage loading whenever possible.
- If peel forces cannot be avoided, a lower modulus (nonbrittle) adhesive having a high peel strength should be used.
- Tapered ends should be used on lap joints to feather out the edge-of-joint stresses. Refer to Fig. 1(b) and (f) for examples.

- Selection tests for structural adhesives should include durability testing for heat, humidity (and/or fluids), and stress, simultaneously.
- Surface preparation should be conducted carefully, avoiding contamination of the bondline with moisture, oil, and so on.
- When received, the adhesive should be tested for compliance with the purchase specification. This may include both physical and chemical tests, such as infrared, moisture content, resin content, base resin, secondary resins, curing agent, and accelerator.
- The adhesive should be stored at the recommended temperature.
- Cold adhesive should always be warmed to room temperature in a sealed container.
- Liquid mixes should be degassed, if possible, to remove entrained air.
- Adhesives that evolve volatiles during cure should be avoided.
- The humidity in the lay-up area should be below 40% relative humidity for most formulations. Lay-up room humidity is adsorbed by the adhesive and is released later during heat cure as steam, yielding porous bondlines and interfering with the cure chemistry.
- The recommended pressure and the proper alignment fixtures should be used. The bonding pressure should be great enough to ensure that the adherends are in intimate contact with each other.
- The use of a vacuum as the method of applying pressure should be avoided whenever possible, since an active vacuum on the adhesive during cure can lead to porosity or voids in the cured bondline.
- Heat curing is almost always preferred, because it yields bonds that have greater strength, heat, and humidity resistance.
- When curing for a second time, such as during repairs, the temperature should be at least 28 °C (50 °F) below the earlier cure temperature. If this is not possible, then a proper and accurate bond form must be used to maintain all parts in proper alignment and under pressure during the second cure cycle.
- Traveler coupons should always be made for testing. These are test coupons that duplicate the adherends to be bonded in material and joint design. The coupon surfaces are prepared by the same method and at the same time as the basic bond. Coupons are also bonded together at the same time with the same adhesive (mix lot, and so on) of the basic joint and subjected to the same curing process simultaneously with the basic bond. Ideally, traveler coupons are cut from the basic part, on which extensions have been provided.
- The exposed edge of the bond joint should be protected with an appropriate sealer, such as an elastomeric sealant or paint. Honeycomb assemblies should be hermetically sealed.

Table 1 Typical characteristics of adhesive types

Type	**Form**	**Cure temperature,°C (°F)**	**Maximum use temperature,°C (°F)**	**Advantages**	Disadvantages
Epoxy	Two-part paste	Room or accelerated at 93–178 (200–350)	Generally below 82 (180)	Ease of storage at room temperature; ease of mixing and use; long shelf life; gap filling when filled	**Not generally as strong or environmentally resistant as typical heat-cured epoxies**
	One-part film	121 (250)149 (300)178 (350)	To 82 (180)149–177 (300–350)	Covers large areas; bondline thickness control; wide variety of formulas; higher-temperature curing materials; better	**Store at 18 °C (0 °F); short shelf life; high-temperature cure; brittle and low peel strength**

				environmental properties	
Acrylic	Two-part liquid or pastes	Room to 100 (212)	105 (221)	Fast setting; easy to mix and use; good moisture resistance; tolerant of surface contamination	**Strong, objectionable odor; limited pot life**
Polyurethane	One or two parts	Room or heat cure	…	Good peel; good for cryogenic use	**Moisture sensitive before and after cure**
Silicone	One- and two-part pastes	Room to 260 (500)	To 260 (500)	High peel and impact resistance; easy to use; good heat and moisture resistance	**High cost; low strength**
Hot melt	One-part	Melt at 190–232 (375–450)	49–171 (120–340)	Rapid application; fast setting; low cost; indefinite shelf life; nontoxic; no mixing	**Poor heat resistance; special equipment required; poor creep resistance; low strength; high melt temperature**
Bismaleimide (BMI)	One-part paste or film	>178 (350) and 246 (475) postcure	177–232 (350–450)	Structural bonds with bismaleimide composites; higher temperature than epoxies; no volatiles; good shelf life	**Brittle and low peel**
Polyimide	Thermoplastic liquids; one- and two-part pastes	260 (500) and postcure	204–260 (400–500)	High-temperature resistance; structural strength	**High cost; low peel strength; high cure and postcure temperatures; volatiles for some forms**
Phenolic-based	**One-part films**	**163–177 (325–350)**	**To 177 (350)**	**High-temperature use**	**Low peel strength**

Highly Loaded Joint Considerations

For highly loaded structural applications, it is fundamental to compare the strength and durability properties of those adhesives that are candidates for selection. It is necessary to know the allowable stresses for the adhesive and to be able to calculate the design stresses on the adhesive in service. Unfortunately, the traditional lap shear test shown in Fig. 4 does not produce the true ultimate stress. Also, this test produces no data for adhesive shear modulus, which is required for a stress analysis of a bonded joint.

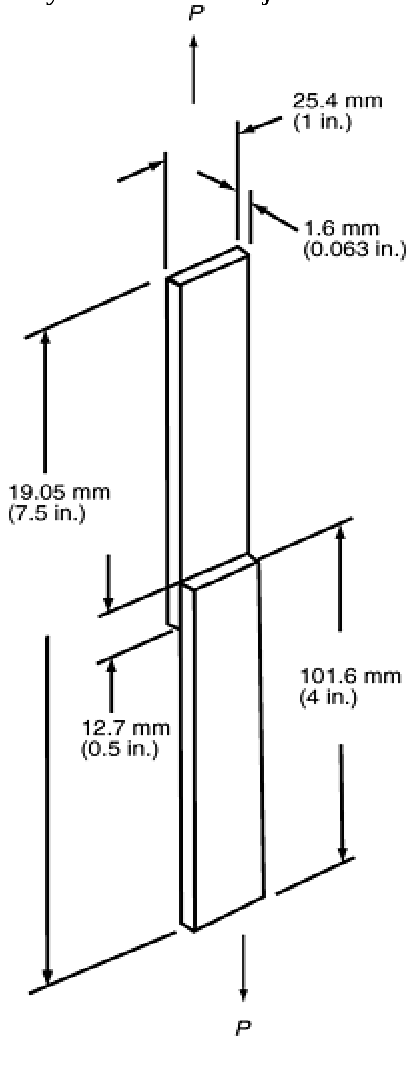

Fig. 4 Single lap shear specimen. *P*, load

The lap shear strength is reported as the failure stress in the adhesive, which is found by dividing the failing load by the bond area. Since the stress distribution in the adhesive is not uniform over the bond area (it peaks at the edges of the joint as shown in Fig. 2), the reported shear stress is lower than the true ultimate strength of the adhesive.

However, lap shear data do have value from a comparative standpoint. One can determine if a certain adhesive has superior strength compared to another even though the actual design strength is not obtained. Also, lap shear values are useful for quality control, such as receiving inspection or as a proof of correct manufacturing processes (i.e., traveler coupons).

The development of the thick adherend test specimen and the KGR-l extensometer allows accurate shear stress and shear strain data to be obtained in the laboratory. Figure 5 and Ref 1 describe the procedures. This test produces a complete, accurate curve of adhesive shear stress versus shear strain for any environment reproducible in the laboratory up to 260 °C (500 °F).

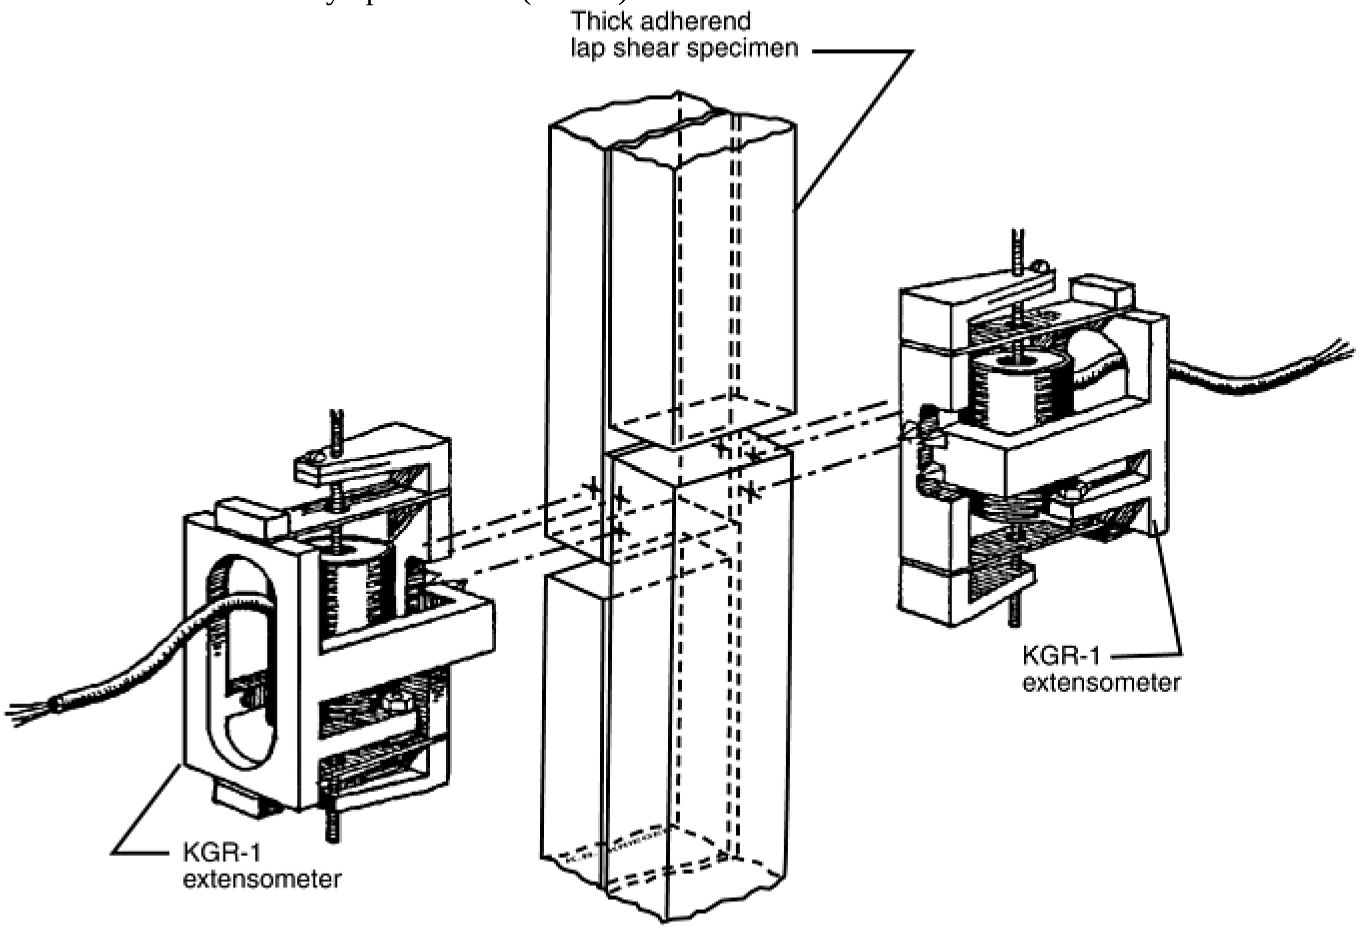

Fig. 5 KGR-1 extensometer with thick adherend specimen. Source: Ref 1

Because the metal is so thick and the metallic adherend strains are therefore small, the thick adherend specimen produces an essentially uniform shear stress over the test area, allowing an accurate experimental determination of the adhesive shear stress-strain response.

The adhesive shear stress distribution for a typical bonded joint (Ref 2) is shown in Fig. 6. The joint shown has been simplified by using a single metal alloy, a single thickness, and a single value of *G*, the adhesive shear modulus. Note that changes in the adhesive shear modulus or bondline thickness will change the peak (critical) shear stress, with no change in load on the structure. This is unique and fundamental to the adhesive-selection process. It enables the designer to select the best adhesive for any environment. When the shear stress-strain curve ceases to be linear—that is, where the shear modulus is no longer constant—much can still be learned. Figure 7 shows a typical shear stress versus shear strain curve with explanations of several characteristics as they predict adhesive performance, while Fig. 8 shows the effects of temperature on the stress and strain properties of a typical structural adhesive.

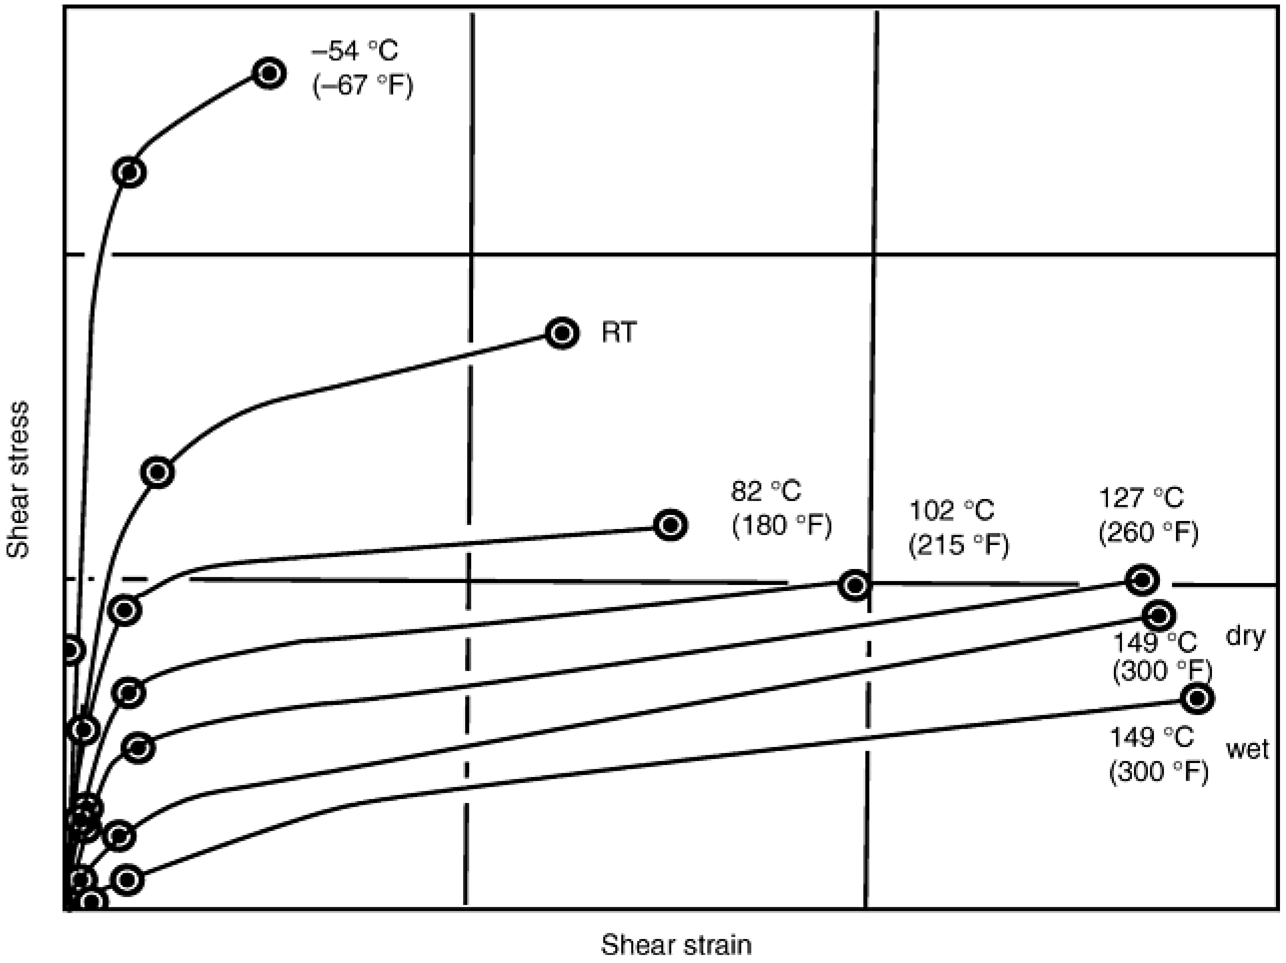

Fig. 8 Shear stress and strain at various temperatures for a typical structural adhesive. RT, room temperature

Bonding to composites rather than to metals introduces significant differences in criteria for adhesive selection for two reasons: (1) composites exhibit a large drop in interlaminar shear stiffness compared to metals and (2) composites have a much lower shear strength than metals. This occurs because the interlaminar shear stiffness and strength depend on the matrix properties and not the higher properties of the fibers. The exaggerated deformations in a composite laminate bonded to a metal sheet and placed under tension are shown in Fig. 9. The adhesive passes the load from the metal into the composite until, at distance *L*, the strain in each material is equal. In the composite, the matrix resin acts as an adhesive to pass load from one fiber ply to the next. Because the matrix shear stiffness is low, the composite plies deform unequally in tension as shown. Failure tends to initiate in the composite ply next to the adhesive near the beginning of the joint or in the adhesive in the same neighborhood. The highest failure loads are achieved by an adhesive with a low shear modulus and high strain to failure, as shown in Fig. 6. This results because *L* will be the largest and the maximum shear stress will be lowest. It should also be noted that there is a limit to the thickness of the composite that can be loaded by a single bondline; however, multiple steps in the composite thickness giving multiple bondlines may be necessary for thick material.

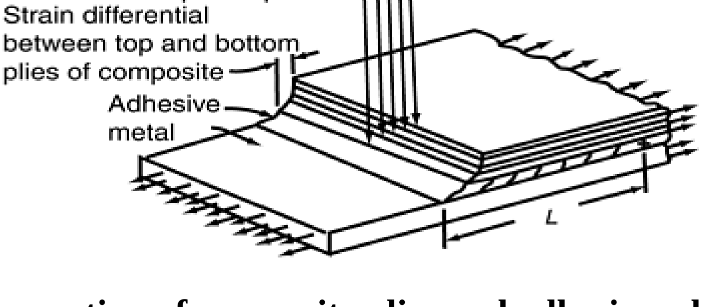

Fig. 9 Exaggerated deformation of composite plies and adhesive when bonded to metal

Basic design practice for adhesive-bonded composite joints should include ensuring that the surface fibers in a joint are parallel to the direction of load to minimize interlaminar shear, or failure of the bonded substrate layer. In designs in which joint areas have been machined to a step-lap configuration, for example, it is possible to have a joint interface composed of fibers at an orientation other than the optimal 0° orientation to the load direction. This tends to induce substrate failure more readily than would otherwise occur.

To determine fatigue and creep performance (including under hostile environment) there are many tests, which like lap shear, do not present accurate shear failure stresses. For these conditions, one can again turn to shear stress versus shear strain data for allowable stresses, as described in Fig. 7 and 8. These allowable stresses can be compared to calculated stresses on the structure using the approach shown in Fig. 7.

The adhesive stress-strain curves can also be used on a comparative basis, that is, to determine whether adhesive A is better or worse than adhesive B. Here Fig. 7 can be used together with shear stress versus shear strain. Comparing *LL* stress values for fatigue performance is not a complete method, since shear modulus (G) can be different for the adhesive being compared. It is more accurate to compare *LL* stress (τ_{LL}) adjusted by the square root of G, for the two adhesives.

Much has been written about joint design. Experience and predominant applications point to using the adhesive in shear as the most effective method. Figure 10 shows a variety of designs. Figures 10(a) to (d) joints are all loaded in shear, while Fig. 10(e) is loaded in tension and Fig. 10(f) is loaded in peel. Note that Fig. 10(e) and (f) exhibit large tensile stress peaks in the adhesive. These peaks can be much higher than those in shear loading and are far less forgiving. Also, these peaks are very sensitive to small eccentricities. These problems make tension and peel, at best, very questionable load paths. Figure 10(d) shows a scarf joint often used for damage repair. It is impressive in that there are no shear peaks in the adhesive stress distribution (i.e., a constant shear stress).

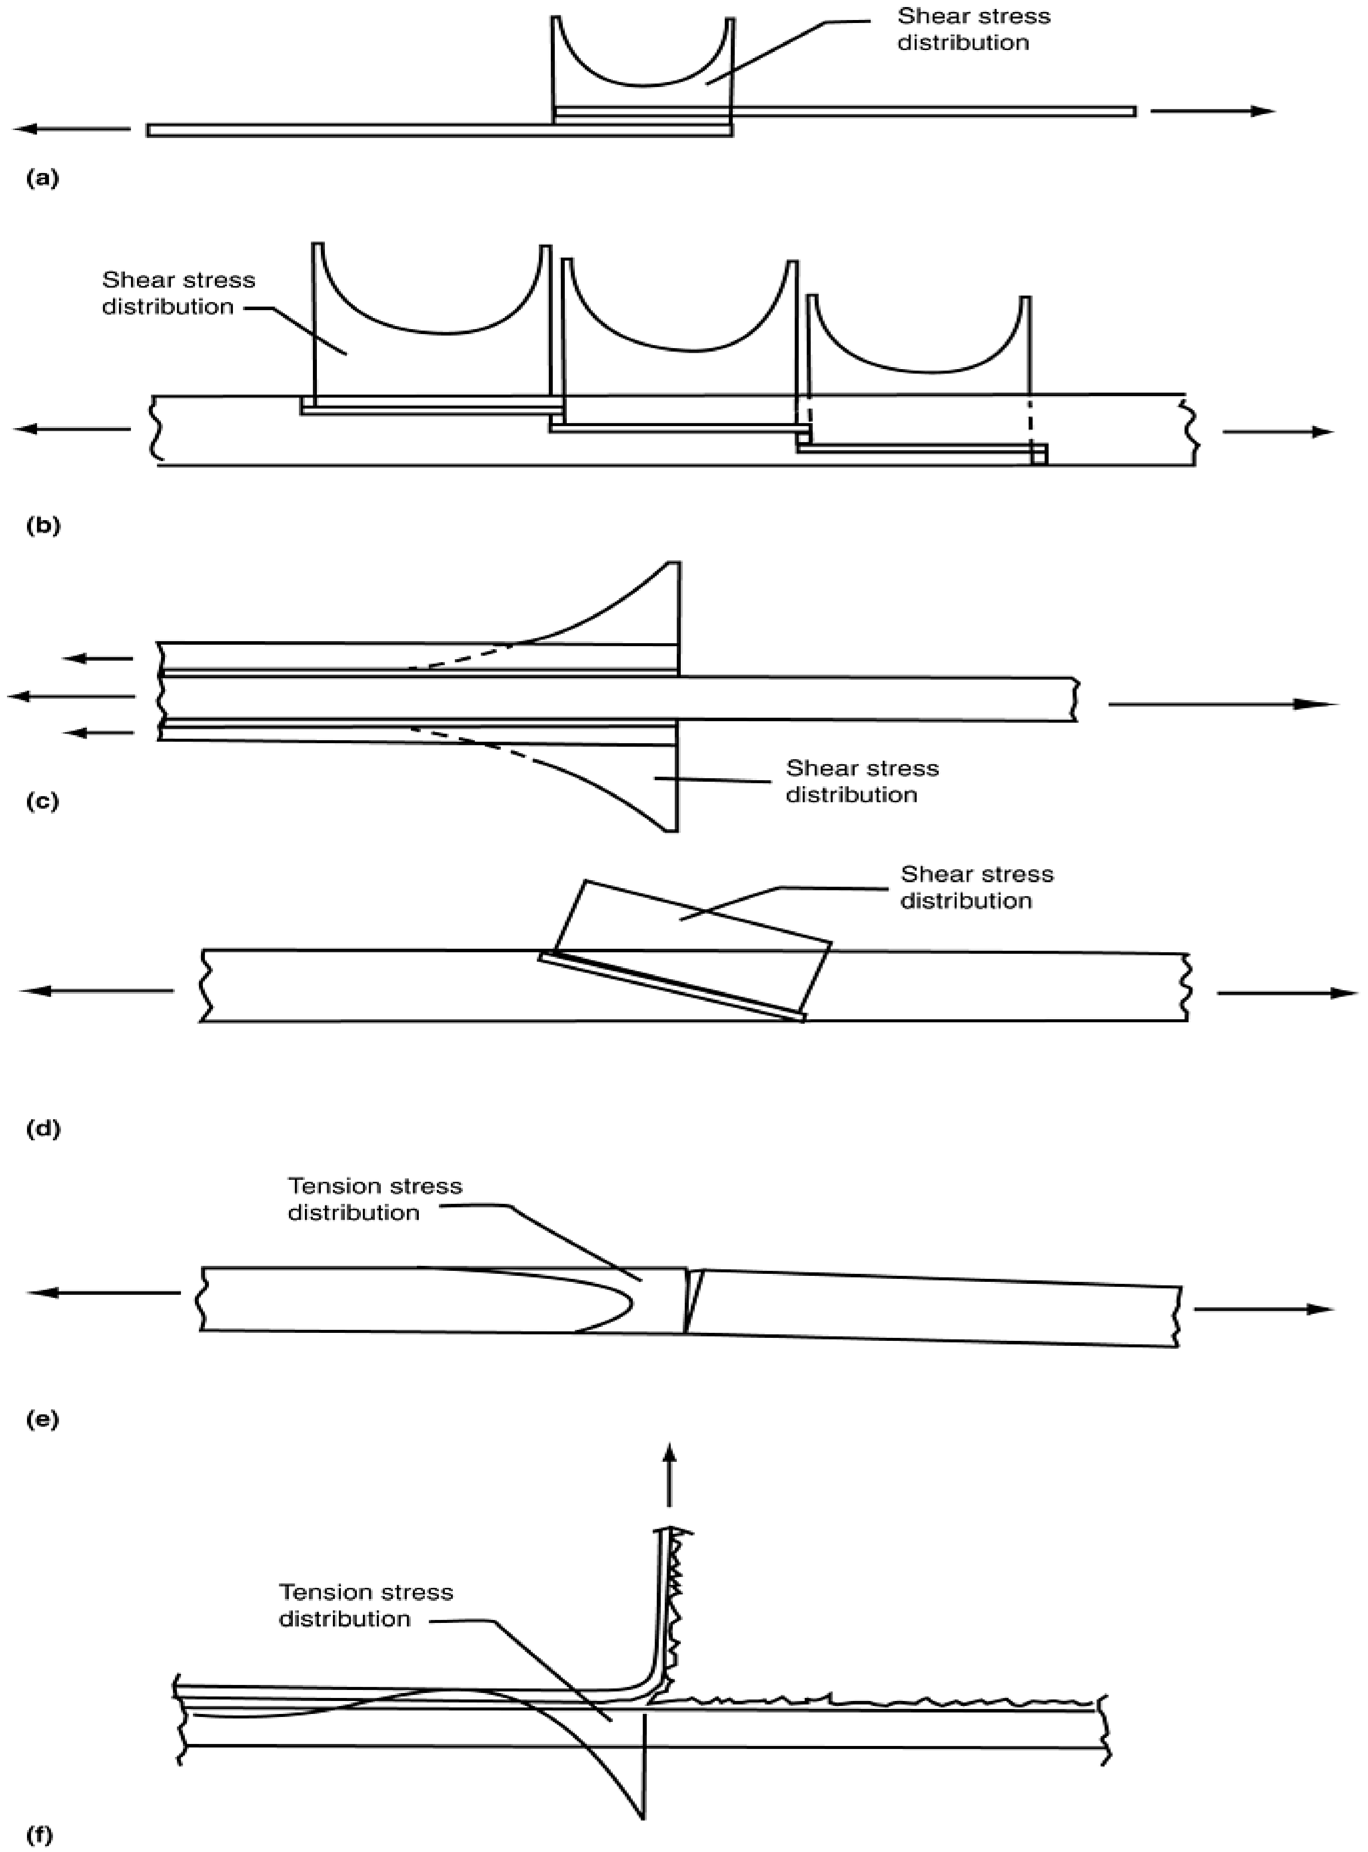

Fig. 10 Various bonded joint configurations. (a), (b), and (c) Shear. (d) Scarf. (e) Tension. (f) Peel

Durability can be evaluated in the adhesive- selection process by using the adhesive shear stress versus shear strain curves as obtained by the KGR-l extensometer. As stated earlier, environments are easily obtained in the laboratory, which include temperatures from below–57 to 260 °C (–70 to 500 °F) and after any fluid saturation assumed to be experienced by the aircraft. Similar to the curves shown in Fig. 8, the shear stress-strain curves for these environments all have the same fundamental shapes and can be evaluated as to adhesive capability in the same way as described for ambient conditions. As shown in the Fig. 8 curve for the test conducted at 149 °C (300 °F) after humidity exposure (wet), hostile environments degrade the structural performance of most adhesives. This again emphasizes the point that it is important to conduct test programs for adhesives using the actual anticipated service environment.

It should be emphasized that bonding to cured composites presents a serious complexity for accurate stress analysis, because the composite has disproportionately low interlaminar shear stiffness and shear strength when compared with isotropic metals. This may well call for tests to verify the analysis for any critically bonded structure. For a more thorough discussion of adhesive-bonded joint design, refer to the article "Bolted and Bonded Joints" in this Volume.

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Epoxy Adhesives

Epoxy-based adhesives are the most commonly used materials for bonding or repair of composite structures. The existence of a large variety of materials—to fit nearly any handling, curing, or performance requirement—results in an extensive list from which to choose. Epoxy adhesives impart high-strength bonds and long- term durability over a wide range of temperatures and environments. The ease of formulation modification makes it fairly easy for the formulator to employ various materials to control specific performance properties, such as density, toughness, flow, mix ratio, pot life/shelf life, shop handling characteristics, cure time/temperature, and service temperature.

Advantages of epoxy adhesives are excellent adhesion, high strength and modulus, low or no volatiles during cure, low shrinkage, and good chemical resistance. Disadvantages include cost, brittleness unless modified, moisture absorption that adversely affects properties, and rather long cure times.

A wide range of one- and two-part systems are available. Some systems cure at room temperature, while others require elevated temperatures.

Chemistry. Epoxy resins used as adhesives are generally supplied as liquids or low-melting- temperature solids. They commonly contain bifunctional epoxy groups, although higher functionalities are available. They can be cured by a variety of curing procedures, including admixture with the stoichiometric proportion of polyfunctional primary amine or acid anhydride. The amine or anhydride groups react with the epoxy groups by a simple addition reaction to give a densely cross-linked structure. Some epoxy compositions can be cured through a homopolymerization reaction initiated by strong organic bases (or rarely, acids). These compositions are less sensitive to the mix ratio, but are seldom encountered as two-part systems. The rate of the reaction may be adjusted by adding accelerators in the initial formulation or by increasing the temperature. To improve structural properties, particularly at elevated temperatures, it is common to cure temperatures close to (or preferably over) the maximum-use temperature for the structure.

Epoxy resin systems are usually modified by a wide range of additives that control particular properties. These additives include accelerators, viscosity modifiers and other flow-control additives, fillers and pigments, flexibilizers, and toughening agents. The versatility of these materials has led to the development of a wide range of epoxy adhesives for specific applications.

Epoxy-based adhesives are available in two basic cure chemistries: room temperature and elevated temperature. Within each cure type, there is a wide range of formulated resins to cover specific application and performance requirements.

One-Part Elevated-Temperature Curing Epoxy Liquid and Paste Adhesives. These materials typically require an elevated-temperature cure of 120 to 177 °C (250-350 °F). The primary chemistry of one-part systems usually consists of a mixture of bifunctional and multifunctional resins with noncatalyzed or imidizole catalyzed dicyanimide. As such, the normal room-temperature shelf life ranges from 15 to 30 days for catalyzed materials and up to six months for noncatalyzed systems. Service temperatures for these materials are generally close to their respective curing temperatures; however, the actual service temperature should always be determined by testing at the expected service conditions.

Typical packaging for the one-part adhesives includes pint, quart, gallon, and five-gallon containers. In addition, for ease of application, most are supplied in cylindrical polyethylene sealant gun cartridges that, depending on their size, can contain up to 500+ g of material. Since the chemistry and performance of some one-part paste adhesives are similar to that of film adhesives, these materials are often referred to as “film adhesive in a tube.”

Two-Part Room-Temperature Curing Epoxy Liquid and Paste Adhesives. These systems are most commonly used when a room- temperature cure is desired. They are available as clear liquids or as filled pastes with a consistency ranging from low-viscosity liquids to heavy-duty putties. Typical cure times are 5 to 7 days; however, in most cases 70 to 75% of the ultimate cure can be achieved within 24 h, and, if needed, the pressure can usually be released at that point. Under normal bondline thickness conditions (0.125–0.250 mm, or 0.005–0.010 in.), cure can be accelerated with heat without fear of exotherm. A typical cure would be 1 h at 82 °C (180 °F). For higher-temperature applications, there are also two-part adhesives that require a high-temperature cure of at least 82 °C (180 °F).

Two-part systems require mixing a part A (the resin and filler portion) with a part B (the curing agent portion) in a predetermined stoichiometric ratio. Two-part epoxy adhesives usually require mixing in precise proportions to avoid a significant loss of cured properties and environmental stability. The amount of material to be mixed should be limited to the amount needed to accomplish the task. The larger the mass, the shorter the pot, or working, life of the material. The pot life is defined as the period between the time of mixing the resin and curing agent and the time at which the viscosity has increased to the point when the adhesive can no longer be successfully applied as an adhesive. To avoid potential exotherm conditions after application, excess mixed material should be removed from the container and spread out in a thin film. This prevents the risk of mass-related heat buildup and the possibility of a fire or the release of toxic fumes.

Many of the bifunctional and multifunctional resin types formulated into one-part systems are also employed in part A of the two-part systems. However, the ability to cure, or cross link, at room temperature is due to different curing agent (part B) chemistries. These are generally mixtures, to various degrees, of modified and unmodified aliphatic amines, polyamides, and modified cycloaliphatic amines. Curing of higher-temperature service two-part systems, which require an elevated-temperature cure, is usually accomplished singularly or with mixtures of aromatic and unmodified cycloaliphatic amines. A number of these materials are primary skin sensitizers, and some caution is necessary to avoid direct contact.

Some of the more reactive aliphatic amines will react with ambient water and carbon dioxide, and, if left exposed too long in the mixed condition prior to part mating, a carbonate layer may form on the adhesive surface. If this occurs, it will inhibit good substrate-to-adhesive contact and will significantly decrease mechanical properties. The opportunity for carbonate formation can be limited by avoiding high-humidity bonding conditions and mating the parts as soon as possible after adhesive application. In cases where carbonate formation cannot be avoided, covering the exposed area with polyethylene film until mating the parts will help minimize carbonate formation. Troweling the surface prior to mating can also be an effective method of disrupting any carbonate formation.

In addition to the packaging methods described for the one-part materials, meter mix equipment is available for continuous application where applicable, usually involving large areas. Mixing of the two parts can be accomplished by pumping material through either a hydraulic mixer or a static mixer. For smaller applications,

dual cartridge kits, in which both part A and B are manually pushed through a static mixer, are also available for most two-part systems. Two- part adhesives can usually be stored at room temperature; however, part A may contain resins that can self-polymerize and require cold storage.
Due to their versatility, two-part resin systems are frequently used to repair damaged composite assemblies. Low-viscosity versions can be used to impregnate dry graphite cloth for repair patches or to inject into cracked bondlines or delaminations. Thicker pastes are used to bond repairs where more flow control is required. For example, if the material has too low a viscosity and is cured under high pressure, the potential for bondline starvation exists due to excessive flow and squeeze out. Viscosity control of two- part adhesives is usually done with metallic and/ or nonmetallic fillers. Fumed silica is frequently added to provide slump and flow control. For more information on composite repair, see the articles “Repair Engineering and Design Considerations” and “Repair Applications, Quality Control, and Inspection” in this Volume.
Many adhesives are of the same resin and curing chemistry family; however, different versions are manufactured (nonfilled, metallic or nonmetallic filled, thixotroped, low density, and toughened) for specific performance requirements. For example, a nonmetallic-filled adhesive may be preferred over a metallic-filled adhesive if there is concern for possible galvanic corrosion in the joint. In thin composite structures where bending or flexing is a concern, a toughened adhesive may be warranted.
In addition to composite bonding and repair applications, two-part epoxy paste adhesives are also used for liquid shim applications during mechanical assembly operations. The ability to tailor flow, cure time, and compressive strength have made these materials ideal for use in areas of poor fit-up.
Epoxy Film Adhesives. Structural adhesives for aerospace applications are generally supplied as thin films supported on a release paper and stored under refrigerated conditions (–18 °C, or 0 °F). Film adhesives are available using high- temperature aromatic amine or catalytic curing agents with a wide range of flexibilizing and toughening agents. Rubber-toughened epoxy film adhesives are widely used in the aircraft industry. The upper temperature limit of 121 to 177 °C (250–350 °F) is usually dictated by the degree of toughening required and by the overall choice of resins and curing agents. In general, toughening of a resin results in a lower usable service temperature. Film materials are frequently supported by fibers that serve to improve handling of the films prior to cure, control adhesive flow during bonding, and assist in bondline thickness control. Fibers can be incorporated as short-fiber mats with random orientation or as woven cloth. Commonly encountered fibers are polyesters, polyamides (nylon), and glass. Adhesives containing woven cloth may have slightly degraded environmental properties because of wicking of water by the fiber. Random mat scrim cloth is not as efficient for controlling film thickness as woven cloth, because the unrestricted fibers move during bonding, although spun-bonded nonwoven scrims do not move and are therefore widely used.

Secondary Adhesive Bonding of Polymer-Matrix Composites

Flake C. Campbell, The Boeing Company—St. Louis

Surface Preparation

Surface preparation of a material prior to bonding is the keystone upon which the adhesive bond is formed. Extensive field service experience with structural adhesive bonds has repeatedly demonstrated that adhesive durability and longevity depend on the stability and bondability of the adherent surface. Combinations of heat, moisture, and stress have been shown to be particularly effective in discriminating among the various surface preparations used in the prebond conditioning or treatment of both metallic and composite surfaces.
Although it should be understood that the satisfactory performance of the bonded joint is the primary objective, technology has made it possible to characterize in detail the chemical and physical properties of surface oxide layers on metals. Instrumental techniques—such as scanning electron microscopy and transmission electron microscopy—and surface analysis techniques—such as Auger and ion microprobe analysis—can be used to gain an intimate knowledge of the influence of surface preparation variables on the oxide that is produced. Therefore, with the availability of these powerful analytical tools, a significantly increased understanding of the required chemical and physical characteristics of a metal prebond surface can be expected.

In the past, surface treatment evaluation techniques were limited to the stressed exposure of lap shear specimens or, perhaps, hot/wet peel testing. These tests, however, did not readily discriminate among surface treatments of varying durability. A test for the discrimination of surface preparations finally became available with the development of the wedge-opening (double- cantilever beam).

In general, high-performance structural adhesive bonding requires that great care be exercised throughout the bonding process to ensure the quality of the bonded product. Chemical composition control of the polymeric adhesives; strict control of surface preparation materials and process parameters; and control of the adhesive lay-up, part fit-up, tooling, and the curing process are all required to produce, for example, airworthy structural assemblies. Of course, this is in contrast to the mechanical joining of components, which requires a lower level of cleanliness control to obtain satisfactory performance. Given this situation and the inherent advantages of adhesive bonding compared to mechanical attachment, surface preparations are required that provide optimal adhesion and maximum environmental resistance, at least for critical aerospace applications.

Great care is needed to obtain the best product possible using state-of-the-art technology to produce adhesive-bonded flight hardware, both primary and secondary structure. This usually requires the development of and strict adherence to detailed and comprehensive materials and process specifications, as well as end-item nondestructive inspection.

Composite Surface Preparation. The first consideration that occurs in preparing a composite part for secondary adhesive bonding is moisture absorption of the laminate itself. Absorbed laminate moisture can diffuse to the surface of the laminate during elevated-temperature cure cycles, resulting in weak bonds or porosity or voids in the adhesive bondline and, in extreme cases where fast heat-up rates are used, actual delaminations within the composite laminate plies. If honeycomb is used in the structure, moisture can turn to steam resulting in node bond failures or blown core. Relatively thin composite laminates (3.17 mm, or 0.125 in., or less in thickness) may by effectively dried in an air-circulating oven at 121 °C (250 °F) for 4 h minimum. Drying cycles for thicker laminates should be developed empirically using the actual adherend thicknesses. After drying, the surface should be prepared for bonding and then the actual bonding operation conducted as soon as possible. It should be noted that prebond thermal cycles, such as verifilm cycles to check for part fit-up prior to actual bonding, can serve as effective drying cycles. In addition, storage of dried details in a temperature- and humidity-controlled lay-up room can extend the time between drying and curing.

Numerous surface-preparation techniques are currently used prior to the adhesive bonding of composites. The success of any technique depends on establishing comprehensive material, process, and quality-control specifications and adhering to them strictly. One method that has gained wide acceptance is the use of a peel ply. In this technique, a closely woven nylon or polyester cloth is used as the outer layer of the composite during lay-up; this ply is torn or peeled away just before bonding or painting. The theory is that the tearing or peeling process fractures the resin-matrix coating and exposes a clean, virgin, roughened surface for the bonding process. The surface roughness attained can, to some extent, be determined by the weave characteristics of the peel ply. Some manufacturers advocate that this is sufficient, while others maintain that an additional hand sanding or light grit blasting is required to prepare the surface adequately. Abrasion increases the surface energy of the surfaces to be bonded and removes any residual contamination, while surface roughening increases the bond area and mechanical interlocking. The abrading operation should be conducted with care, however, to avoid exposing or rupturing the reinforcing fibers of the surface.

The use of peel plies on composite surfaces to be structurally bonded certainly deserves careful consideration. Factors that need to be considered include: the chemical makeup of the peel ply (e.g., nylon versus polyester) as well as its compatibility with the composite-matrix resin, the surface treatment used on the peel ply (e.g., silicone coatings that make the peel ply easier to remove also leave residues that inhibit structural bonding), and the final surface preparation (e.g., hand sanding versus light grit blasting) employed. The reader is referred to Ref 3 and 4 for a more in-depth analysis of the potential pitfalls of using peel plies on surfaces to be bonded. The authors of Ref 3 and 4 maintain that the only truly effective method of surface preparation is a light grit blast after peel ply removal. Nevertheless, peel plies are very effective at preventing gross surface contamination that could occur between laminate fabrication and secondary bonding.

A typical cleaning sequence would be to remove the peel ply and then lightly abrade the surface with a dry grit blast at approximately 138 kPa (20 psi). After grit blasting, any remaining residue on the surface may be removed by dry vacuuming or wiping with a clean, dry cheesecloth. Although hand sanding with 120 to 240 grit silicon carbide paper can be substituted for grit blasting, hand sanding is not as effective as grit blasting in reaching all of the impressions left by the weave of the peel ply on the composite surface. In addition, the

potential for removing too much resin and exposing the carbon fibers is actually higher for hand sanding than it is for grit blasting.

If it is not possible to use a peel ply on a surface requiring adhesive bonding, the surface may be precleaned (prior to surface abrasion) with a solvent such as methyl ethyl ketone (MEK) to remove any gross organic contaminants. In cases where a peel ply is not used, some type of light abrasion is required to break the glazed finish on the matrix resin surface. The use of solvents to remove residue after hand sanding or grit blasting is discouraged due to the potential of recontaminating the surface.

Another method can be used to avoid abrasion damage to fibers. When the graphite composite is first laid up, a ply of adhesive is placed on the surface where the secondary bond is to take place. This adhesive is then cured together with the laminate. To prepare for the secondary bond, the surface of this adhesive ply is abraded with minimal chance of fiber damage; however, this sacrificial adhesive ply adds weight to the structure.

Surface-conditioning techniques can be automated for use in high-production situations. All surface treatments should have the following principles in common. The surface should be thoroughly cleaned prior to abrasion to avoid smearing contamination into the surface. The glaze on the matrix surface should be roughened without damaging the reinforcing fibers or forming subsurface cracks in the resin matrix. Any residue should be removed from the abraded surface. The prepared surface should be bonded as soon as possible.

Metal Surface Preparation. The following surface preparations are used for various metals to be bonded to the cured composite. Although seemingly adequate bond strength can often be obtained with rather simple surface treatments (e.g., surface abrasion or sanding of aluminum adherends), long-term durable bonds under actual service environments can suffer significantly if the metal adherend has not been processed using the proper chemical surface preparation.

Several methods are used with titanium. Any method developed for titanium should undergo a thorough test program prior to production implementation and then must be monitored closely during production usage. A typical process used in the aerospace industry involves:

1. Solvent wiping to remove all grease and oils
2. Liquid honing at 275 to 345 kPa (40–50 psi) pressure
3. Alkaline cleaning in an air agitated solution maintained at 93 to 100 °C (200–212 °F) for 20 to 30 min
4. Thoroughly rinsing in tap water for 3 to 4 min
5. Etching for 15 to 20 min in a nitric-hydrofluoric acid solution maintained at a temperature below 38 °C (100 °F)
6. Thoroughly rinsing in tap water for 3 to 4 min followed by rinsing in deionized water for 2 to 4 min
7. Inspecting for a water-break-free surface
8. Oven drying at 38 to 77 °C (100–170 °F) for 30 min minimum
9. Adhesive bonding or applying primer within 8 h of cleaning

The combination of liquid honing, alkaline cleaning, and acid etching results in a complex chemically activated surface topography containing a large amount of surface area for the adhesive to penetrate and adhere. The adhesive bond strength is a result of both mechanical interlocking and chemical bonding.

Another method used to prepare the surface of titanium for bonding, called dry chromic acid anodizing, involves:

1. Degreasing using solvent-wipe (acetone or MEK may be used) if the metal surface is contaminated with oil or grease
2. Soaking/cleaning metal parts in alkaline cleaner bath until a water-break-free surface is obtained (10–15 min)
3. Rinsing with hot water (>43 °C, or 110 °F) for 5 min.
4. Etching in a nitric-hydrofluoric acid bath for 1.5 min
5. Rinsing with cold water for at least 5 min
6. Anodizing in a chromic acid bath for 20 min at 5 V potential, with a current density of 13.45A/m^2 (1.25 amp/ft^2)
7. Rinsing with cold water for at least 5 min.
8. Drying using hot air (66 °C, or 150 °F)

Several different methods are also used to prepare aluminum alloys for adhesive bonding. Forest Products Laboratory (FPL) etching is a chromic sulfuric acid etch, and its procedure is found in ASTM D 2651. It is perhaps the earliest method developed for preparing aluminum for bonding. Chromic acid anodizing is a later method and is perhaps more widely used than the FPL etch. Different manufacturers use minor variations of this method, usually in the sealing steps after anodizing. Phosphoric acid anodize (PAA) is the most recent of the well-established procedures and has an excellent service record for environmental durability. It also has the advantage of being very forgiving of minor variations in procedure. A detailed procedure of this surface preparation can be found in ASTM D 3933.

Because metallic cleaning is such a critical step, dedicated processing lines are normally constructed, and chemical controls, as well as periodic lap shear cleaning control specimens, are employed to ensure in-process control. Automated overhead conveyances are used to transport the parts from tank to tank under computer-controlled cycles to ensure the proper processing time in each tank.

Due to the rapid formation of surface oxides on both titanium and aluminum, the surfaces should be bonded within 8 h of cleaning or primed with a thin protective coat of epoxy primer. For parts that will undergo a severe service environment, priming is always recommended because today's primers contain corrosion-inhibiting compounds that enhance long-term durability. Once the primer has been cured, the parts may be stored in an environmentally controlled clean room for quite long periods of time (e.g., up to 50 days or longer would not be unusual). All cleaned and primed parts should be carefully protected during handling or storage to prevent surface contamination. Normally, clean white cotton gloves are used during handling, and wax- free Kraft paper may be used for wrapping and longer storage.

Sandwich Structures

Sandwich construction has been used extensively in the aerospace industry because it is an extremely lightweight structure that exhibits high stiffness and strength-to-weight ratios. A typical sandwich structure consists of two thin, high-strength facings bonded to a thick, lightweight core. Each component by itself is relatively weak and flexible, but when combined into a sandwich panel they produce a structure that is stiff, strong, and lightweight. A honeycomb sandwich panel, formed by adhesively bonding thin skins to honeycomb core, is shown in Fig. 11.

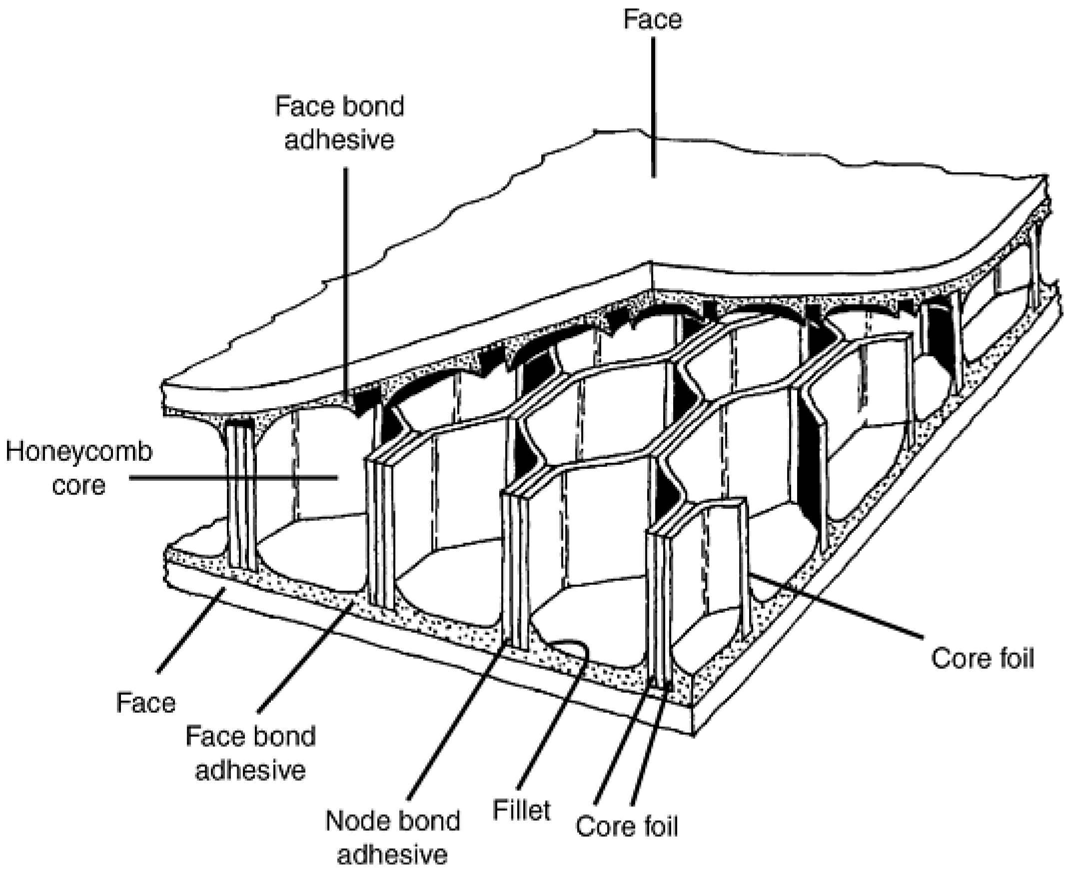

Fig. 11 Components of a honeycomb panel

The basic concept of a sandwich panel is that the facings carry the bending loads and the honeycomb core carries the shear loads. In most cases, the facing stresses are uniformly distributed. Facing materials that are normally used are aluminum, fiberglass, graphite, and aramid. Typical aerospace structure has relatively thin facing sheets (0.25–3.17 mm, or 0.010–0.125 in.) with core densities in the range of 61 to 128 kg/m^3 (3.8–8.0 lb/ft^3).

Supported film adhesives are normally used to bond composite structural honeycomb assemblies. The primary considerations for selecting an adhesive system are strength requirements, service temperature range, and ability to form a fillet at the cell wall ends. Sandwich panels are typically used for their structural, electrical, and energy absorption characteristics, or a combination thereof.

Honeycomb Core

Most honeycomb used today is adhesively bonded aluminum hexagonal-cell honeycomb core that is subsequently bonded to facings to form a sandwich panel. The most common nonmetallic core materials are Nomex or Korex (aramid), fiberglass, or graphite. Nonmetallic core is normally dipped in liquid phenolic, polyester, or polyimide resin to achieve the final density, although other resin systems can be used. There are three basic cell configurations: hexagonal, overexpanded, and flexible. For a more in-depth discussion of honeycomb core and its properties, refer to the article "Lightweight Structural Cores" in this Volume.
